It is typically assumed that all components of the element are small compared to a wavelength. The desire is to have the element face dimension be half of a wavelength in water so that multiple-element arrays can be phased for beam steering. The head mass should be kept light by using a low-density metal, such as aluminum or magnesium, and a minimal thickness determined by setting its flexural resonance at about twice the fundamental resonance. The ceramic stack design must consider the number of ceramics, dimensions, compliance, electric field limits, power-handling capability, electrical impedance, electromechanical coupling coefficient, and cost. For most cases the ceramic used for transducers that both transmit and receive is PZT-4 (Navy type I). If high acoustic fields are required, then projectors use PZT-8 (Navy type III) to minimize high-power heating effects. Designs typically use multiple stacked rings of 4 to 6 ceramics for low-impedance, high-power applications where the transducer must also receive. An even number of rings is used so that they can be connected in parallel with alternating polarity and electric fields. The maximum usable electrical field limit of ceramics is often a limit for the operation of the transducer. For PZT-4 (Navy type I), the maximum field is about 2400 V/cm (6 V/mil), and for PZT-8 (Navy type III) it is about 4000 V/cm (10 V/mil). The maximum voltage that can be applied to a transducer is equal to the field limit times the thickness of a single ceramic. For more information on the power-handling capabilities of ceramics, see Berlincourt *et al.* (1964).

To maximize the displacement of the head, the tail mass should be made as large as possible and have a mass 3 to 5 times that of the head. Typically a high-density metal such as tungsten, stainless steel, or brass is used. The in-water mechanical Q will typically have a value of 5 to 7; however, when assembled into an array, the Q will drop to a value of 2 to 5. A bolt is typically used between the head and tail to place a compressive load of 2000 to 6000 lb/in.^{2} on the ceramic so that high drive levels do not place the ceramics into tension. Placing the ceramics into tension may result in creating microcracks that will lead to failure.

The tonpilz transducer is capable of very high source levels, has an efficiency of (80–90)%, and is typically formed into arrays, which can form patterns capable of being steered to different angles. These arrays are used for imaging and locating objects. The cavitation threshold for the transducer or the array is calculated using Eq. (25). The intensity times the array face area gives a cavitation limited maximum power.

5.2 Thickness Vibrators

At frequencies higher than 100 kHz, solid ceramic shapes are typically used. These transducers can become a significant portion of a wavelength in size, and it is often necessary to account for vibration modes set up in the ceramic. The mathematics of analysis may become more complex, but the design itself has less flexibility than the low-frequency designs. It is at these frequencies that the broad-area transducers such as PVDF and the 1-3 PZT composites are becoming popular. These newer materials have greatly reduced or eliminated unwanted structural vibrations, allowing single transducers with a size of many wavelengths.

A thickness vibrator is a thin plate in which both the electrical field and the polarization are in the thickness direction. A *length expander* is a long thin bar with the electrical field parallel to the length. The polarization is also in the same direction as the electric field. To determine the fundamental resonance frequency for these vibration modes as well as for others, the equations are presented in Table 3 as a function of the *frequency constant* and the controlling dimension of the vibrator. This is a very useful table for determining the ceramic dimensions needed for a particular design. Fish finders, mine-hunting transducers, bottom profilers, ultrasonic medical transducers, and nondestructive testing transducers are typically fabricated by starting with a ceramic plate, dicing it into small elements, and then filling the gaps with a polymer. These are, in essence, 1–3 composite materials that have a specific design and application. Complex shape transducers using injection-molded 1–3 composite materials have been fabricated by the author using electroplating techniques. Complete arrays and large-area projector/hydrophone transducers are possible because of the mode decoupling achieved in a 1–3 composite.

When an air-backed transducer is excited by a pulse, little energy is lost and it rings at its resonance frequency. This impedance mismatch at the back of the transducer is desirable for continuous-wave operation; however, it is very undesirable for medical ultrasonic transducers. Lateral resolution in ultrasonic imaging is dependent on the transducer reproducing a pulse with little ringing present. Ringing can be reduced by using absorptive backings such as a tungsten-loaded epoxy. The penalty with using an absorptive backing to reduce ringing is a reduction in the sensitivity. A more current approach is to apply matching layers of suitable thickness (approximately quarter wavelength) and characteristic impedance between the ceramic and the medium. These layers permit efficient power transfer from the ceramic to water (the human body) without much loss in sensitivity. Typically a light acoustic backing will also be used. The use of matching layers to reduce ringing also results in a broader bandwidth. See Shung (1992) for more detail.

Table 3. Vibration modes for common transducer configurations.

					Frequency constant in kHz-m (kHz-in)			
Shape and electrode position	Vibration mode	Type of coupling	Direction of polarization	Controlling dimension	Type I PZT-4	Type III PZT-8	Type IV $BaTiO_3$	Type VI PZT-5H
Long, thin bar or strip	 Longitudinal mode Length varies	k_{31}	↓	L	1.60 (63)	1.75 (69)	2.34 (92)	1.41 (56)
Plate or Thin disc	 Thickness mode Thickness varies	k_{33}	↓	T	2.03 (80)	2.13 (84)	2.87 (113)	1.75 (69)
Thin disc	 Radial mode Radius varies	k_p	↓	D	2.16 (85)	2.36 (93)	3.18 (125)	1.98 (78)
Thin walled tube	 Radial mode Mean diameter varies	k_{31}	↖↑↗ ↙↓↘	D	1.02 (40)	1.07 (42)	1.47 (58)	0.89 (35)
 Shear plate	 Thickness shear mode rectangular cross-section is distorted into a rhombus	k_{15}	←	T	1.32 (52)	1.33 (57)	1.59 (62)	1.10 (43)
 Thin walled sphere	 Radial mode Mean diameter varies	k_p	↖↑↗ ↙↓↘	D	1.72 (68)	1.83 (72)	2.46 (97)	1.47 (58)
Hemisphere	 Radial mode Mean diameter varies	k_p	↖↑↗ ↙↓↘	D	2.08 (82)	2.26 (89)	3.02 (119)	1.85 (73)
 Bender transducer	 Flexural mode Free end moves at right angle to beam axis	k_{31}	↓ or ↑ ↑ ↓	$\frac{L^2}{t}$	0.51 (20)	0.56 (22)	0.74 (29)	0.46 (18)

5.3 Shaped Ceramic Transducers

Ceramic piezoelectric materials can be fabricated into a wide variety of shapes and sizes, and they lend themselves to designs for specific applications that would be difficult for single ceramic pieces. The shapes shown in Table 3 are an example.

Spherical transducers are typically the choice for omnidirectional patterns. Complete omnidirectionality can be obtained by using a spherical transducer that has a diameter smaller than a wavelength. One of the problems of a sphere is attaching leads to the inner electrode. For this reason two hemispheres are used, with the wires being attached prior to bonding the two pieces together. Small *cylindrical transducers* will also produce omnidirectional patterns and are often easier to fabricate. When used as a hydrophone, the cylinder dimensions are determined by the frequency range over which a flat response is desired. The upper limit of the flat range is slightly below the lowest resonance frequency. When operating as a projector, the fundamental resonance mode will produce the peak acoustic pressure level. There are three fundamental modes of vibration: length mode (a half-wavelength resonator), radial mode (the breathing mode, calculated using the mean diameter), and wall-thickness mode. Some coupling is present between these various modes of vibration. The coupling between the length and radial modes becomes very strong when the length is approximately three times the mean radius, and results in distorted patterns and frequency responses. This ratio is a design "forbidden zone" and should be avoided. See Hueter and Bolt (1955) for more detail. The cylindrical ceramic typically has its ends capped to shield the inner cylindrical surface from the acoustic medium. Since the outside and inside surfaces are electroded, and the polarization is radial, the electrical impedance is low. Also, the cylinder has a large radiating area in relation to the cross section of the ceramic, resulting in the mechanical impedance of the element being much lower than a solid ceramic of the same dimension. This permits a better acoustic match between the ceramic and the water.

A *bimorph* is a bender transducer (see Table 3), which flexes and has the capability for handling larger motions and smaller forces than single piezoelectric plates. This transducer is fabricated by bonding two shear-mode plates or two longitudinal-mode plates together in such a manner that when a voltage is applied, the plates will deform in opposite directions, resulting in a bending or twisting action. One example is the low-frequency flextensional transducer discussed earlier. The bimorph is typically a high-frequency transducer operating in air and is often used for ac and dc relays, audio alarms, tweeters, and micromanipulators. A shear-mode transducer has been used in shear accelerometers and for generating surface waves on structures.

6. OTHER TRANSDUCERS

Parametric transducers are used to create very narrow beamwidths at low frequencies. They rely on the nonlinear properties of water at high source levels. When two frequencies are generated at high amplitudes, intermodulation products are produced in the nonlinear medium such that the column of fluid in front of the transducer acts as a thin line array radiating in the direction of propagation. This characteristic is equivalent to an end-fire acoustic array. The low-frequency difference beam, called the secondary frequency component, has nearly the same beamwidth as at the primary frequency. The narrow beamwidth is achieved by use of a transducer that has a much smaller aperture than a conventional transducer. Even though the narrow beamwidth is very attractive, the parametric array is not typically used because the process is very inefficient.

In *fiber optic sensors* the variation in pressure in acoustic waves affects the optical properties of thin fiber optic cables. Compared to other hydrophones, it has high sensitivity and is insensitive to electromagnetic interference. In almost all of the standard configurations the sensing of the acoustic wave is accomplished in an optical detector that is sensitive to phase differences between light that has traveled a distance in fiber exposed to the sound and light that has traveled about the same distance but was not exposed to the sound. Mechanical noise pickup is a problem.

Chemical acoustic sensors result from phenomena in electrolytes that permit sensing acoustic pressure by measuring electrochemical potential. An acoustic wave that strikes an electrode where gas is being liberated by electrolysis causes an alternating component of the electrical potential. In another phenomenon, when a layer of electrolyte-filled nonconducting fiber surrounds an electrode, an electrokinetic effect in the fiber changes the electrode potential relative to the surrounding electrolyte. A microphone for low-frequency sounds called the solion infrasonic microphone uses a chemical reaction that depends on the flow of ions through an acoustic resistance placed in the electrolyte between the electrodes.

INTRODUCTION

Transformers are passive devices used to transform voltage and current. They are used in countless applications and come in a variety of forms and sizes. However, the principles of operation are the same for all of them.

The voltage and current scaling property of transformers is used for impedance

digital Encyclopedia of Applied Physics

matching between a source and a load. Moreover, they provide electrical insulation between input and output, which allows ground shifting and polarity inversion.

Two classes of transformers can be identified: power transformers and electronic transformers. The term power transformer is normally used for transformers operating over a narrow frequency range (50–60 Hz) and used in distribution systems for electric utilities. The term electronic transformers is basically used for all other types of transformers. Examples of electronic transformers are audio and wide-band transformers, pulse transformers, magnetic amplifiers, and transformers used in high-frequency switching power supplies.

Many electronic components come as off-the-shelf standardized parts, but only a limited selection of off-the-shelf transformers is available. The problem is that transformers need to be specifically tailored and optimized for specific applications. As a result, transformers tend to be expensive.

Another characteristic of transformers is that they tend to be bulky, especially in comparison with other miniaturized electronic components. For this reason in many applications designers try to do without them if possible.

In Sec. 1 the theory of operation of transformers is reviewed starting from the ideal transformer and then introducing various nonidealities. In Sec. 2 various issues related to transformers are discussed: ferromagnetism and ferromagnetic materials, core and copper losses, leakage inductances, and parasitic capacitances. In Sec. 3 the wide-band transformer is analyzed in the frequency domain, whereas in Sec. 4 the pulse transformer is analyzed in the time domain. Sec. 5 discusses transformers in high-frequency switching power supplies. Finally, Sec. 6 deals with magnetic amplifiers.

1. THEORY OF OPERATION

The case of an ideal transformer is discussed first, and the impedance scaling law of transformers is derived. An ideal transformer satisfies three assumptions: no internal energy storage, perfect magnetic coupling between the windings, and no power loss. These assumptions are relaxed one by one in subsequent sections, and the relative equivalent models are presented.

1.1 The Ideal Transformer

In order to understand the basics of transformers, the case of an ideal transformer is considered here. The physical system is shown in Fig. 1(a), and the circuit representation of an ideal transformer is shown in Fig. 1(b). The following assumptions are made:

1. There is perfect magnetic coupling between primary and secondary windings.
2. There is no instantaneous energy storage in the transformer.
3. The transformer is lossless.

Real-life transformers only approximately satisfy these assumptions, but the transformer designer usually strives to come as close as possible to satisfying them.

Assumption 1 states that the same flux ϕ couples the two windings. Application of Faraday's law gives

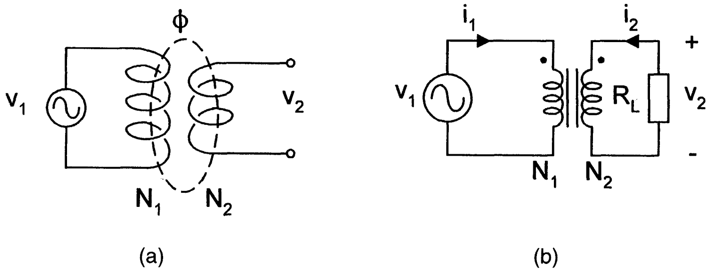

FIG. 1. Ideal transformer: (a) physical system and (b) circuit representation.

$$\frac{d\phi}{dt} = \frac{v_1}{N_1} = \frac{v_2}{N_2}. \tag{1}$$

From Eq. (1),

$$v_1/v_2 = N_1/N_2. \tag{2}$$

This is the *voltage scaling law* of transformers, which says that the voltage in the various windings is proportional to the number of turns. In the circuit representation of Fig. 1(b), the voltage polarity in the various windings is given by the *dot convention:* a positive voltage applied to the marked terminal of one winding induces a positive voltage on the corresponding marked terminal of the other winding.

From assumptions 2 and 3 it follows that there is no net power flowing into the transformer at any time, and therefore the power balance requires that

$$v_1 i_1 + v_2 i_2 = 0. \tag{3}$$

Combining Eqs. (2) and (3) gives

$$i_1/i_2 = -N_2/N_1. \tag{4}$$

This is the *current scaling law* of transformers.

Dividing (2) by (4) we get the *impedance scaling law* of transformers

$$\frac{v_1/i_1}{-v_2/i_2} = \frac{R_L'}{R_L} = \left(\frac{N_1}{N_2}\right)^2. \tag{5}$$

The secondary load impedance R_L appears at the primary as an impedance

$$R_L' = (N_1/N_2)^2 R_L. \tag{6}$$

This is a very useful property of transformers. In electronics, it frequently happens that a source that would operate most efficiently or with least distortion having as a load an impedance R_L' must be connected to a load of impedance R_L. In these cases a transformer can be inserted between source and load to provide the desired impedance scaling.

1.2 Transformers with Internal Energy Storage

With respect to the ideal transformer of Sec. 1.1, the assumption of no energy storage in the transformer is now relaxed. As a result, a magnetizing inductance, representing the energy stored in the transformer, is defined.

1.2.1 The Case of a One-Winding Inductor In order to describe the basic operation of a transformer, we start with only one winding with N_1 turns wound around a high-permeability magnetic core, as shown in Fig. 2. Current i_m flowing in the winding generates a magnetic flux ϕ that closes in the magnetic core. The relationship between voltage and flux is given by Faraday's law

$$v_1 = N_1\frac{d\phi}{dt}. \tag{7}$$

Ampère's law

$$I = \oint \mathbf{H}\cdot d\mathbf{l} \tag{8}$$

states that the integral of the magnetic field **H** along a closed path is equal to the enclosed current *I*.

Ampère's law is now applied to the mean magnetic path inside the core shown in Fig. 2. The path encloses the N_1 turns, and therefore the enclosed current is $N_1 i_m$. This quantity is called the *ampere-turns* linked by the magnetic flux path. It is assumed that the magnetic field **H** is of constant amplitude, and it is parallel to the integration path at all points as in Fig. 2. Under these assumptions, Eq. (8) becomes

$$Hl = N_1 i_m, \tag{9}$$

where l is the length of the mean magnetic path. This equation gives the relationship be-

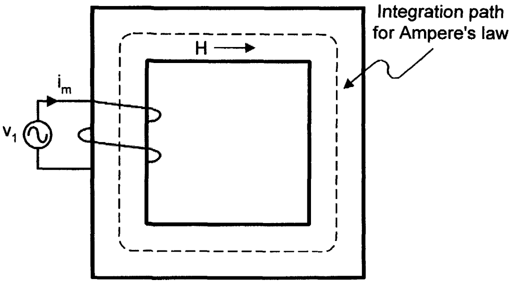

FIG. 2. Magnetic core with one winding.

tween magnetic field H and exciting current i_m.

The relationship between magnetic field H and magnetic induction B is in general nonlinear for the high-permeability materials normally used for transformer cores, and it is discussed in Sec. 2.1 on ferromagnetic materials. For now a linear relationship

$$B = \mu H \tag{10}$$

is used, where μ is the material *permeability*. Assuming that the magnetic induction is constant throughout the core cross section S, flux ϕ in the core is

$$\phi = BS. \tag{11}$$

The left-hand side of Eq. (9) is multiplied and divided by the constant μS. Taking into account Eqs. (10) and (11), we get

$$\phi \mathcal{R}_c = N_1 i_m \tag{12}$$

where $\mathcal{R}_c$ is the *reluctance* of the magnetic flux path in the core and is defined as

$$\mathcal{R}_c = l/\mu S. \tag{13}$$

Both sides of Eq. (12) are now multiplied by N_1 and, after rearranging, we have

$$N_1 \phi = L_m i_m, \tag{14}$$

with the *magnetizing inductance* L_m defined as

$$L_m = N_1^2/\mathcal{R}_c. \tag{15}$$

Equation (14) states that *flux linkage*, i.e., flux multiplied by the number of turns linking the flux, is proportional to the current that generates it, and magnetizing inductance L_m is flux linkage per unit current. The current i_m that generates the magnetic flux ϕ is called the *magnetizing current*.

1.2.2 The Case of a Two-Winding Transformer A second open-circuited winding with N_2 turns is now added, and the transformer shown in Fig. 3(a) is obtained. The current i_1 in the first winding is unchanged. If the two windings are perfectly coupled, flux ϕ generated by the primary winding links the secondary winding also, and Eqs. (1) and (2), derived in the case of an ideal transformer, hold.

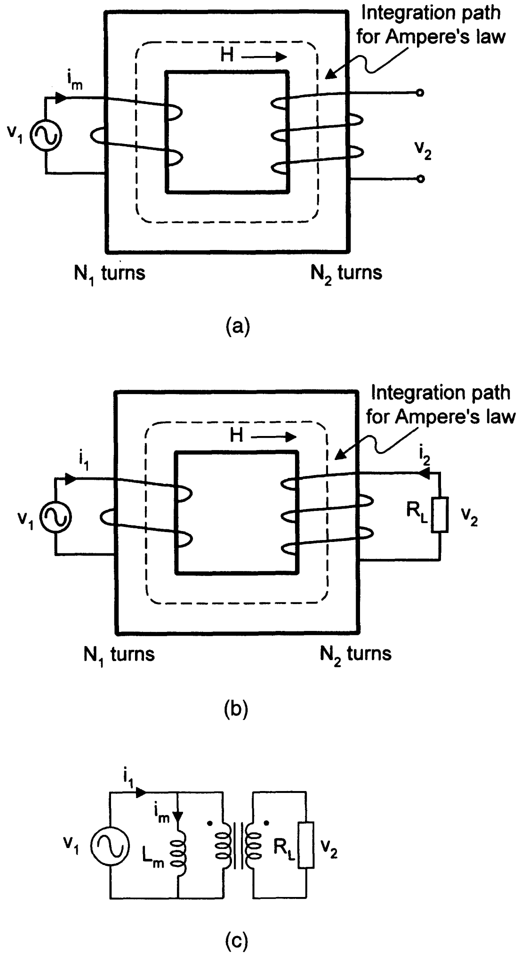

FIG. 3. Magnetic core with two windings: (a) no load, (b) load R_L, and (c) equivalent circuit.

Suppose now that we connect a load R_L on the secondary of the transformer as in Fig. 3(b). Neglecting second-order effects (like, for example, resistive voltage drops in the windings), the primary and secondary voltages v_1 and v_2 are unchanged. Equations (1) and (2) still hold. Current i_2 is dictated by the load impedance:

$$i_2 = -v_2/R_L. \tag{16}$$

Ampère's law can be applied to the path shown in Fig. 3(b). Notice that this path encloses both N_1 primary turns and N_2 secondary turns:

$$Hl = N_1 i_1 + N_2 i_2. \tag{17}$$

Following the same steps as in Sec. 1.2.1, we multiply and divide the left-hand side by μS, and we get

$$\phi \mathfrak{R}_c = N_1 i_1 + N_2 i_2. \tag{18}$$

This equation is compared with Eq. (12) derived in the case of a one-winding inductor. Flux ϕ in the core, which is determined by the winding voltage, is unchanged, and therefore the left-hand sides of the two equations are identical. Equating the right-hand sides gives

$$i_1 = i_m - (N_2/N_1) i_2. \tag{19}$$

This equation can be interpreted in the following way: the primary current i_1 has two components; one is the magnetizing current i_m, which generates the flux in the core, and the other component is the reflected load current. This current cancels the ampere-turns generated by current i_2 and does not generate any flux in the core, as can be seen substituting (19) into (18).

Equation (19) should be compared with Eq. (4) for the ideal transformer. The difference is the term i_m, related to the energy stored in the transformer.

The circuit model is shown in Fig. 3(c). Magnetizing inductance L_m defined in (14) appears in parallel with the ideal transformer.

1.3 Transformers with Nonperfect Magnetic Coupling

At this point the assumption of perfect magnetic coupling between primary and secondary is relaxed.

As shown in Fig. 4(a), the flux coupled with each winding can be divided into two components: coupled flux ϕ and leakage fluxes ϕ_{l1} and ϕ_{l2},

$$\phi_1 = \phi_{l1} + \phi, \tag{20}$$

$$\phi_2 = \phi_{l2} + \phi. \tag{21}$$

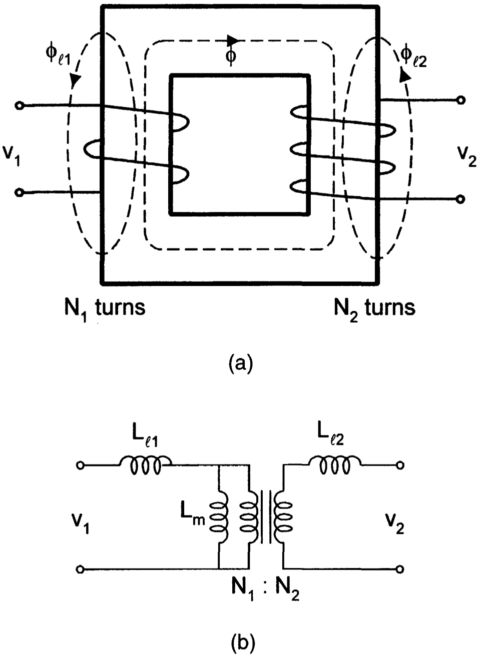

FIG. 4. Transformer with leakage fluxes: (a) physical system and (b) equivalent circuit.

The reluctances of the leakage flux paths of ϕ_{l1} and ϕ_{l2} are called $\mathfrak{R}_{l1}$ and $\mathfrak{R}_{l2}$, respectively. The corresponding leakage inductances, defined in the same way as (14), are

$$L_{l1} = N_1^2/\mathfrak{R}_{l1}, \tag{22}$$

$$L_{l2} = N_2^2/\mathfrak{R}_{l2}. \tag{23}$$

The equivalent model is shown in Fig. 4(b).

Notice that the value of magnetizing inductance L_m is a function of nonlinear core-material characteristics, and therefore it is not constant. On the other hand, leakage inductances represent flux in air, which is a linear medium, and therefore they are approximately constant. For a more complete discussion of leakage, refer to M.I.T. (1943).

1.4 Transformers with Power Losses

Next the assumption of no loss in the transformer is relaxed. In a real-life transformer there are various loss mechanisms:

- Conduction losses. These are Ohmic losses in the windings. Current distribution in the conductors is frequency dependent (skin and proximity effects) and so are

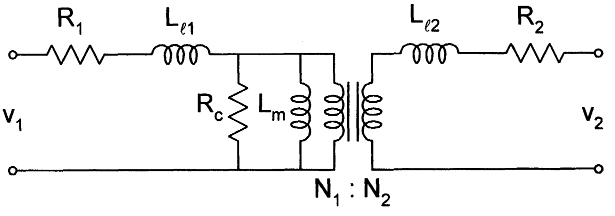

FIG. 5. Low-frequency equivalent model of a transformer.

conduction losses. These losses are modeled by series resistances R_1 and R_2.

- Core losses. ac fluxes in ferromagnetic materials cause losses, which are a nonlinear function of flux swing, flux bias, excitation frequency, and previous magnetization history. These losses are usually modeled by a nonlinear resistor R_c in parallel with magnetizing inductance L_m.

The equivalent model is shown in Fig. 5. This model is valid at low frequencies. At high frequencies, transformer parasitic capacitances must be included also, as explained in Sec. 2.5.

2. DESIGN CONSIDERATIONS

2.1 Ferromagnetism

In the derivation of magnetizing inductance L_m of a transformer in Sec. 1.2, a linear relationship between magnetic field H and magnetic induction B was assumed [Eq. (10)]. In this section the nonlinear characteristics of ferromagnetic materials are discussed (see Smit, 1971).

A typical magnetization curve of a ferromagnetic material (see Charap, 1974) is shown in Fig. 6. If H is varied from a large negative value to a large positive value and back again, the *B-H* curve describes a loop, called *hysteresis curve,* which is transversed in the direction indicated by the arrows in Fig. 6. The following observations can be made.

Material permeability is higher than free-space permeability. *Relative permeability* is defined as the ratio of material permeability to free-space permeability. Relative permeabilities of magnetic materials vary from 10–100 for powdered cores to 100 000 for nickel alloys. The high relative permeability of ferromagnetic materials is the main reason why they are used for transformers. Their effect is to reduce reluctance $\mathcal{R}_c$ of the flux path in the core and boost magnetizing inductance L_m, as can be seen from Eqs. (13) and (15).

The magnetization tends to lag the magnetic field. When H increases from a negative to a positive value, B takes a given set of values, and, when H decreases, B takes a different set of values, higher than before. In particular, when H decreases to zero, B still has a positive value B_r called *remanent magnetization.* In order to bring the magnetization to zero, a negative magnetic field H_c called *coercive force* must be applied. B_r and H_c are shown in Fig. 6.

The shape of the hysteresis loop changes with the frequency of excitation. In particular, the hysteresis loop becomes wider at higher frequencies, as shown in Fig. 7.

The *B-H* characteristic exhibits magnetic saturation. The slope of the *B-H* curve at a given point is called *differential permeability.* For low values of magnetic field, differential permeability is high, but for higher values it decreases, and it eventually becomes equal to the permeability of free space. A family of hysteresis curves can be obtained for different values of ac excitation at a given frequency. Such a family of curves is shown in

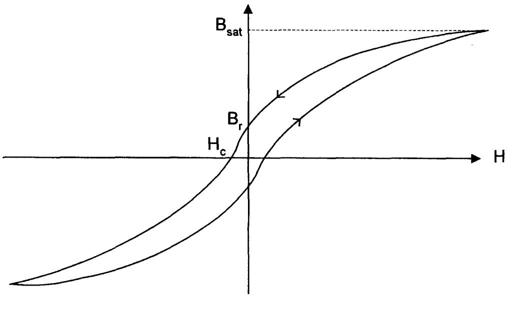

FIG. 6. *B-H* hysteresis characteristic.

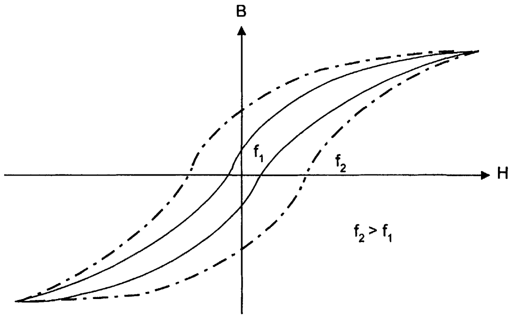

FIG. 7. *B-H* loop widens with frequency.

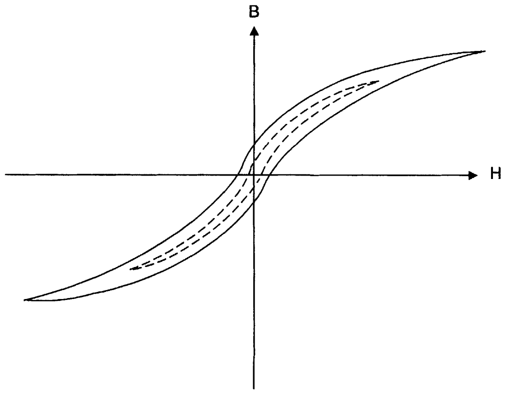

FIG. 8. Family of *B-H* loops for various amplitudes of excitation.

Fig. 8. Magnetic saturation gives an upper limit to the usable flux swing in the core.

2.1.1 From Material Characteristics to Inductance Characteristic Suppose we have a transformer built using a ferromagnetic material with a characteristic of the type shown in Fig. 9(a). It is instructive to relate the material characteristic (*B-H* loop) to the circuit characteristics ($N_1\phi$-i_m curve) of the transformer (see Watson, 1980).

The process involves two steps: physical scaling and number-of-turns scaling.

2.1.1.1 Physical Scaling. We start from the *B-H* curve. Slope in this curve represents permeability. The x axis is scaled by the magnetic path length l, so that it represents ampere-turns (9). The y axis is scaled by core cross section S, so that it represents flux ϕ in the core. The resulting characteristic is shown in Fig. 9(b). The slope represents the inverse of reluctance, $\mathcal{R}_c^{-1}$ (also called *permeance*).

2.1.1.2 Number-of-Turns Scaling. The y axis is now scaled by number of turns N_1, so that it represents flux linkage $\lambda = N_1\phi$. The x axis is scaled by $1/N_1$, so that it represents current i_m. The slope of the resulting characteristic of Fig. 9(c) is magnetizing inductance L_m. Notice how it changes as we move along the hysteresis loop.

2.1.2 Core Loss Core loss is the power dissipated in the core. Two different loss mechanisms can be identified: hysteresis loss (see Chen, 1978; Tan *et al.*, 1995) and eddy-current loss.

2.1.2.1 Hysteresis Loss. Let us consider a winding of N_1 turns wound on a ferromagnetic core (e.g., the primary of a trans-

i_m

FIG. 9. From material characteristic to inductance characteristic.

former with no secondary load) as in Sec. 1.2.1. The energy delivered to the core in an interval Δt is

$$J = \int v_1 i_m dt. \tag{24}$$

Substituting Eqs. (7), (9), and (11) yields

$$J = \int N_1 \frac{d\phi}{dt}\frac{Hl}{N_1} dt, \tag{25}$$

$$= Sl \int H\, dB. \tag{26}$$

The quantity Sl represents the core volume, and therefore the integral represents the energy delivered to the core per unit volume.

Now we want to find the energy lost during one period of ac excitation, i.e., during one transverse of the hysteresis loop of Fig. 10.

The differential energy per unit volume delivered to the core while the magnetic field has an incremental increase dB (path 1–2) is represented by the sum of the shaded and hatched areas of Fig. 10. The hatched portion of this energy is returned to the external circuit when, later during the ac period, magnetic field decreases by dB (path 3–4), and it represents reactive energy exchanged back and forth between core and external circuit. The shaded area in Fig. 10 represents energy dissipated in the core. Notice that in the case of a single-valued B-H characteristic with no hysteresis there is no such loss, and all energy delivered to the core is then returned.

From the previous discussion it follows that the energy lost in one period of ac excitation is equal to the area of the hysteresis loop. The power loss is

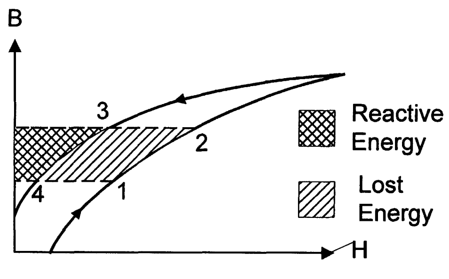

FIG. 10. Hysteresis loss calculation from *B-H* loop.

$$P_{\text{loss}} = Vf \oint H\, dB, \tag{27}$$

where V is the core volume, f is the excitation frequency, and the integral is calculated along the hysteresis loop. As shown in Fig. 7, the hysteresis loop widens with frequency, and therefore hysteresis loss increases more than proportionally to frequency.

2.1.2.2 Eddy-Current Loss. Eddy-current losses are resistive losses due to circulating currents in a conductive magnetic core. The varying flux in the core induces currents in it in the same way as currents are induced in the secondary of a transformer. These currents tend to be large because metals and other alloys used for magnetic cores have rather low resistivity. A solution to mitigate this problem is to reduce the path in the core available for current flow by using core laminations insulated from each other and stacked together. To be effective, the lamination plane should be normal to the induced current direction.

Losses in metals become unacceptable for radio and microwave frequencies. Ferrites, which have much higher resistivity, are used at these frequencies. Ferromagnetic materials are discussed in Sec. 2.2.

2.1.3 Ferromagnetic Distortion

Ferromagnetic distortion is the distortion in the current and voltage wave forms of a transformer due to the nonlinear core characteristic. This distortion is usually undesirable. Given the nonlinear B-H loop characteristic, if the applied voltage is sinusoidal, the magnetizing current will be distorted, and, conversely, if the applied current is sinusoidal, the flux in the core and the voltage induced in the secondary will be distorted. The actual voltage and current wave forms depend on the external circuit as well as on the core characteristic.

2.1.3.1 Low Source Impedance. In the case of low source impedance, the applied voltage is approximately sinusoidal. Figure 11 shows the salient wave forms. The flux is sinusoidal, 90° delayed with respect to the voltage (7). If the hysteresis curve is linear, the current is sinusoidal in phase with the flux. Otherwise, the relationship between current and flux is given by the ϕ-i characteristic of Fig. 9(b) obtained from the hysteresis characteristic. The current is distorted

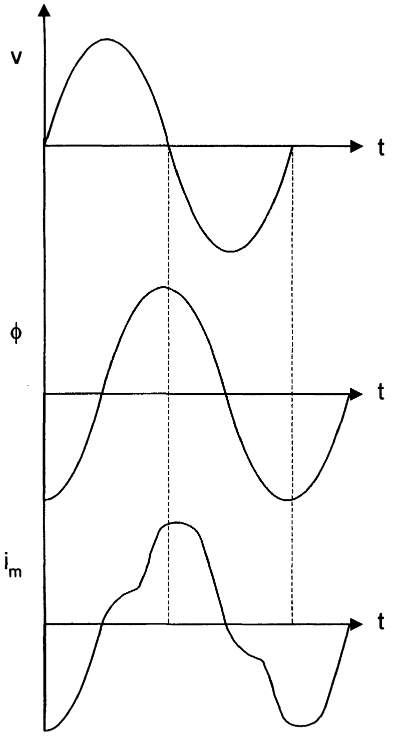

FIG. 11. Ferromagnetic distortion.

as shown in Fig. 11. However, if the core flux is sinusoidal, the voltage induced on the secondary is also sinusoidal. It may seem that the distorted magnetizing current is of no consequence, but in reality this current will cause harmonic voltages on the transformer winding resistances and any other parasitic resistances, so that the voltage on the transformer primary will have harmonic components and the induced secondary voltage will be distorted. It should be stressed that the current shape depends on the hysteresis loop shape. For example, a square hysteresis loop gives approximately a square-wave current in phase with the voltage.

2.1.3.2 High Source Impedance. If the source impedance is large, the external circuit acts as a current source, and the source current is sinusoidal. In this case the flux will be distorted and so will be the induced voltage.

2.1.4 Introduction of an Air Gap In transformers discussed up to this point, the high-permeability core forms a closed high-permeability path for the magnetizing flux. As a result, high values of magnetizing inductance can be achieved. This is usually regarded as a desirable property, since the transformer better approximates the behavior of the ideal transformer of Sec. 1.1, which has infinite magnetizing inductance.

However, there are two problems:

- Distortion. The magnetizing inductance is nonlinear on account of the nonlinear *B-H* loop, and this causes distortion, especially at low frequencies, as explained in Sec. 2.1.3.
- Saturation. Even a small amount of dc current in one of the windings may cause core saturation.

To solve these problems, an air gap can be introduced in the magnetic flux path. The result is a reduction of the value of magnetizing inductance, an increase of dc current capability of the transformer, and a stabilization of the value of magnetizing inductance, which is now dominated by gap reluctance. Figures 12(a) and 12(b) show the idealized transformer characteristic for the ungapped and gapped cores, respectively. The core characteristic is sheared as an effect of gap.

A transformer with an air gap can be analyzed following the steps of Sec. 1.2.1. When an air gap is introduced, the flux in the core flows through the gap. Maxwell's equation states that

$$\oint_S \mathbf{B}\cdot d\mathbf{S} = 0, \tag{28}$$

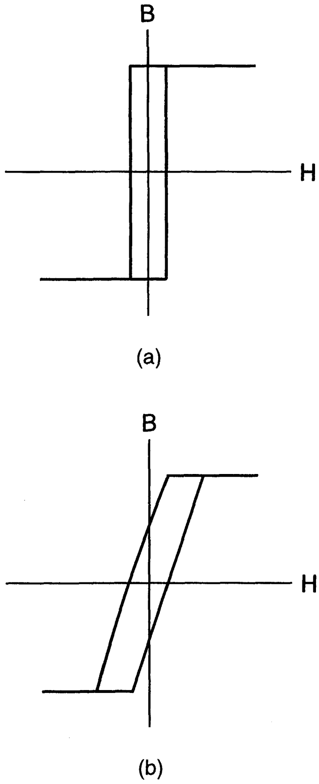
which means that the magnetic field does not have sources or sinks. As a result, induction B in the core and in the gap is the same, as shown in Fig. 13. It follows that

$$B_c = B_g, \tag{29}$$

$$\mu H_c = \mu_0 H_g, \tag{30}$$

where μ and μ_0 are the permeabilities of the core and of free space, respectively. H_c and H_g, the magnetic field in the core and in the gap, respectively, are assumed constant throughout the cross section S.

Referring to Fig. 13(a), we can apply Ampère's law (8):



(a)

(b)

FIG. 12. Idealized transformer characteristic (a) for ungapped core and (b) for gapped core.

$$H_c l + H_g l_g = N_1 i_m, \tag{31}$$

where l is the length of the magnetic flux path in the core and l_g the length of the magnetic flux path in the gap, i.e., the gap size. The first term of (31) is multiplied and divided by μS and the second term by $\mu_0 S$.

The result is

$$\phi(\mathcal{R}_c + \mathcal{R}_g) = N_1 i_m, \tag{32}$$

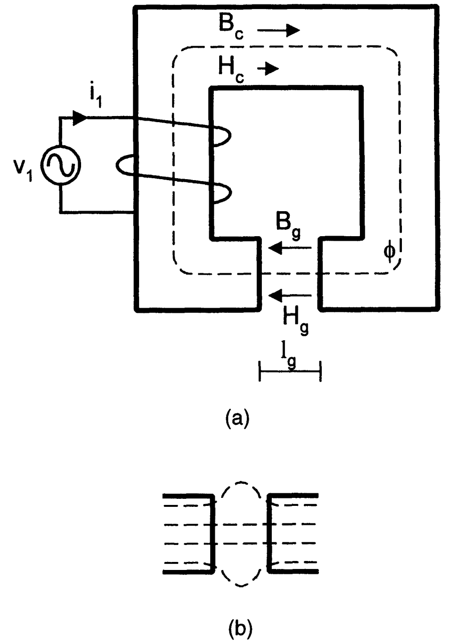
where $\mathcal{R}_c$ is the core reluctance defined in (13) and $\mathcal{R}_g$ is the gap reluctance defined as

$$\mathcal{R}_g = l_g/\mu_0 S. \tag{33}$$

Usually $\mathcal{R}_g \gg \mathcal{R}_c$, and therefore gap reluctance dominates. Multiplying Eq. (32) by N_1 and rearranging, we get

$$\lambda = N_1 \phi = L_m i_m \tag{34}$$

with



(a)

(b)

FIG. 13. (a) Introduction of an air gap in the core and (b) detail of fringing flux at gap.

$$L_m = N_1^2/(\mathcal{R}_g + \mathcal{R}_c). \tag{35}$$

Magnetizing inductance L_m in the presence of the gap is reduced from the ungapped case of (14).

The calculation of gap reluctance $\mathcal{R}_g$ described above does not take into account the effect of *fringing flux.* The flux lines crossing the gap tend to spread out as shown in Fig. 13(b). As a result the effective cross section of the gap is bigger than the core cross section, and the measured inductance is bigger than the value one would expect based on (33) and (35). This effect is particularly significant for big gaps.

2.2 Magnetic Materials

Different magnetic materials with different properties are available. The following material characteristics are of interest:

- Shape of the *B-H* loop. Magnetic materials are characterized as hard or soft materials. Hard materials, which have high remanent magnetization B_r and coercive force H_c, are good for permanent magnets because they have high flux density with no excitation (remanent flux density) and they are hard to demagnetize (high coercive force). Soft materials, which have low coercive force, are good for transformers and inductors, because they have less hysteresis losses.

- Resistivity. This is important for eddy-current losses in the core. See Sec. 2.1.2.
- Saturation flux density. Materials with higher saturation flux density are desirable because they allow a reduction of the magnetic core physical size. However, full utilization of the available flux swing is often prevented by excessive core losses, especially at higher frequencies.
- Curie temperature. This is the temperature at which the material loses its ferromagnetic properties. It gives an upper bound to the operating temperature of a transformer.
- Cost.

2.2.1 Metallic Alloys The main ferromagnetic materials are iron, nickel, cobalt, and their alloys. These materials are used mostly at power frequencies. They are fairly good conductors, and therefore their use at higher frequencies is limited by eddy-current losses.

2.2.1.1 Iron–Silicon Alloys. Silicon steel is widely used for low- and intermediate-frequency applications. Addition of silicon (from 0.5% to 4.5%) to steel reduces both hysteresis and eddy-current losses.

Silicon steel is sold in laminations of various thicknesses, usually insulated, to reduce eddy currents. Silicon steel can be obtained in *grain-oriented* form: the material is cold rolled to obtain the easy magnetization direction parallel to the rolling direction. As a result it exhibits very low core losses.

2.2.1.2 Iron–Nickel Alloys. These alloys have a 45% to 80% nickel content. They are used for low-field applications where high permeability is required. These types of applications are common at higher frequencies, where core losses become a limiting factor. Extremely square-loop materials can also be obtained with proper processing.

2.2.1.3 Iron–Cobalt Alloys. Iron–cobalt alloys are used when a high magnetic saturation is required. Supermendur is an iron–cobalt alloy with 2% vanadium, 49% iron, and 49% cobalt. Grain orientation is obtained by annealing the material under a magnetic field. Supermendur has a high saturation flux density (2.2 T), and it has the highest permeability at elevated flux levels (100 000 relative permeability at 2 T) and the highest remanent magnetization of any alloy. These materials are extremely expensive.

2.2.2 Ferrites Ferrites (see Snelling, 1969, 1983) are nonmetallic ferromagnetic oxides that are used from the high audio range well into the megahertz range. The main advantage of these materials is the high electrical resistivity (10^6 to 10^{10} Ω cm), normally 10^6 times that of metallic magnetic alloys, which makes them attractive at higher frequencies. Different ferrite materials with different compositions are optimized for a certain range of operating frequencies. Ferrites are limited by their low Curie temperature and by their low saturation flux density (0.3–0.5 T), which decreases with temperature. Material permeability, which ranges from few hundreds to 10 000, is also lower than the permeability of metallic magnetic alloys.

2.2.3 Powdered Cores These materials are used for higher-frequency applications into the 200-kHz range. Powdered ferromagnetic materials are compacted with an insulating binder, thereby significantly reducing eddy-current losses. This process effectively builds a "distributed gap" in the material, which lowers the relative permeability to values between 3 and 100, depending on the mix used. The advantage is that the permeability is fairly stable in value at high dc current levels, and the material exhibits a soft (not abrupt) saturation characteristic.

2.2.4 Amorphous Alloys Also called magnetic metallic glasses (see Raskin and Davis, 1981; Boll and Warlimont, 1981; Graham and Egami, 1980), these amorphous alloys, recently (1970–1980) introduced, have significantly lower losses than comparable crystalline alloys, which makes them attractive at high frequencies. They represent an alternative to ferrites with the advantage of higher saturation flux densities (1.6 T). They are alloys of iron, boron, and silicon, which are quenched so rapidly that crystal formation typical of other magnetic alloys is prevented. Disadvantages are that the material is very brittle and very strain sensitive, and that only a limited set of shapes are available on account of manufacturing difficulties.

2.3 Leakage Inductances

As explained in Sec. 1.3, leakage flux in a transformer is flux generated by one winding that does not couple (or only partially couples) with the other winding. This is usually undesirable. For example, it reduces the high-frequency bandwidth of wide-band transformers and pulse transformers.

In order to reduce leakage, windings are physically placed as close as possible. Factors that limit how close the windings are placed are insulation thickness, the need to limit capacitive coupling between layers, and cost of manufacturing.

A very effective approach to reduce leakage and improve coupling is to split the windings into sections and then to sandwich them. This process is called *sectionalization* or *interleaving*. The case of a secondary split into two with interleaved primary is shown in Fig. 14.

Another way to reduce leakage, frequently used especially with toroidal cores operated at high frequencies, is to use *bifilar windings*, i.e., wind primary and secondary together around the core.

Leakage inductances can be calculated by calculating the energy stored in the leakage magnetic field between and through the windings. As frequency increases, leakage inductance decreases because the leakage magnetic field is confined to the surface of the conductors by the skin effect (see Dowell, 1966).

2.4 Conduction Loss: Skin and Proximity Effects

Conduction losses in high-frequency transformer windings are higher than one would expect on the basis of dc resistance measurements. This is due to nonuniform current distributions inside the windings caused by the varying magnetic field produced within the conductor by its own current and by the currents in neighboring conductors. These phenomena are often called *skin effect* and *proximity effect*.

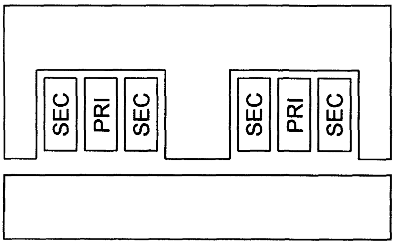


FIG. 14. Transformer with interleaved windings.

Skin effect can be studied analytically for some simple geometries—for example, in the case of a semi-infinite conductor or a round conductor (see Ramo *et al.*, 1984). The result is that the electric and magnetic fields decay exponentially as they penetrate the conductor. The depth of penetration or *skin depth* δ is found to be

$$\delta = 1/\sqrt{\pi f \mu \sigma}, \tag{36}$$

where f is the excitation frequency, μ is the permeability, and σ is the conductivity.

A way to visualize skin effect is to say that the magnetic field induces a current in the conductor by Faraday's law, which tends to oppose the variation of flux. These eddy currents limit the penetration of the magnetic field to a region near the surface of the conductor.

Proximity effect is analyzed in Dowell (1966) and Vandelac and Ziogas (1987). Another approach to the study of proximity effects is to use finite-element simulations (see Goldberg *et al.*, 1989a,b).

2.5 Parasitic Capacitances

When a transformer is powered, different electric field gradients arise almost everywhere. A number of different capacitances can be identified as in Fig. 15:

- between turns,
- between layers,
- between windings, and
- between the core and the windings.

Since the voltages change from point to point, distributed capacitances should be considered. For analysis purposes, these capacitances are usually lumped together into equivalent capacitances.

Usually the capacitances between adjacent layers of a winding and the capacitances between different windings (or, more precisely, the capacitances between adjacent layers of

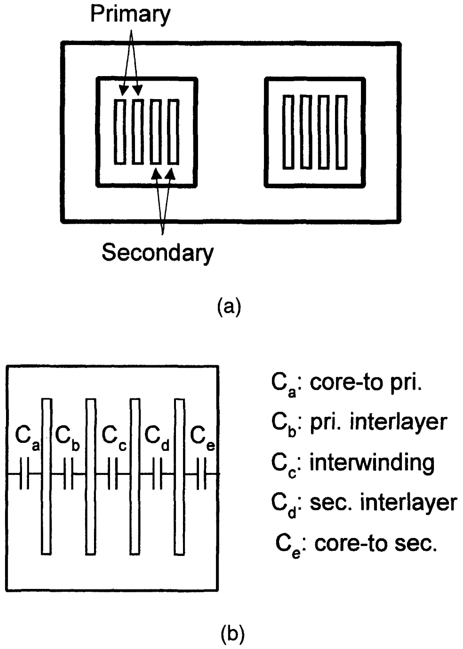

FIG. 15. (a) Example of transformer and (b) detail of windings showing parasitic capacitances.

different windings) are the most relevant ones.

Let us consider two adjacent layers AB and CD (which may or may not belong to the same winding) as in Fig. 16(a). During transformer operation, the voltage of a layer at a given moment changes linearly from point to point. Because of this, the equivalent capacitance is different from the static capacitance C_0 of Fig. 16(b), and it can be calculated from the energy stored between the layers. It can be easily shown that the equivalent capacitance referred to a terminal with voltage V is

$$C_{\text{eq}} = \frac{C_0(V_{\text{AC}}^2 + V_{\text{AC}}V_{\text{BD}} + V_{\text{BD}}^2)}{3V^2}. \tag{37}$$

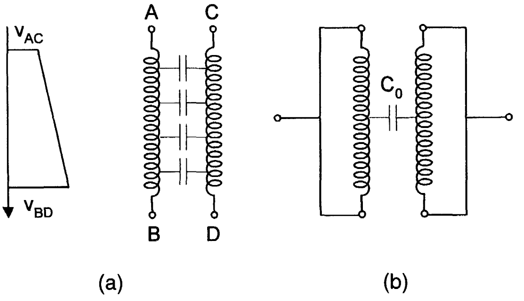

FIG. 16. (a) Calculation of parasitic capacitance. (b) dc measurement of interwinding capacitance does not give correct result.

The different capacitances can be calculated and then combined together.

A Π network of lumped capacitances C_1, C_2, and C_{12} is frequently used for modeling purposes, as shown in Fig. 17(a). These capacitances have an effect on the high-frequency behavior of the transformer. In order to operate a transformer at higher frequencies, it is necessary to try to reduce them. A way to eliminate undesirable capacitive couplings is to use a *screen,* i.e., a grounded conductive layer placed between the two layers of windings where no capacitive coupling is desired.

2.6 Other Considerations

In the design of transformers, various additional considerations are of importance: insulation, thermal management, magnetic shielding, and mechanical construction. Refer to Flanagan (1993), Grossner (1983), and Lee *et al.* (1988) for further discussion of these issues. For more discussion on design procedures, refer to McLyman (1978, 1981), Ray and Sartori (1971), and Ohri *et al.* (1976).

3. WIDE-BAND TRANSFORMERS

A wide-band transformer (see Lord, 1950; Flanagan, 1993; Grossner, 1983; Lee *et al.*, 1988) is a transformer specifically designed to transmit signals with a wide frequency spectrum accurately and without distortion. Wide-band transformers are analyzed in the frequency domain, and the desired performance characteristics are also specified in the frequency domain. They are used to transmit complex wave forms like voice and music or a train of pulses.

The requirement of undistorted transmission of signals puts a limit to the operating frequency range of wide-band transformers. A typical frequency response is shown in Fig. 18. In the midband frequency range, the am-

plitude and phase are constant, which means that the signal will be transmitted without distortion. In the low- and high-frequency ranges, the frequency response amplitude decreases, and the signal is distorted.

3.1 Transformer Equivalent Models

Equivalent models are used to study the behavior of wide-band transformers. The problem in the modeling of a wide-band

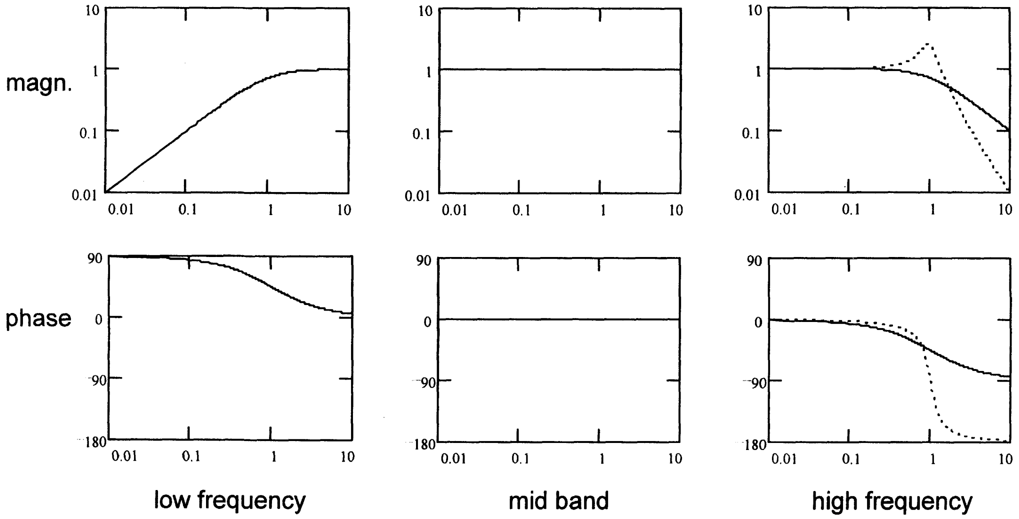

FIG. 18. Wide-band transformer frequency response.

transformer is in finding a model complete enough to describe accurately the behavior of the transformer over the desired frequency range and yet simple enough to lend itself to analysis and design.

In order to study the performance of a transformer in a given electric circuit, the characteristics of the electric circuit itself (source impedance and load impedance) must be taken into account. In the following, source and load impedances are assumed to be purely resistive. In the equivalent circuit of Fig. 17(a), R_G is the source resistance and R_L is the load resistance.

A reasonably complete equivalent model for a wide-band transformer is shown in Fig. 17(a). This model consists of an ideal 1:n transformer, magnetizing inductance L_m, resistance R_c that models core loss, primary and secondary leakage inductances L_{l1} and L_{l2}, primary and secondary winding resistances R_1 and R_2, and the Π network of lumped capacitances C_1, C_2, and C_{12} that model the distributed capacitances described in Sec. 2.5.

Usually the turns ratio is chosen to match the load to the source, i.e.,

$$n = \sqrt{R_L/R_G}. \qquad (38)$$

This ensures maximum power transfer and also prevents reflections from transmission-line effects. Half of the power is delivered to the load, and the other half is dissipated in the source resistance R_G.

A first simplifying step is to "refer" the entire circuit to the primary, eliminating the 1:n ideal transformer. The result is shown in Fig. 17(b), where

$$L'_{l2} = L_{l2}/n^2, \qquad (39)$$

$$R'_2 = R_2/n^2, \qquad (40)$$

$$R'_L = R_L/n^2. \qquad (41)$$

Capacitances C_1, C_2, and C_{12} become (see M.I.T., 1943, pp. 396–398)

$$C'_1 = C_1 + C_{12}(1 - n), \qquad (42)$$

$$C'_2 = n^2C_2 + nC_{12}(n - 1), \qquad (43)$$

$$C'_{12} = nC_{12}. \qquad (44)$$

For analysis purposes, the transformer models of Figs. 17(a) and 17(b) are assumed to be linear and all circuit elements to be constant. It should be kept in mind that this is an approximation: magnetizing inductance is nonlinear (see Sec. 2.1.1), core losses are frequency dependent, winding resistances change with frequency as an effect of skin and proximity effects, and distributed capacitances are only approximated by lumped capacitances.

The equivalent circuit of Fig. 17(b) is fairly complicated. It is customary to study separately the behavior of the wide-band transformer in the midband frequency, low-frequency, and high-frequency ranges. Appropriate approximations simplify the analysis in each case. The starting point of the following analysis is the equivalent circuit reflected to the primary side of Fig. 17(b). For simplicity, the apices will be omitted in the notation, e.g., reflected load resistance R'_L becomes R_L.

3.2 Midband Frequency Response

Midband frequency is defined as the frequency range where all reactive elements can be neglected: shunting reactive elements have high impedance, and series reactive elements have low impedance. Winding resistances R_1 and R'_2 can be included in the generator or load resistances. The midband equivalent circuit is shown in Fig. 19. The ratio of output to input voltage is

$$\frac{E_L}{E_G} = \frac{R_L}{R_L + R_G}. \qquad (45)$$

3.3 Low-Frequency Response

As frequency decreases, the impedance of the magnetizing inductance decreases. A significant magnetizing current flows in L_m and causes a voltage drop on the source resis-

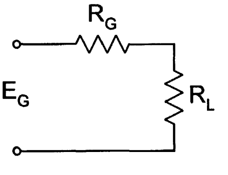

FIG. 19. Midband frequency equivalent model.

tance. As a result, the output voltage decreases.

The equivalent circuit of Fig. 20(a) is used. Application of Thévenin's theorem gives the circuit of Fig. 20(b). Resistance R_{par} is defined as

$$R_{\text{par}} = R_G R_L/(R_G + R_L). \tag{46}$$

The ratio of output to input voltage is

$$\frac{E_L}{E_G} = \frac{R_L}{R_L + R_G}\frac{j\omega L_m}{j\omega L_m + R_{\text{par}}}. \tag{47}$$

This equation can be rewritten as

$$\frac{E_L}{E_G} = \frac{R_L}{R_L + R_G}\frac{1}{1 + \omega_L/j\omega}, \tag{48}$$

where

$$\omega_L = R_{\text{par}}/L_m. \tag{49}$$

The first term of Eq. (48) represents the midband attenuation and the second term the low-frequency pole due to the magnetizing inductance. From Eq. (49) it follows that to extend the transformer operation to lower frequencies it is necessary either to decrease R_{par} or to increase L_m. Since usually the transformer designer does not have control over the value of R_{par}, the only option is to increase L_m, which requires an increase in the physical size of the transformer. Therefore, the desired low-frequency performance dictates transformer size.

3.3.1 Low-Frequency Distortion Distortion due to nonlinear behavior of the system is not modeled by the linear equivalent circuit of Fig. 20. Two distinct causes of distortion can be identified:

1. Ferromagnetic distortion. It is due to nonlinear L_m, and it is discussed in Sec. 2.1.3. It is a problem at low frequency in particular, because, for an ac signal of constant amplitude, the ac flux increases as frequency decreases. At some point core saturation ensues. Usually distortion becomes unacceptable before saturation occurs.
2. Generator distortion. A generator of limited volt-ampere capabilities or with nonlinear source impedance can cause distortion.

3.4 High-Frequency Response

At high frequency the impedance of shunt magnetizing inductance L_m becomes large, and it can be neglected. Two factors limit the high-frequency response: impedance of series leakage inductance increases, and it acts as a voltage divider with load impedance; the impedance of shunt capacitances decreases, so that more current is drawn from the source and flows through the source resistance causing the output voltage to drop.

The equivalent circuit at high frequency is shown in Fig. 21(a). Leakage inductance L_l is the combination of primary and secondary leakage inductances L_{l1} and L_{l2}. This circuit is fairly complicated to analyze. Two special cases will be considered here.

3.4.1 Model with Leakage Inductance If capacitances are neglected (usually a valid approximation for audio transformers, i.e., transformer with an upper frequency below 20 kHz), the circuit of Fig. 21(b) can be studied. The voltage ratio is

$$\frac{E_L}{E_G} = \frac{R_L}{R_L + R_G}\frac{1}{1 + j\omega/\omega_{H1}} \tag{50}$$

with

$$\omega_{H1} = R_{\text{ser}}/L_l, \tag{51}$$

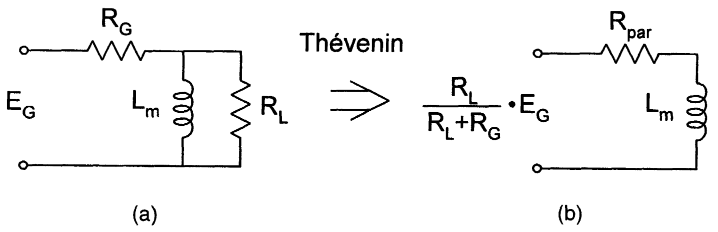

FIG. 20. Low-frequency equivalent model.

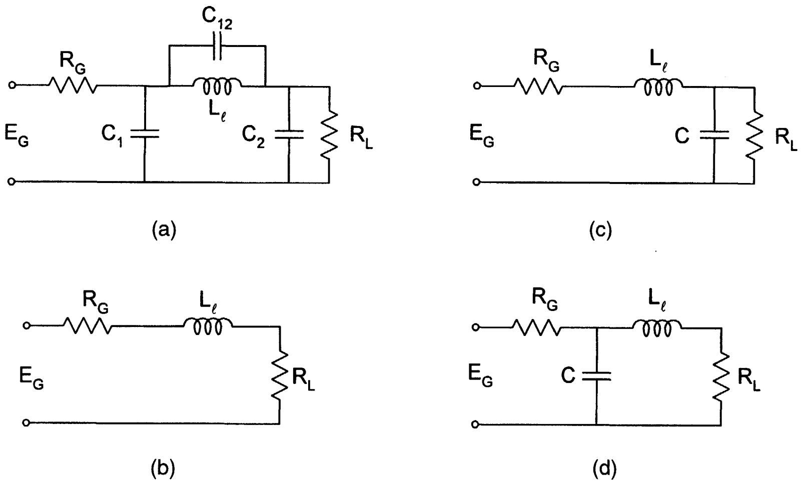

FIG. 21. High-frequency equivalent models: (a) complete model, (b) model with leakage inductance only, (c) step-up transformer, and (d) step-down transformer.

$$R_{\text{ser}} = R_G + R_L. \tag{52}$$

The frequency response has a pole at frequency ω_{H1}.

The ratio of the highest to lowest operating frequencies, a figure of merit for transformers, is given by the ratio of (51) to (49),

$$\frac{\omega_{H1}}{\omega_L} = \frac{R_{\text{ser}}}{R_{\text{par}}}\frac{L_m}{L_l} \tag{53}$$

and is proportional to the ratio of magnetizing to leakage inductance. The frequency range can be increased by any means that increases the magnetizing inductance without a corresponding increase of leakage inductance—for example, using high-permeability core materials. On the other hand, increasing number of turns does not help: both inductances L_m and L_l increase, and the operating frequency band moves to lower frequencies.

3.4.2 Model with Leakage Inductance and Shunt Capacitance In wide-band transformers operating beyond the audio-frequency range, shunt capacitances C_1 and C_2 usually cannot be neglected. It is frequently possible to include only one of these capacitances. Since the shunting effect is more significant on the high-impedance side of the transformer, the capacitance of the side with higher number of turns is usually retained. The case of a step-up transformer with secondary capacitance C is considered [Fig. 21(c)]. The output-to-input voltage ratio is

$$\frac{E_L}{E_G} = \frac{R_L/(1 + j\omega CR_L)}{R_G + j\omega L_l + R_L/(1 + j\omega CR_L)}, \tag{54}$$

and, after rearranging,

$$\frac{E_L}{E_G} = \frac{R_L}{R_L + R_G}\left[1 + \frac{j\omega}{\omega_{H2}}\left(\frac{K_1K_2 + 1}{K_1 + K_2}\right) - \left(\frac{\omega}{\omega_{H2}}\right)^2 \frac{K_2}{K_1 + K_2}\right]^{-1} \tag{55}$$

with

$$\omega_{H2} = 1/\sqrt{L_lC}, \tag{56}$$

$$Z = \sqrt{L_l/C}, \tag{57}$$

$$K_1 = R_G/Z, \tag{58}$$

$$K_2 = R_L/Z; \tag{59}$$

ω_{H2} is the corner frequency, Z is the transformer characteristic impedance, and K_1 and K_2 are dimensionless parameters. Notice that when $K_1 = K_2$ load and source resistances are matched. If $K_1 = K_2 = 1$, the transformer characteristic impedance is also matched to the source and load.

3.5 Special Types of Wide-Band Transformers

The wide-band transformer is normally used to perform basic functions such as matching a generator to its load. In this section, two special types of wide-band transformers are briefly described: hybrid transformers and transmission-line (balun) transformers.

Hybrid transformers are multiport transformers used to combine and split signals. They are common in communications. For more information, refer to Sartori (1968).

Transmission-line transformers (also called *balun transformers*) are used at high frequencies when dc isolation is not required. Usually the high-frequency operation of transformers is limited by resonance of distributed capacitance with leakage inductance. Balun transformers (see Ruthroff, 1959) are built as transmission lines with the windings arranged so that interwinding capacitance becomes part of the characteristic impedance of the line. The transmission line is usually realized with bifilar winding wound around a toroid. Very broad bandwidths can be obtained, as high as 0.1 to 1000 MHz within ±1 dB.

4. PULSE TRANSFORMERS

As the name implies, pulse transformers (see Lord, 1971; Glasoe and Lebacqz, 1948) are transformers specifically designed to transmit pulses. The term pulse indicates a square wave with low repetition rate.

A typical application of pulse transformers is as an interface between a pulse generator and a magnetron oscillator in a radar system. The pulse transformer provides matching of the pulse generator to the load for maximum power transfer, electrical insulation, and, if needed, polarity reversal. In this type of application the power delivered during the pulse can be very large. Pulse transformers have been built capable of delivering pulses of amplitude in the tens of kilovolts and power in the tens of megawatts. Pulse transformers are also used in pulse-type blocking oscillators and solid-state trigger circuits for firing SCRs and other power semiconductors.

Pulse transformers are specified and studied in the time domain. Figure 22 illustrates the output of a pulse transformer for a rectangular input pulse. Some commonly used terms describing features of the pulse are shown in this figure. Three separate periods can be identified: a rise period in which the voltage ramps up, a top period in which the voltage is constant, and an off period in which the voltage goes back to zero. Ideally, the pulse should be faithfully transmitted by the transformer. The three periods are now separately considered and different equivalent circuits identified.

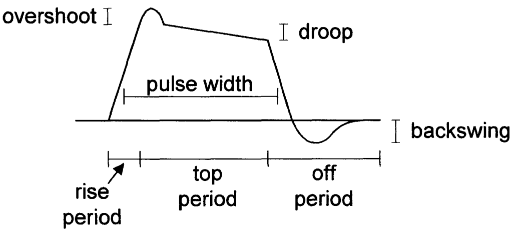

FIG. 22. Pulse response of transformer.

4.1 The Rise Period

The equivalent circuit is shown in Fig. 23. This circuit is identical to the high-frequency model of Fig. 21(c), because in this period the transformer is excited with high-frequency components. The pulse rise is the response of the system to a step of amplitude E_G applied at the input.

The Laplace transform expression of the step response is [see (54)]

$$\frac{E_L(s)}{E_G} = \frac{R_L}{R_L + R_G}\left\{s\left[1 + s\left(\frac{R_G}{L_l} + \frac{1}{R_L C}\right) + s^2 L_l C \frac{R_L}{R_L + R_G}\right]\right\}^{-1}. \tag{60}$$

In the second-order term in the denominator

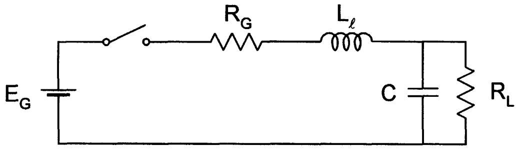

FIG. 23. Rise interval equivalent circuit.

of (60), a natural frequency ω_R and a damping factor ζ_R can be identified:

$$\omega_R = \sqrt{\frac{R_L + R_G}{R_L}} \cdot \frac{1}{\sqrt{L_l C}}, \tag{61}$$

$$\zeta_R = \frac{R_G R_L C + L_l}{2\sqrt{R_L L_l C (R_G + R_L)}}. \tag{62}$$

Equation (60) becomes

$$\frac{E_L(s)}{E_G} = \frac{R_L}{R_L + R_G} \cdot \frac{1}{s[1 + 2\zeta_R s/\omega_R + (s/\omega_R)^2]}. \tag{63}$$

The normalized response

$$\frac{e_L(t)}{E_G} \frac{R_L + R_G}{R_L}$$

is shown in Fig. 24 as a function of normalized time

$$T = (\omega_R/2\pi)t \tag{64}$$

with damping ζ as a parameter. From (64) it is clear that a large value of ω_R guarantees a fast response. That requires keeping leakage inductance L_l and capacitance C as small as possible. Notice that for low damping the response is faster but it is oscillatory, whereas for high damping it is monotonic but slower. Usually a big overshoot is undesirable, and the transformer is designed to be critically damped or slightly underdamped.

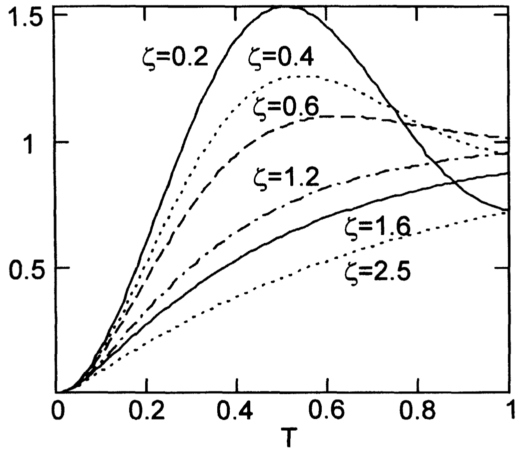

FIG. 24. Normalized rise period response as a function of damping ζ.

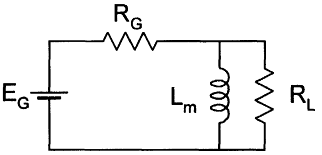

FIG. 25. Top period equivalent circuit.

4.2 The Top Period

The top of the pulse is studied using the equivalent circuit of Fig. 25, which is identical to the low-frequency equivalent circuit of Fig. 20. The top of the pulse depends on the value of magnetizing inductance. The output voltage has a droop, which becomes more pronounced the smaller the magnetizing inductance.

The response is

$$\frac{e_L(t)}{E_G} = \frac{R_L}{R_L + R_G} \exp(-\omega_L t) \tag{65}$$

with

$$\omega_L = R_{\text{par}}/L_m. \tag{66}$$

4.3 The Off Period

At the end of the pulse the supply voltage source E_G is usually opened (disconnected). The equivalent circuit of Fig. 26 is used for the analysis. The initial conditions are

$$V_C(0) = E_G, \tag{67}$$

$$I_L(0) = E_G \tau / L_m, \tag{68}$$

where E_0 is the voltage at the top of the pulse, neglecting the droop for simplicity, and τ is the pulse duration.

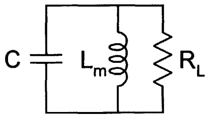

FIG. 26. Off period equivalent circuit.

The Laplace-transform expression of the response is

$$E_L(s) = \frac{sL_mCV_C(0) - L_mI_L(0)}{1 + sL_m/R_L + s^2L_mC}. \tag{69}$$

We can define the quantities

$$\omega_0 = 1/\sqrt{L_mC}, \tag{70}$$

$$Z = \sqrt{L_m/C}, \tag{71}$$

$$D = Z/2R_L, \tag{72}$$

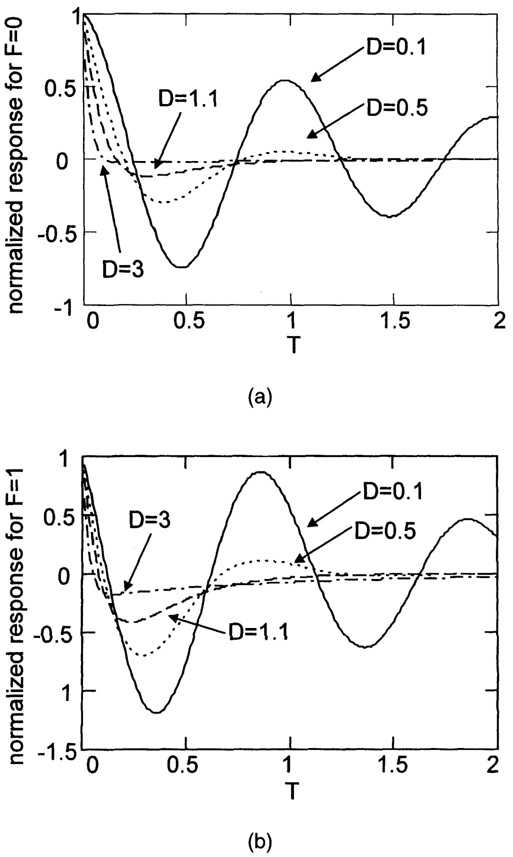
$$T = (\omega_0/2\pi)t, \tag{73}$$

$$F = \omega_0\tau, \tag{74}$$

where ω_0 is the natural frequency of the LC circuit, Z the characteristic impedance, D the damping factor, T the normalized time, and F the initial current factor. Equation (69) becomes

$$\frac{E_L(s)}{E_G} = \frac{(1/\omega_0)(s/\omega_0 - F)}{1 + 2Ds/\omega_0 + s^2/\omega_0^2}. \tag{75}$$

The response is a function of two parameters, the initial current factor F and the damping factor D. Two families of curves, for $F = 0$ and $F = 1$, are shown in Fig. 27. A certain amount of backswing is unavoidable. A more serious problem is that if the system exhibits oscillatory behavior (low value of damping D), the backswing will become positive again on the first oscillation. This may be erroneously interpreted as a second pulse.



(a)

(b)

FIG. 27. Off period response of the transformer for (a) $F = 0$ and for (b) $F = 1$.

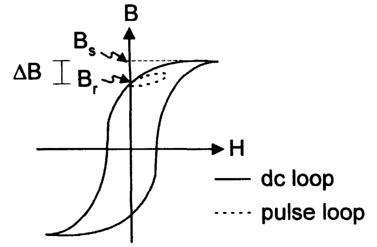
4.4 Design Issues

Here are some comments relevant to the design of pulse transformers:

1. *Leading-edge response.* In order to have a fast leading-edge response, it is critical to make the corner frequency ω_R as high as possible, which means to make L_l and C small. This requires careful choice of winding geometry and coil arrangements.
2. *Top-period response.* The performance of the pulse transformer during the top period depends on magnetizing inductance L_m. The maximum acceptable droop determines the minimum value of L_m. It is desirable to use high-permeability core materials, which allow large values of L_m with relatively few turns. In this way L_l and C can be small, and a satisfactory leading-edge response can be obtained.
3. *Off-period response.* The backswing response is usually of less concern to the pulse transformer designer. If needed, external circuits can be added to improve it.

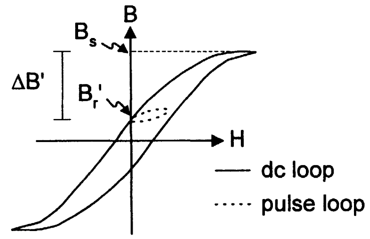
It is interesting to look at the *B-H* loop of a pulse transformer as in Fig. 28. In this figure both the dc and the pulse loop are shown. The *pulse permeability* μ_p, given by the slope of a line connecting the apices of the pulse loop, is smaller than the dc permeability of the material. The area of a pulse loop represents core losses per unit volume, as explained in Sec. 2.1.2.

If the core is ungapped as in Fig. 28(a), at



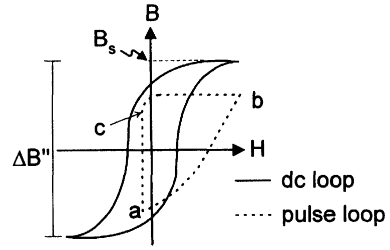
ungapped core
no resetting

(a)



gapped core
no resetting

(b)



ungapped core
with core reset

(c)

FIG. 28. *B-H* loop of pulse transformer in various cases.

the end of each pulse the magnetization returns to the dc residual magnetization B_r. The available flux swing ΔB is limited by core saturation flux density B_s and is

$$\Delta B = B_s - B_r. \tag{76}$$

If the core is gapped as in Fig. 28(b), the sheared loop has much lower residual magnetization B_r' and the available flux swing $\Delta B'$ is correspondingly increased. Another way to increase flux swing capability is to "reset" the core at the end of each pulse, i.e., to force a negative current in one of the windings (possibly an auxiliary winding) with the effect of moving the magnetization to a negative value. Figure 28(c) shows a pulse loop with reset using a constant negative current (vertical line c–a).

5. ELECTRONIC POWER TRANSFORMERS

For simplicity, only the case of high-frequency dc-to-dc converters (see Middlebrook and Ćuk, 1983; Kassakian *et al.*, 1991) is considered here. Other types of switching converters (ac-to-dc, dc-to-ac, and ac-to-ac) can usually be considered as modifications of dc-to-dc converters.

Three nonisolated converters are shown in Fig. 29. In all cases, transistor Q is operated as a controllable switch: It is turned on during interval t_{ON} and turned off during interval t_{OFF}. The "freewheel diode" D acts as a complementary switch and turns on during the OFF period to give the inductor current a path to flow. The voltage gain of these converters can be derived under the assumption

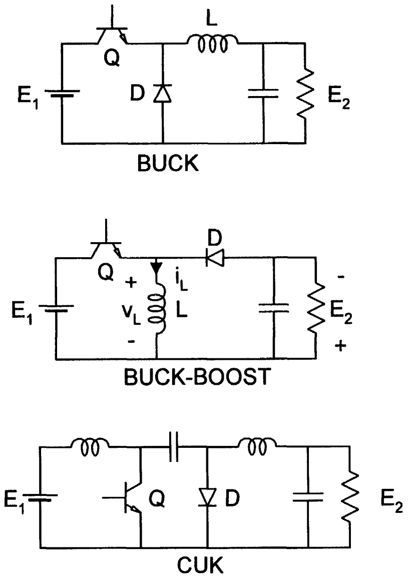


FIG. 29. Nonisolated converters.

of steady-state operation. For example, in the case of the buck-boost converter of Fig. 29(b), inductor voltage v_L is equal to the input voltage E_1 during the ON interval and to the output voltage E_2 during the OFF interval. Since in steady state the average inductor voltage during a period must be zero (otherwise inductor current would grow without limits), the voltage balance during a period is

$$E_1 t_{\mathrm{ON}} = E_2 t_{\mathrm{OFF}}. \tag{77}$$

From this equation, the voltage gain of the converter is

$$E_2/E_1 = t_{\mathrm{ON}}/t_{\mathrm{OFF}}. \tag{78}$$

This shows that output voltage can be controlled by varying the ratio of ON interval to OFF interval.

Operating wave forms are shown in Fig. 30. The switch voltage v_Q is a square wave, and the inductor current is a triangular wave.

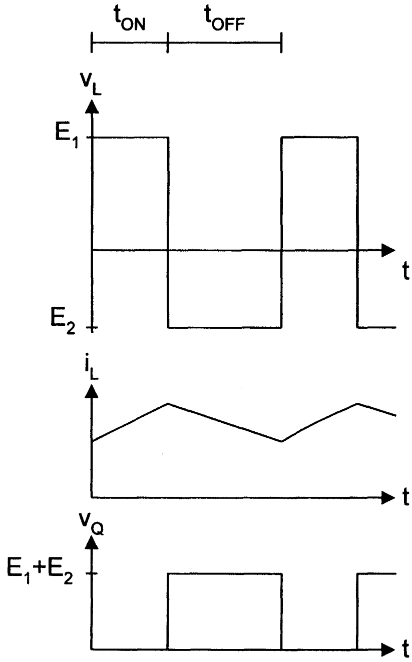

FIG. 30. Operating wave forms of buck-boost converter.

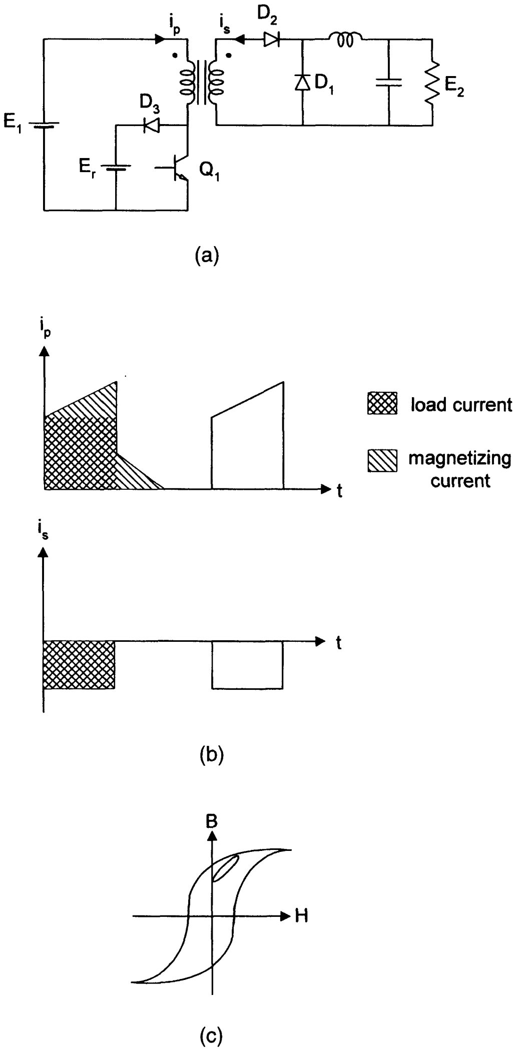
5.1 Transformers in Switching Converters

Transformers are introduced in dc-to-dc converters for two reasons: to provide electrical insulation and to reduce component stresses that result when input–output voltage conversion ratio is far from unity.

The converters of Fig. 29 can be modified to accommodate an insulation transformer as shown in Figs. 31–33. It is interesting to examine these converters, because the insulation transformers operate in three different regions of the *B-H* loop.

5.1.1 Forward Converter The forward converter shown in Fig. 31(a) is a modifica-



(a)

(b)

(c)

FIG. 31. Forward converter.

tion of the buck converter of Fig. 29(a). Additional elements are added to allow *resetting* of the transformer. During the ON interval, switch Q conducts, and primary voltage is equal to E_1. In order to prevent core saturation, a negative voltage must be applied during the OFF interval, so that the average transformer voltage is zero (transformer reset). Diode D_2 is needed to allow the reset: Without it, conduction of diode D_1 during the OFF interval would short the secondary and make reset impossible. During the OFF interval diode D_3 conducts, and auxiliary voltage E_r resets the transformer. Figure 31(b) shows primary and secondary currents distinguishing between magnetizing and load components. The B-H loop of Fig. 31(c) shows that the converter operates with excitation in one direction only. The resetting circuit brings magnetic field H back to zero at the end of the cycle. A small gap is usually inserted in the transformer to reduce remanent magnetization.

5.1.2 Flyback Converter The flyback converter of Fig. 32 is a straightforward modification of the buck-boost converter. As can be seen from the current wave forms, energy is stored in the transformer during the ON interval and delivered to the load during the OFF interval. The transformer is required to store significant energy, and all the current in the transformer is magnetizing current. There is no load current component since primary and secondary never conduct at the same time. The flyback transformer has a significant gap to increase current capability: The transformer operates along a minor B-H loop in the first quadrant as shown in Fig. 32(c).

5.1.3 Isolated Ćuk Converter In the isolated Ćuk converter of Fig. 33(a), the transformer is a true ac transformer. Capacitors C_1 and C_2 block any dc voltage. The magnetizing and load components are shown in Fig. 33(b). The load current is a square wave, and triangular components represent the magnetizing current. The B-H loop shown in Fig. 33(c) is centered around the origin, and it has no dc bias as in the other two cases.

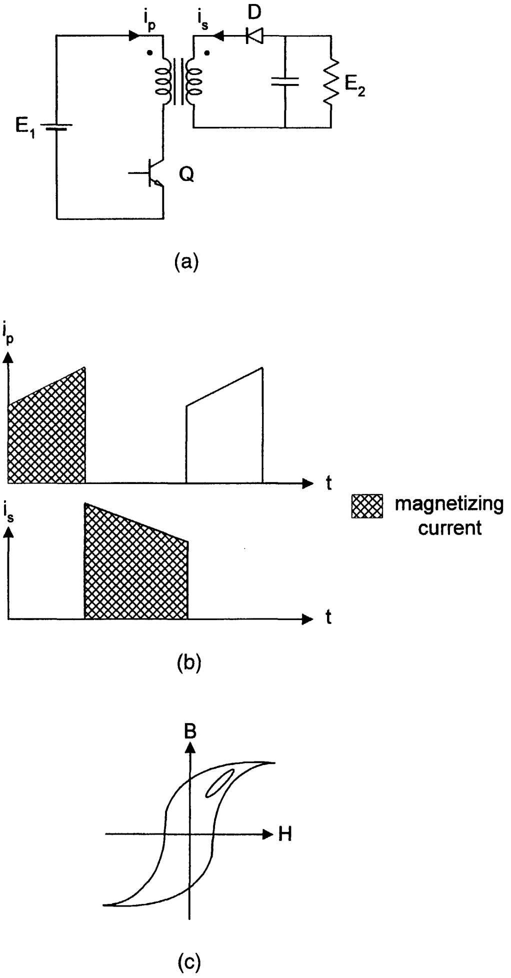


FIG. 32. Flyback converter.

5.2 Requirements for Electronic Power Transformers

The overriding requirements of switching converters are high efficiency and small size. In recent times switching converters have been operated at higher and higher frequencies in order to reduce the reactive component sizes. Commercial converters usually operate at frequencies between 30 and 300 kHz, with some converters operating at 1 MHz or more.

Transformers in switching converters are excited by a train of voltage pulses at the switching frequency. The techniques used in the study of pulse transformers may be used in this case as well (see Lee *et al.*, 1988). In the following, specific requirements of trans-

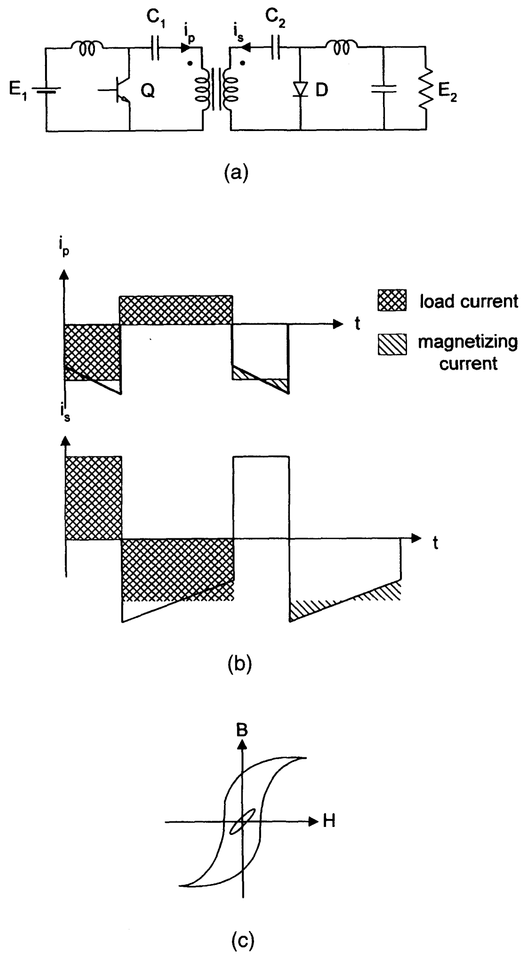

FIG. 33. Isolated Ćuk converter.

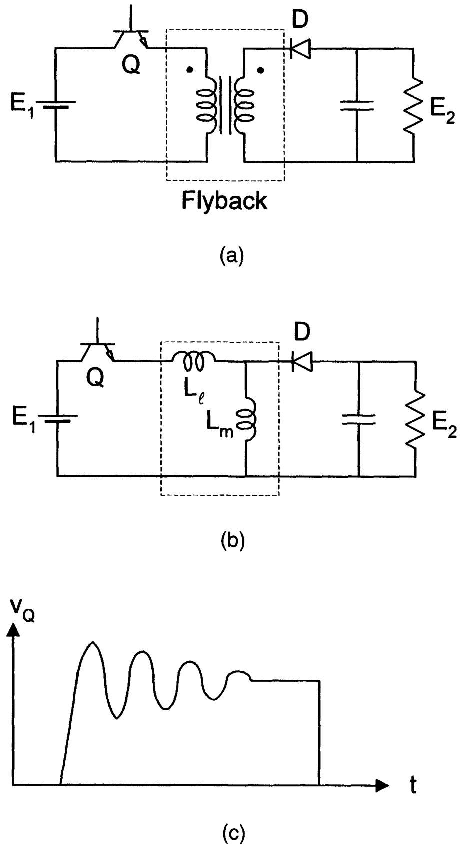

FIG. 34. (a) Flyback converter, (b) flyback converter with transformer equivalent model, and (c) switch wave form with overshoot.

formers in switching converters are discussed.

1. *Magnetizing inductance.* The value of magnetizing inductance is dictated by the switching frequency and by the desired amount of magnetizing current.
2. *Leakage inductance.* Leakage inductance should be reduced as much as possible, because it causes overshoot and ringing of the switch voltages. To illustrate this, the case of a buck-boost and its isolated counterpart, the flyback converter, is considered. In the nonisolated case, the main switch wave form in a properly designed converter is not very different from the idealized wave form of Fig. 30. The case of the flyback converter is shown in Fig. 34(a). Introducing an equivalent circuit for the transformer consisting of magnetizing inductance L_m and leakage inductance L_l, we obtain the circuit of Fig. 34(b). The main switch wave form is shown in Fig. 34(c). When the switch turns off, the leakage inductance resonates with all the parasitic capacitances of the circuit, such as switch capacitance and transformer capacitance. Since the converter is designed for high efficiency, the oscillation is lightly damped. Usually, a *snubber* circuit is added to damp this oscillation. Significant energy is dissipated in these circuits unless extra circuitry is added to recover the snubber energy. In any case, the penalty for leakage inductance is either lower efficiency or added cost. For this reason, power electronics transformers are built for low leakage, with extensive interleaving. Safety requirements of high-voltage insu-

lation between primary and secondary sometimes make it difficult to achieve the desired low leakage.

3. *Transformer capacitance.* Primary-to-secondary transformer capacitance should be kept low for EMI (electromagnetic interference) reasons. During transformer operation, this capacitance acts as a source of common mode noise (see Nave, 1991). Shielding is frequently necessary to meet EMI emission requirements.
4. *Core material.* For high-frequency operation the core material of choice is ferrite for its low eddy-current losses. Hysteresis core losses, however, can still be significant, especially at higher frequencies. The ac flux swing is frequently limited by core losses rather than by saturation.
5. *Copper losses.* The windings must be sized to carry the load currents with reasonably low losses. Skin and proximity effects can increase copper losses significantly.

5.3 Coupled Inductors and Zero Current Ripple

In certain converters, separate inductors can be combined together in transformerlike structures called *coupled inductors* in the case of two inductors and *integrated magnetics* in the case of three or more inductors. In the case of a Ćuk converter it can be shown that the two inductors have identical voltage wave forms, and they can therefore be combined in a coupled inductor structure, usually with significant reduction in size. If the coupled inductors meet a certain zero current ripple condition (having to do with leakage and turns ratio), the current ripple can be steered into one winding, leaving the other one virtually ripple free. The situation is depicted in Fig. 35. The output current is pure dc, and the filtering capacitor C can be reduced with savings in size and cost. For an explanation of the zero ripple phenomenon, refer to Ćuk (1978), Polivka and Ćuk (1983), Zhang and Ćuk (1986), and Santi and Ćuk (1993, 1994).

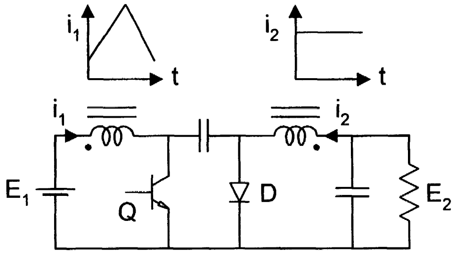

FIG. 35. Coupled-inductor Ćuk converter with zero current ripple at the output.

6. MAGNETIC AMPLIFIERS

Saturation in magnetic cores, usually regarded as a drawback, is put to use in a number of electronic circuits. Amplifiers with saturable reactive elements are called *magnetic amplifiers.* In this section one example of magnetic amplifiers is given. For more information refer to Frost-Smith (1966), Storm (1955), and Fink and Christiansen (1989).

The main idea is as follows. In an ungapped transformer a small amount of dc current can cause the core to saturate. Suppose one winding of a transformer is interposed between an ac source and a load. The power delivered to the load will be almost zero if the core is not saturated, because the transformer magnetizing impedance is very high. On the other hand, if the core is saturated, the magnetizing impedance is small and the ac source is effectively connected to the load. In summary, the saturable transformer acts as a switch, connecting or disconnecting the ac source to the load. The switch is controlled by a small amount of dc power applied to a second winding and used to saturate the core. Power amplification is possible in such an arrangement.

6.1 Simple Magnetic Amplifier

A so-called *simple magnetic amplifier* is shown in Fig. 36(a). In this circuit voltage E_{AC} is the unregulated supply voltage. The voltage applied to load R_L is controlled by dc control voltage E_c. The circuit uses two identical saturable transformers A and B. The secondaries are connected in series with the ac source E_{AC} and the load R_L. The primaries are connected in series with opposite polarity to the control voltage source E_c. This arrangement decouples the dc and the ac circuits. If only one transformer were used, ac voltages would be induced in the dc winding, and they would be effectively shorted by the dc voltage source E_c.

(b)

FIG. 36. Simple magnetic amplifier: (a) electrical circuit and (b) wave forms.

If current i_c is zero, the two transformers are designed not to saturate during the ac period. The high impedance of the transformer prevents current from flowing through the circuit, except for a small magnetizing current. The load voltage is practically zero.

Let us assume now that a positive current i_c is applied. Wave forms are shown in Fig. 36(b). This current adds to the magnetizing current in transformer A and subtracts from the magnetizing current in transformer B according to the current conventions of Fig. 36(a). At some instant t_1 during the positive semiperiod, transformer A saturates and ac supply voltage E_{AC} is applied to the load. During interval $t_1 - t_2$, current i_L is dictated by load R_L. Notice that transformer B is not saturated since the control current i_c demagnetizes it. If resistor R_c is small, current i_c is dictated by current i_L in the secondary of transformer B. In the case of 1:1 turns ratio, current i_c is identical to current i_L. During the other semiperiod the roles of transformers A and B are interchanged. In short, the magnetic amplifier provides control of the output voltage by controlling the saturation of the saturable transformer.

6.2 Other Magnetic Amplifier Circuits

Many different magnetic amplifier circuits are given in the literature. In order to reduce the dc control power, so-called *self-saturated magnetic amplifiers* saturate with zero control current delivering full voltage to the load. The control current unsaturates the core for part of the period reducing the output voltage. Another circuit (see Ramey, 1951a,b) generates an output voltage proportional to the dc control voltage. A circuit similar to the one in Fig. 36 can be used to measure a dc current (see Geyger, 1957, pp. 313–314). Magnetic amplifiers are also used in switching power converter applications (see Brkovic *et al.,* 1993; Vollin *et al.,* 1993).

GLOSSARY

Magnetic Amplifier: An amplifier that uses saturable reactive elements.

Pulse Transformer: A transformer specifically designed to transmit pulses.

Wide-Band Transformer: Transformer designed to transmit with minimal distortion a wide-band signal.

INTRODUCTION

The invention of the transformer in the late 1870s made possible for the first time the transmission of electrical energy over large distances. Among the first applications of the transformer, one can mention the Paris World Exhibition, the All-Russian Industrial Exhibition, the lighting installation at Great Barrington, Massachusetts, and the transmission of polyphase power from Lauffen to Frankfurt, Germany. Various claims have been made for the invention itself. Among the pioneers who should be mentioned are P. N. Yablochkov, I. F. Usagin, M. O. Dolivo-Dobrovolsky, W. Stanley, N. Tesla, G. Ferraris, C. E. L. Brown, and W. Boveri, as previously reported by Kostenko and Piotrovsky (1974).

The *transformer* is a device for transferring electrical energy from an alternating circuit to another having different voltage or current levels. A schematic representation of a transformer is shown in Fig. 1. It consists essentially of two or more independent electric circuits coupled by a common magnetic circuit. The electric circuits are made up of windings of insulated magnet wires and the magnetic circuit of steel laminations. The winding connected to the supply side is called *primary* and is denoted by the subscript 1; those connected to the receiver circuits are called *secondaries* and are denoted by the subscript 2. The laminations are stacked to form the *core.*

When the primary of the transformer is connected to the supply mains but its secondaries are open, only a small current referred to as the *magnetizing current* flows through the winding. This current establishes an alternating *magnetic flux* Φ through the core. This flux, in turn, establishes a voltage, or *counter emf,* across the terminals of the primary. The counter emf equals in magnitude the voltage V_1 of the mains less a small voltage drop due to the impedance of the primary. The alternating flux also establishes a voltage V_2 across the terminals of each secondary that is equal to the primary voltage

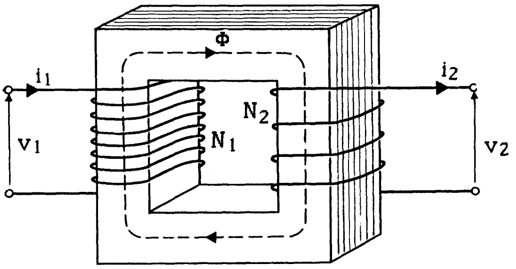

FIG. 1. Schematic representation of a transformer (adapted from Slemon and Straughen, 1980).

multiplied by the *ratio* of the number of *turns N* in the two windings.

When the terminals of a secondary circuit are connected to an impedance or *load,* a current *I* will flow that will tend to demagnetize the core. To compensate for this effect and maintain the flux at the level required by the voltage impressed on the primary, additional current is drawn from the supply mains. The ratio of the magnitudes of the primary and secondary currents is inversely proportional to the turns ratio in their windings.

This article deals with the transformers that constitute the main elements of an electric power supply system. At the source is an alternator, mostly a three-phase synchronous generator, whose rating varies usually from 30 to 1700 MVA at a voltage level up to 25 kV. Its terminals are connected directly to a *unit transformer* whose function is to reduce the current by stepping up the voltage, in order to minimize the Joule losses in the transmission lines. Transmission-line voltages are approaching today the megavolt range. At the receiving end of these lines there are substations in which the voltage level is reduced to subtransmission levels (69–230 kV) by what are properly called *power transformers.* The subtransmission circuits spread out from these substations to others located at the load centers, where other power transformers further reduce the voltage level (2.3–69 kV). Finally distribution lines reach industrial loads or residential areas, where *distribution transformers* (up to 200 kVA) reduce the voltage to consumer levels, in U.S. practice 120/240 V when single phase, or 120/208 V, or 240 V, or 480 V, or even higher when three phase. Three-phase power may be transformed either by a *bank* of *single-phase transformers,* or by a single *three-phase transformer.*

This article presents the elements of the construction, theory, and design of power transformers and, for completeness sake, also some special transformers, such as voltage and current regulators, instrument transformers, and reactors or choke coils.

1. CONSTRUCTION

1.1 Core

The core of a transformer is usually made of silicon sheet-steel laminations. For 60-Hz transformers, a 3% to 4.5% silicon steel sheet, 0.012 to 0.014 in. (0.3 to 0.35 mm) thick is used; for low frequency, 25 Hz, a 2.5% to 3.0% silicon steel sheet up to 0.019 in. (0.48 mm) thick is often used. Silicon steel is used because of its nonaging properties and low eddy-current and hysteresis losses. The magnetic steel is cold rolled and grain oriented, so that the rolling direction is the same as that of the flux lines. Much lower losses obtain with ferromagnetic amorphous metals, because of reduced eddy currents due to reduced conductivity. Since they come in the form of ribbons, usually the core is not made up as a stack of laminations, but as a roll of wound ribbon. There are three types of construction in common use: core, shell, and distributed-core type. In the core type each leg carries half of the primary and half of the secondary winding, as shown in Fig. 2 for a single-phase transformer and in Fig. 3 for a three-phase one. In the shell type the primary and secondary windings are located on an interior leg and are surrounded by exterior legs, as shown in Fig. 4 for a single-phase transformer and in Figs. 5(a) and 5(b) for a three-phase one. The cross section of the exterior legs and yokes is about half of that of the interior ones, because they carry about half of the flux. In the distributed-core type the core is built of a few parts, as shown in Fig. 6 for four parts.

1.2 Windings

The windings of transformers are built up of turns connected in series or in parallel. The material of the conductors is either cop-

per or aluminum. They must be insulated with materials having high dielectric and mechanical strength and not soluble in hot transformer oil. They are usually insulated with enamel, cotton, or treated paper held in place by bands of cotton thread. To avoid large eddy-current losses, large conductors must be built up of several small, separately insulated conductors connected in parallel. When the parallel conductors are wound with a uniform orientation to one another, a

FIG. 6. Distributed core for a transformer.

circulating current is induced, because the conductors do not link the same amount of magnetic flux. This circulating current can be eliminated by transposing the conductors with respect to one another. Coils with high layer voltage require heavy insulation between layers. Paper and empire cloth are generally used for layer insulation. The insulation between core and windings generally consists of molded cylindrical or rectangular tubes. The windings of transformers may be arranged concentrically with reference to one another with the low-voltage winding on the inside, sometimes referred to as a "barrel" winding, or they may be arranged in groups of high- and low-voltage coil disks stacked alternately one above the other, sometimes referred to as "pancake" winding.

1.3 Tank

Transformers are cooled by one of the following methods:

1. *Natural-air-cooled,* in which the natural circulation of the surrounding air is relied upon to carry away the heat generated by the losses. A sheet metal enclosure protects the windings from mechanical injury.
2. *Natural-oil-cooled,* in which the transformer is immersed in transformer oil that carries the heat to the walls of the containing tank and sometimes to a heat exchanger, by natural convection.
3. *Oil-and-water-cooled,* in which the transformer is immersed in transformer oil and cooling water is circulated through coils of pipe placed near the top of the tank, but under the surface of the oil.
4. *Cooled by forced circulation of the oil,* in which the oil is drawn from the tank, passed through a heat exchanger on the outside of the tank, and returned to the bottom of the tank.
5. *Air-blast-cooled,* in which a continuous stream of cool air is forced through the core and windings.

The welded steel tank is used almost exclusively. In the larger-capacity transformers, the radiating surface is increased by welding cooling vanes to the tank, or by using corrugated-sheet steel. Terminals of transformers connected to overhead lines or open bus work usually consist of porcelain bushings. Oil-filled terminal chambers for cable potheads are frequently used for direct connection to underground cables.

1.4 Insulating Oils and Liquids

The function of insulating liquids is to provide electrical insulation and heat transfer, and the viscosity selected is often a compromise between the two. Other considerations are flammability, solidification at low temperatures, and pressure development at high temperatures in sealed systems. Low cost, high dielectric strength, and ability to recover after dielectric overstress make mineral oil refined from crude the most used transformer insulating material. Chlorinated aromatic-Askarel liquids have somewhat higher dielectric strength, but have limited ability to recover after dielectric overstress. Some transformer liquids that in the past have been widely used are not environmentally sound, because they develop poisonous polychlorinated biphenyls (PCB's), and are being phased out.

2. ELEMENTARY THEORY

The transformer is a straightforward application of the laws of the electromagnetic field. Faraday's law in integral form expresses the electromotive force as

$$\text{emf} = \int_l \mathbf{E} \cdot d\mathbf{l} = -\frac{d\phi}{dt}, \tag{1}$$

where $\mathbf{E}$ is the electric field intensity, $d\mathbf{l}$ is an element of length, t is time, and Φ is the magnetic flux, which, assuming a uniform density B over the cross section A of the core, is

$$\phi = BA. \tag{2}$$

On the assumption that the winding has N turns and that the voltage impressed on its terminals is sinusoidal with radian frequency ω and frequency f, the rms value of the voltage is

$$V = (1/\sqrt{2})\omega N \Phi_m = 4.44 f N B_m A, \tag{3}$$

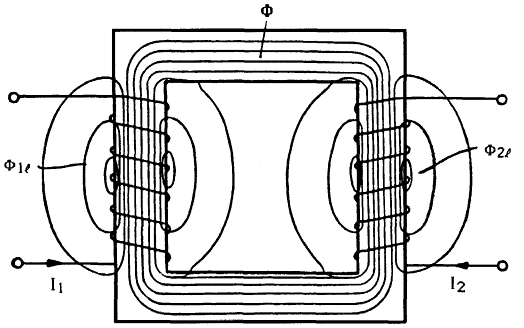

FIG. 7. Schematic representation of leakage flux.

where the subscript m stands for the peak value.

Ampère's law in integral form expresses the magnetomotive force as

$$\text{mmf} = \int_l \mathbf{H}\cdot d\mathbf{l} = \int_S \mathbf{J}\cdot d\mathbf{s} = \sum I, \tag{4}$$

where **H** is the magnetic field intensity, **J** is the current density, and ΣI is the total current enclosed in the magnetic circuit.

Figure 7 represents the flux paths in a single-phase transformer. Under ideal conditions all the turns of the windings completely encircle a magnetic flux Φ traveling in a magnetic circuit of uniform cross section and infinite permeability. It follows from Eq. (3) that the ratio of the voltages in the primary (1) and in the secondary (2) windings equals the turns ratio, or $V_1/V_2 = N_1/N_2$ and that H and, therefore, the mmf are zero, so that, according to Eq. (4), $I_1/I_2 = -N_2/N_1$. In practice, however, the permeability of the iron is not infinite, and part of the flux closes outside the iron, as indicated schematically by Φ_{1l} and Φ_{2l} in Fig. 7. The part of the flux that is not common to both windings can be represented by a leakage inductance. In terms of lumped parameters, R for winding resistance, L for leakage inductance, and M for mutual inductance, the governing equations can be written as

$$\begin{aligned} v_1 &= R_1 i_1 + \frac{d}{dt}[(L + M)i_1] + \frac{d}{dt}(Mi_2), \\ v_2 &= R_2 i_2 + \frac{d}{dt}[(L + M)i_2] + \frac{d}{dt}(Mi_1), \end{aligned} \tag{5}$$

where the lower case denotes instantaneous value.

These equations can be represented by an equivalent circuit when the secondary quantities are referred to the primary, so that $v_2' = (N_1/N_2)v_1$, $i_2' = (N_2/N_1)i_2$, $R_2' = (N_1/N_2)^2R_2$, and $L_2' = (N_1/N_2)^2L_2$. The equivalent circuit per phase is shown in Fig. 8. A resistance R_m has been added in parallel with M to account, in an approximate way, for the core losses. The magnetizing current i_μ is practically equal to the no-load current i_0. When the transformer has more than one secondary, these can be represented by attaching additional branches to the upper node. Both Eq. (5) and the equivalent circuit apply, in general, to both transients and steady state. Taking into account the sinusoidal variation with time of v and i in steady state and introducing phasor notation, one arrives at the diagram of Fig. 9. One advantage of this diagram is that it puts in evidence the phase relations among the variables. Also it puts in evidence the variation of the secondary voltage with the magnitude and phase of the

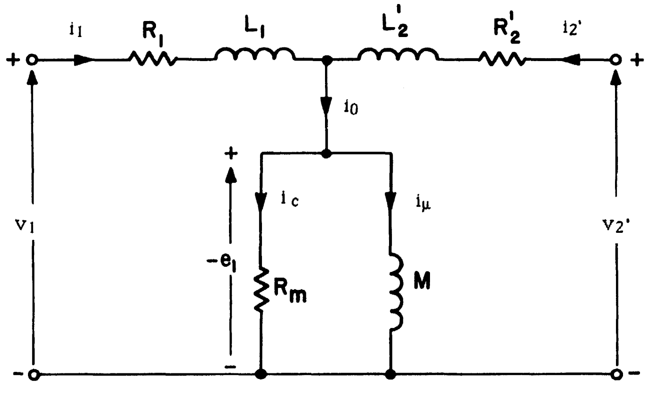

FIG. 8. Equivalent circuit per phase.

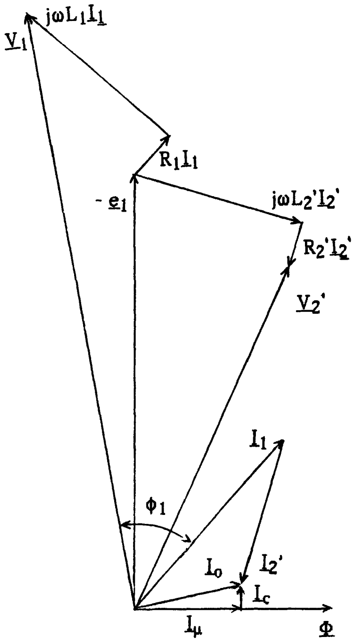

FIG. 9. Phasor diagram.

load. The locus of the secondary voltage when only the phase of the load changes and the small magnetizing current is neglected is known as the Kapp diagram and is shown in Fig. 10. It appears that a possibly dangerous overvoltage, known as the "Ferranti rise," can occur when the load is capacitive. This may happen at no load when the transformer feeds a long transmission line, especially if this is underground. In contrast, the secondary voltage is reduced when the load is inductive. A particular case of inductive load is short circuit, because when V_2' is reduced to zero, the current is limited by the impedance of the windings, which is predominantly reactive. For this reason, in the design stage, the leakage reactances are made larger the larger the VA capacity of the transformer, and may reach over 20% of the rated load impedance in the MVA range. In general the variation of the secondary voltage with load is expressed by the percentage *regulation*

$$\epsilon = 100(V_{2\ \text{no-load}} - V_{2\ \text{rated}})/V_{2\ \text{rated}}, \qquad (6)$$

which may reach 10% in large-size transformers. High leakage reactances, while reducing the magnitude of the short-circuit currents, increase the regulation at reactive power factors.

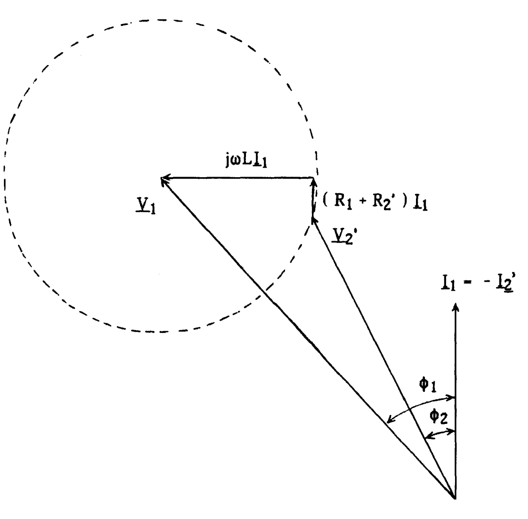

FIG. 10. Kapp's diagram.

3. DESIGN GUIDELINES

The starting point for the design is a set of performance specifications, which usually conform with standards issued by organizations such as the Institute of Electrical and Electronic Engineers (IEEE), American National Standards Institute (ANSI), and National Electrical Manufacturers Association (NEMA) in the U.S., VDE in Germany, and the International Electrotechnical Committee. Transformers may be designed for minimum first-investment cost without regard to the losses, or for minimum total losses and, thus, minimum running expenses. There is a lower limit to the cost, because heating limits the current density in the conductors, and the flux density in the iron core is limited by magnetic saturation. The lowest-cost transformer is generally the one in which the costs of iron and copper are approximately equal. With given current density in the conductors and magnetic flux density in the core, the transformer will have the maximum efficiency at full load when the losses in the copper are equally partitioned between the primary and the secondary and the loss in the iron equals the total loss in the copper. However, if the load is light during the greater part of the day, as in the case of lighting, the core loss should be as small as possible. The losses of a conductor in watts per cubic meter are given by

$$p_{\mathrm{co}} = J^2/\gamma, \tag{7}$$

where J, the current density, ranges from 1.5×10^6 A/m^2, in transformers up to about 50 kVA, to 4×10^6 A/m^2 in large oil-cooled transformers, and γ, the conductivity at 75 °C, is 4.7×10^7 S/m for copper and 2.67×10^7 S/m for aluminum. The losses in the iron core in watts per cubic meter can be expressed as

$$p_{\mathrm{Fe}} = afB_m^2 + b(\Delta f B_m)^2, \tag{8}$$

where B_m is the peak value of B, f is the frequency, Δ is the thickness of the laminations in millimeters, a is about 114, and b is about 3.8. Here the first term accounts for the hysteresis loss, and the second, for the eddy-current loss.

The mechanical construction of a transformer is determined in large measure by the forces of repulsion between the primary and the secondary windings that occur during short circuit. Taking into account the maximum value of the instantaneous dc component, the initial short-circuit current is about $2.8V_1/\omega(L_1 + L_2')$, and the force in newtons exerted on a conductor of length l and carrying the current I is IBl.

The number of turns in a winding is given, according to Faraday's law Eq. (3), by

$$N = V/4.44fB_mA, \tag{9}$$

where B_m can be selected near the knee of the magnetization curve of Fig. 11. The cross section of the core A can be determined by the following considerations. The apparent power of a single-phase transformer is

$$VA = V_1I_1 = (4.44fN_1B_mA)(J_1s_{1\,\mathrm{co}}), \tag{10}$$

where $s_{1\,\mathrm{co}}$ is the cross section of the primary conductor. If we assume that the volumes of the primary and secondary windings are equal, their total volume is

$$\mathcal{V}_{\mathrm{co}} = 2N_1s_{1\,\mathrm{co}}l_{\mathrm{co}} \tag{11}$$

where l_{co} is the average length of one turn in both windings. Assuming that the core and yoke have the same cross section, and denoting by l_{Fe} the total length of the magnetic circuit, the volume of the iron is

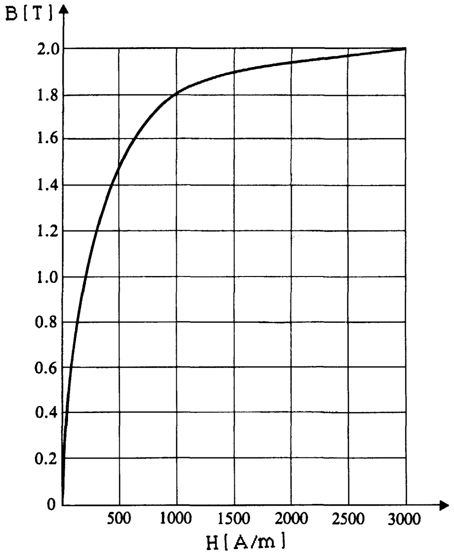

FIG. 11. Magnetization curve of grain-oriented steel.

$$\mathcal{V}_{\mathrm{Fe}} = Al_{\mathrm{Fe}}. \tag{12}$$

Multiplying Eq. (10) by Eq. (12), one obtains

$$VA\mathcal{V}_{\mathrm{Fe}} = 4.44fN_1B_mA^2J_1s_{1\,\mathrm{co}}l_{\mathrm{Fe}}. \tag{13}$$

Making use of Eq. (12) and introducing the total losses P_{co} and P_{Fe}, one obtains for the cross section of the core

$$A = \sqrt{\frac{VA}{4.44}}\sqrt{\frac{P_{\mathrm{Fe}}}{P_{\mathrm{co}}}}\sqrt{\frac{p_{\mathrm{co}}}{p_{\mathrm{Fe}}}}\sqrt{\frac{2}{fB_mJ}}\sqrt{\frac{l_{\mathrm{co}}}{l_{\mathrm{Fe}}}}. \tag{14}$$

This equation is not limited to single-phase transformers but also holds for polyphase ones. The ratio of the lengths $l_{\mathrm{co}}/l_{\mathrm{Fe}}$ is approximately 0.57 for single-phase transformers and 0.38 for three-phase ones.

The height of the core and, therefore, of the window is mainly a function of the type of cooling, because it determines the surface for the transfer to the cooling medium of the heat generated by the core and conductor losses. It is expressed in terms of the linear current density K as

$$h = (N_1I_1 + N_2I_2)/K, \tag{15}$$

where K is approximately equal to 90 $(\mathrm{kVA})^{0.15}$ in air-cooled transformers and 520 $(\mathrm{MVA})^{0.24}$ in oil-cooled ones, kVA or MVA being the rating of the transformer.

The last main dimension of the transformer, the width of the window, is determined by the cross sections of the conductors and of the insulation, whose thickness increases with the voltage, and can be expressed in terms of a filling coefficient f_{co}, which represents the ratio of the cross section of the conductors to the total cross section of the window. The filling coefficient is approximately equal to 0.13 $(\mathrm{kVA})^{0.22}$ for air-cooled transformers and 0.12 $(\mathrm{MVA})^{0.13}$ for oil-cooled ones.

Once the main dimensions of the transformer have been established, one can proceed to determine the parameters of the equivalent circuit. The resistance of a winding is

$$R = Nl_{\mathrm{co}}/s_{\mathrm{co}}\gamma. \tag{16}$$

Physically it is not possible to distinguish between the primary and secondary leakage inductances, and so in the equivalent circuit of Fig. 8, half of the total inductance L is assigned to L_1 and half to L_2'. If we denote by a_1 and a_2 the thicknesses of the primary and secondary and by b the separation between them, the inductance can be expressed approximately as

$$L = 4\pi \times 10^{-7} \frac{fl_{\mathrm{co}}N_1^2}{h}\left(b + \frac{a_1 + a_2}{6}\right) \tag{17}$$

for a concentric winding and, if c denotes the number of disks in the primary winding,

$$L = 4\pi \times 10^{-7} \frac{fl_{\mathrm{co}}N_1^2}{ch}\left(b + \frac{a_1 + a_2}{6}\right) \tag{18}$$

in a stacked-disk winding.

According to Ampère's law, Eq. (4), the magnetizing current is given by

$$I_\mu = \frac{\int_l \mathbf{H} \cdot d\mathbf{l}}{\sqrt{2}N_1} = \frac{(\mathrm{AT})}{\sqrt{2}N_1}, \tag{19}$$

where the numerator, also called the total ampere turns (AT), can be determined with the help of Fig. 11 with B determined by the continuity of the magnetic flux. An approximate value of the mutual or magnetizing inductance M can then be derived with the help of the equivalent circuit of Fig. 8 as

$$M = \frac{V_1}{\omega I_\mu} \approx \frac{\sqrt{2}N_1^2}{(\mathrm{AT})} BA. \tag{20}$$

An approximate value of the magnetizing resistance R_m can be obtained in terms of the total iron losses P_{Fe} as

$$R_m = (mV_1^2)/P_{\mathrm{Fe}}, \tag{21}$$

where m is the number of phases.

4. THERMAL CHARACTERISTICS AND COOLING

If all the dimensions of a transformer are increased in the same ratio, all surfaces, including the cooling surfaces, and all the cross sections are increased as the square of the ratio. For given densities, the flux and the mmf increase as the square of the ratio, and, therefore, the apparent power increases as the fourth power. Since all losses increase with the volume and, therefore, only with the cube of the ratio, it follows that the efficiency increases with the power. However, since the losses increase faster than the cooling surface, more effective cooling methods must be used. Natural air cooling is adequate only for sizes up to a few kVA. For larger sizes oil cooling is needed.

The temperature rise affects the lifespan of the insulation in two ways: It accelerates chemical reactions, such as oxidation, and it subjects the insulation to mechanical stresses due to the differential elongation between adjacent materials. The first process is the dominant cause of failure in organic materials. The second process is the dominant cause of failure in insulation known as class H, which includes materials characterized by poor abrasion properties, such as polyimides. The lifetime of the insulation, which is commonly expressed in the form of Arrhenius relations, decays exponentially with the temperature rise and, in the range of practical interest, is reduced by about one-half with every increase in temperature of about 10 K. This consideration has resulted in peak allowable temperatures of 110–120 °C.

The thermal characteristics of transformers involve

1. dissipation of the heat resulting from the iron and the copper losses,
2. variations in the kVA rating with temperature rise in steady load conditions,
3. temperature rise under transient conditions (heating up and cooling down),
4. effects of certain factors such as altitude, color of tank, and sunshine under service conditions, and
5. the effect of the temperature on the lifetime.

Three modes of heat transfer are involved in the dissipation of heat in a transformer: conduction, convection, and radiation.

4.1 Conduction

Thermal transfer through solids is governed by Fourier's law according to which the temperature rise in one dimension is

$$\theta = ql/\lambda, \tag{22}$$

where q is the heat flow per unit area, l is the length of the path, and λ, the thermal conductivity of the medium, is equal to 345 W/m·K in copper and 207 W/m·K in aluminum.

4.2 Convection

Convection is the thermal transport from a solid surface by a fluid in motion and can be related to the heat transfer coefficient h as

$$\theta = q/h. \tag{23}$$

The flow of the coolant may be laminar or turbulent, depending on the speed of the fluid. Turbulent flow is much more effective for cooling purposes than laminar. The heat transfer coefficient ranges from 40 $\mathrm{W/m^2 \cdot K}$ with air cooling to 200 $\mathrm{W/m^2 \cdot K}$ with oil cooling.

4.3 Radiation

Radiation is the process by which heat is transferred by means of electromagnetic waves according to the laws of optics. Since wave propagation can occur in vacuum, it is most important for cooling in outer space applications. It is less important in terrestrial applications, in which convection is dominant. The power radiated per unit surface is proportional to the difference between the fourth powers of the absolute temperatures of the hot body and of the ambient, according to the Stefan–Boltzmann law. In transformers the temperature rise is small and so is the radiated power. It is, therefore, possible to make a linear approximation and lump the radiated power together with the heat transferred by convection. This is done by augmenting h in Eq. (23) by a factor 1.5.

5. POLYPHASE CONNECTIONS

5.1 Three-Phase Transformations

The delta–delta (Δ-Δ), star (or wye)-delta (Y-Δ), delta-star (or wye), (Δ-Y), and star–star or wye–wye (Y-Y) connections are the most common; they are illustrated in Fig. 12. The first two are used in step-up transformers for moderate voltages. The star-delta connection has the advantage of providing a grounding point in the low-voltage system that does not shift with unbalanced load and has the additional advantage of being free of third-harmonic currents and voltages (see Sec. 6). The delta–delta connection has the advantage of permitting operation in "V" in case of fault in one of the phases. The delta-star step-up and the star-delta step-down connections are most commonly used for high-voltage transmission, because they provide a point at which the system can be grounded either directly or through an impedance to damp oscillations and to limit line-to-ground fault currents. The star–star connection must be provided with a delta tertiary, in order to provide a path for the third-harmonic component of current.

5.2 Two- to Three-Phase Transformations

The one most commonly used is the Scott connection shown in Fig. 13. It uses two single-phase transformers that are electrically but not magnetically connected. Across the lines B and C is the so-called *main* transformer that has a 50% tap. The *auxiliary* or *teaser* transformer has an 86.6% tap and is

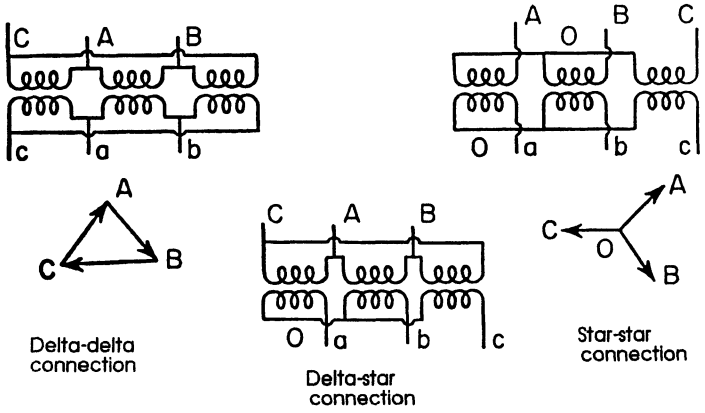

FIG. 12. Common three-phase transformer connections.

connected between the other line terminal, *A* in this case, and the center tap on the main transformer. If the two transformers have the same number of turns, the voltage per turn and, therefore, the flux is the same. A neutral point could also be provided on the three-phase side, and from the geometry of the triangle, this tap would have to be located at 33% from *D*. The windings on the three-phase side of the transformers must be designed to carry 115.5% of the current that the single-phase ratings of the transformers indicate. Alternatively, if the additional extra copper is not provided, the rating of the bank should be reduced to 86.6% of the combined single-phase ratings. This can be deduced from Fig. 13. Assuming for simplicity that $N_1 = N_2 = N$ and neglecting the magnetizing current, one obtains for the teaser transformer

$$0.866N\underline{I}_A + N\underline{I}_a = 0 \quad \text{or}\ \underline{I}_A = 1.15\underline{I}_a, \tag{24}$$

where the underline denotes a phasor, the capital subscript denotes the three-phase side, and the lower-case subscript the two-phase side. For the main transformer one has

$$\underline{I}_B N/2 - \underline{I}_C N/2 - \underline{I}_b N = 0 \quad \text{or}$$
$$\underline{I}_b = (\underline{I}_B - \underline{I}_C)/2, \tag{25}$$

and letting $\underline{I}_C = -\underline{I}_A - \underline{I}_B$, one obtains

$$\underline{I}_B = -\underline{I}_A/2 + \underline{I}_b \ \text{and similarly}$$
$$\underline{I}_C = -\underline{I}_A/2 - \underline{I}_b \tag{26}$$

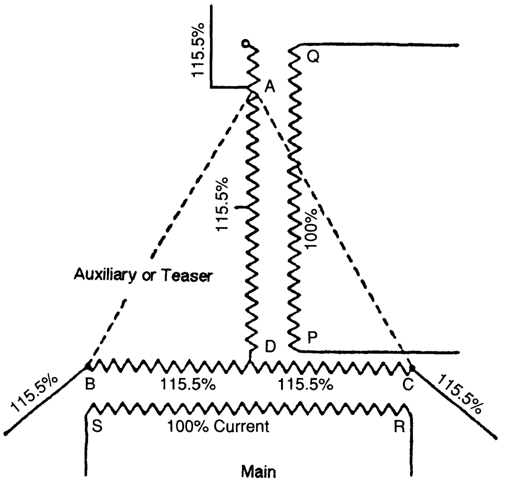

FIG. 13. Scott connection (adapted from Knowlton, 1941).

5.3 Zig-zag Connection

It is possible to obtain an arbitrary desired phase shift with a polyphase transformer if the primary and/or the secondary are divided into a number of sections. The zig-zag connection may suppress third harmonics in the line-to-neutral and line-to-line voltages. As shown in Fig. 14, half sections are connected in opposition, thus giving a larger fundamental voltage, but causing the co-phasal third harmonics to cancel out. The fundamental line-to-neutral voltage is only 0.86 times the arithmetic sum of the two section voltages, and this means that additional turns and copper are required. However, a better distribution of the load is obtained on the primary side when the secondary load is unbalanced.

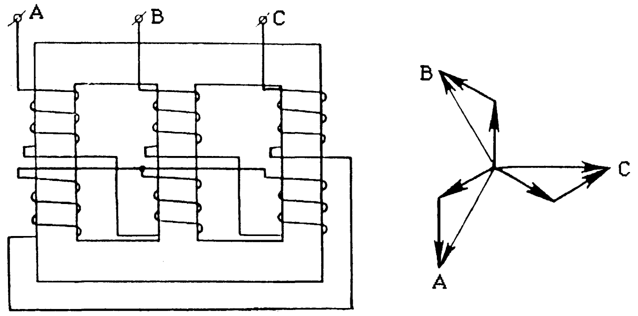

FIG. 14. Zig-zag connection.

5.4 Three- to Six-Phase Transformations

Twelve-pulse rectifiers must be supplied by six phases. These can be implemented either by connecting the center taps of the secondary windings or by having two secondary windings connected in double *Y* with a 180° phase difference between one *Y* and the other, or with one *Y*-*Y* connection and one *Δ*-*Y* connection.

5.5 Load Tap Changing

To permit some adjustment of the voltage or to maintain the secondary voltage against supply or load variations, tappings are brought out to terminals so that the number of turns on one winding, usually the high-voltage winding, can be changed by ±2.5% to 5%. In order to change the turns ratio without interfering with the load, the current is shunted from one tap to the next with the help of bridging resistances, or reactors. The underlying principle is illustrated in Fig. 15 with the current-carrying portions drawn in black. The procedure is to transfer the line current first from contact 1 to contacts 2 and 3 and resistances R_1 and R_2 and next to contact 4. Tap changing is implemented by a special motor. Alternatively, the mechanical contacts may be replaced by semiconductors. Typically, one uses two silicon-controlled rectifiers (SCRs) connected in antiparallel. For voltages above about 6 kV, a series connection of SCRs is required. The advantages are as follows: no pitting of contacts, switchover in a few microseconds exactly at the zero crossing of the current, no voltage drop during the switchover, and unlimited number of successive switchings that with resistances is limited by heating. Tap changing with SCRs is used especially in electric locomotives and is appropriate also for furnace or rectifier transformers.

5.6 Autotransformer

This uses a single winding with part of the winding common to both the primary and secondary. When the ratio of transformation approaches unity and most of the

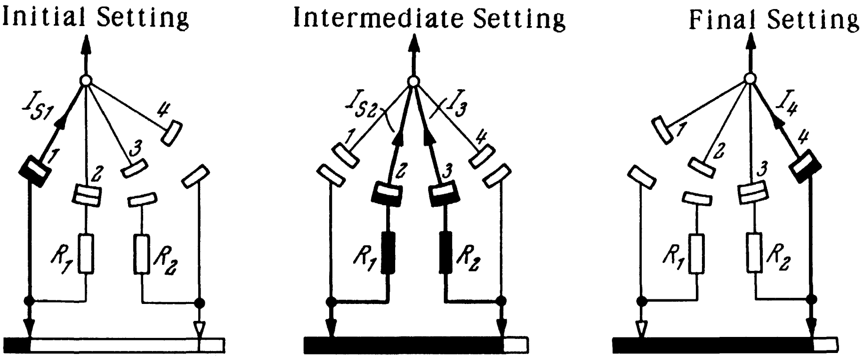

FIG. 15. Load tap changer (adapted from Boedefeld-Sequenz, 1971).

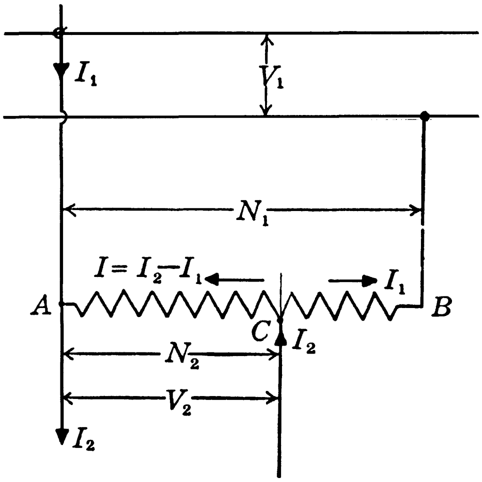

FIG. 16. Schematic diagram of autotransformer.

winding is common, the autotransformer offers great advantages with regard to regulation, reduced weight and size per kVA, lower cost, higher efficiency, and lower magnetizing current. However, the autotransformer has the disadvantage that it does not provide electrical isolation between the primary and the secondary circuits. Figure 16 shows a schematic diagram. As in a two-winding transformer, the core flux is determined by the impressed voltage V_1, the number of primary turns N_1, and the line frequency f. The common part of the winding carries a current that is the difference between I_1 and I_2. One of the most common applications of the autotransformer is the "Variac," "Regavolt," or "Regulac." These have a toroidal core and winding, with a thin carbon brush making contact with the winding in any desired position, as shown in Fig. 17. The output voltage can be varied between zero and about 120% of the input voltage.

5.7 Parallel Operation

Two or more transformers are often operated in parallel to deliver power to a load over a common busbar. In order to avoid local flow of current circulating in the paralleled windings, the following conditions must be satisfied in single-phase transformers:

1. proper connection with regard to polarity,
2. identical voltage levels,
3. equal turn ratios,
4. ratio of the winding impedances inversely proportional to the current ratio, and
5. ratio of the winding resistances equal to the ratio of the reactances.

In addition, in three-phase transformers, the phase angles must be identical.

6. HARMONICS AND NOISE

Harmonic currents are sources of losses, voltage distortion, electromagnetic and acoustic noise, and telephone interference. They are becoming a major concern of the utilities due to the ever-increasing diffusion of nonlinear loads containing solid-state switching elements. One must distinguish between sources that are intrinsic in the transformer itself and sources in the load. Starting with the first, the magnetization curve of Fig. 11 is nonlinear on account of iron saturation. Therefore, if it is desired to keep B, and therefore Φ and V, sinusoidal, the magnetizing current must contain harmonic components of which the third and its multiples, the triplen, are the dominant ones. Then, as was already mentioned in the previous section, the transformer must be provided with at least one delta winding in which these current components can flow freely. The associated losses, however, cause

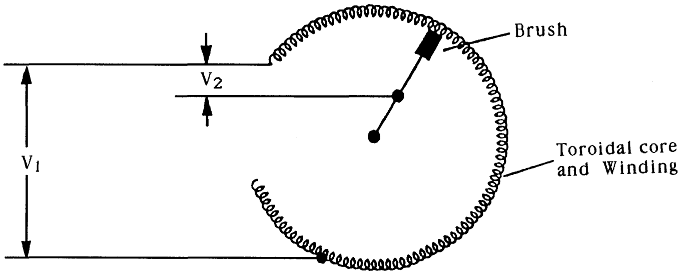

FIG. 17. Schematic diagram of "Variac" (adapted from Hindmarsh, 1965).

additional heating, which must be taken into account in the design stage.

The harmonics that originate in nonlinear loads, such as fluorescent lighting, computers, and adjustable-speed drives, must be kept under control, if needed, by imposing penalties on the consumers when they do not comply with standards, such as IEC 1000 or IEEE 51a. Limits on the total harmonic distortion (THD), which is the ratio of the root mean square value of the harmonics to the amplitude of the fundamental component, and on the telephone influence factor (TIF), which is given by a weighting curve of the relative interfering effects, are set by standards, such as those of the ANSI-IEEE and of the European Community. When harmonics are present, the associated losses are unavoidable and must be taken into account in the rating of the transformer. In transformers that feed rectifiers the current may contain a dc component that may drive the iron core into saturation.

The transformer also has an intrinsic source of noise that is due to magnetostriction of the iron laminations. This consists of an elongation in the direction of the flux. The noise, whose dominant frequency is twice that of the supply, can be attenuated by avoiding mechanical resonances or by attaching dampers to the external walls of the tank.

Another source of noise is the auxiliary cooling equipment, such as fans, blowers, and pumps.

7. SPECIAL TRANSFORMERS

7.1 Voltage Regulators

These are used when the power transformer is not adequately provided with taps. In this case the taps and switches are placed in the winding of a separate autotransformer.

7.2 Constant-Current Transformers

These are used mainly for street lighting when the lamps are connected in series, and they maintain the current within ±1/2%, regardless the number of lamps connected in series. In these transformers the primary and secondary windings are stacked one on top of the other with the primary stationary and the secondary free to move vertically. Counterweights are used to effect a balance between the weight of the secondary and the force of repulsion between the two windings. Any increase in current increases the repulsion force, thereby increasing the leakage reactance and, thus, decreasing the secondary voltage to the value required to produce the rated current.

7.3 Instrument Transformers

These are divided into two classes: potential (PT) and current (CT) transformers. Their principle of operation is essentially the same as that of the power transformer. They are built with high-quality iron operating at very low flux densities so that I_0 is very small. The PT is designed with an impedance as small as possible, in order to keep the voltage ratio practically constant. The CT often has only one turn formed by passing the line conductor through the window of the iron core. The CT's secondary must never be left open-circuited, because, without the secondary ampere turns, the primary current would become entirely a magnetizing current I_μ, which would saturate the core and induce dangerous overvoltages in the secondary.

Each instrument transformer serves two purposes:

1. to insulate the high-voltage circuit from the measuring one, in order to protect the measuring apparatus and the operator, and
2. to make possible the measurement of high voltages with low-voltage voltmeters (usually 115 V), or large currents with low-current ammeters (usually 5 A).

These transformers are also used to operate relays, solenoids, and circuit breakers, or other controlling devices.

7.4 Reactors or Choke Coils

Their main applications are for limiting the fault current, when connected in series with feeder lines or with neutral ground connections, and for supplying the charging current, when connected in shunt with underground cables. They store energy in magnetic form, and their VA rating is, therefore.

$$N = 2\pi f L I^2. \qquad (27)$$

Their structure may be air-cored or iron-cored. However, even in the latter case the energy is stored outside the iron core in so-called air gaps distributed inside the coil. The function of the steel is to concentrate the energy storage in small volumes of high flux densities and thus reduce the coil size and the electrical losses. The coils must be designed to withstand the strong radial stresses that develop during short circuits. The inductance of iron-cored reactors can be controlled by introducing a dc current component and thus driving the iron into saturation during an adjustable part of the half cycles.

GLOSSARY

Coil: A series of turns of electric wire.

Conduction: Transmission of heat through a medium.

Convection: The circulating motion that occurs in a fluid at a nonuniform temperature due to the variation of its density and the action of gravity.

Core: The part of the magnetic circuit that carries most of the flux, usually made of a stack of ferromagnetic laminations.

Harmonic: A component frequency that is an integral multiple of the fundamental frequency.

Noise: Acoustic or electromagnetic radiation that involves random changes in frequency or amplitude.

Primary: The electric circuit connected to the power supply.

Radiation: Emission of energy in the form of waves.

Reactor: A device used to introduce reactance into an electrical circuit.

Secondary: The electric circuit connected to the user.

Tank: The metallic envelope of a transformer.

Transformer: A device employing mutual inductance to convert variations of current in a primary electric circuit into variations of voltage and current in a secondary circuit.

Turn: A single round of wire.

Winding: A series of coils wound around the core.

INTRODUCTION

The seeds of the electronics revolution were planted in the early part of the industrial revolution by Lee Deforest, Yale Class of 1899, when he invented the vacuum tube triode amplifier in 1906. He immediately applied it to radio, with which it was his ambition to "bring culture to millions." But radio found a major market and financial sponsor during World War I. At the beginning of World War II, television had been on display at the 1939 World Fair in New York, and again a major drive developed to create all sorts of military radio and other complex electronic systems, which by 1945 were being produced with "peanut tubes" the size of your thumb, packed together so closely that the boxes containing them were hot as a light bulb. Subsequent scaling down of electronic circuits soon ran into a power-density limit. And the power was being used only to drive electrons out of a metal cathode, already brilliantly designed to minimize the work function, and not to perform any of the electronic functions themselves. To get around this problem, studies were already under way to find ways of controlling electron flow inside materials without the use of heaters.

At the Bell Telephone Laboratories materials science had produced high-quality single germanium crystals, with growth-controlled group III or V inpurities. While looking for electric-field effects on the surface of a polished crystal, theorist John Bardeen and experimentalist Walter Brattain discovered in December 1947 that the current between two closely spaced points, an emitter and a collector, on the surface of a germanium base could be controlled by a current between the emitter and the base and, further, that the controlled current was larger than the current controlling it. The bipolar junction transistor (BJT) was born.

It had taken about 50 years to get the hot filament out of the electronic amplifying valve. Dissidents from Bell Laboratories then moved to Texas Instruments to initiate a silicon technology, leading to the second 50

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

years it has taken to complete the electronics revolution. The outcome has ushered in another revolution, the information revolution. What DeForest has taught us, and he himself stressed, is not how to build the vacuum-tube triode, but what one can accomplish with an electronic amplifying device. The message was not lost on David Sarnoff and others who have used it, some for selfish gain but all, unwittingly, to build a truly global community.

1. SEMICONDUCTOR BASICS

The semiconductor concepts and relationships vital to BJT device physics are summarized in Fig. 1. Quantities referenced therein are defined in the context of the following discussion. Descriptive terms are defined in the context of the next section. The physics leading up to these fundamentals can be found in SEMICONDUCTORS, ELEMENTAL—ELECTRONIC PROPERTIES; SEMICONDUCTORS, ELEMENTAL—MATERIAL PROPERTIES; Shockley (1939, 1950), and texts that deal with semiconductor physics (e.g., Kittel, 1996, or Sze, 1981). The essentials are as follows.

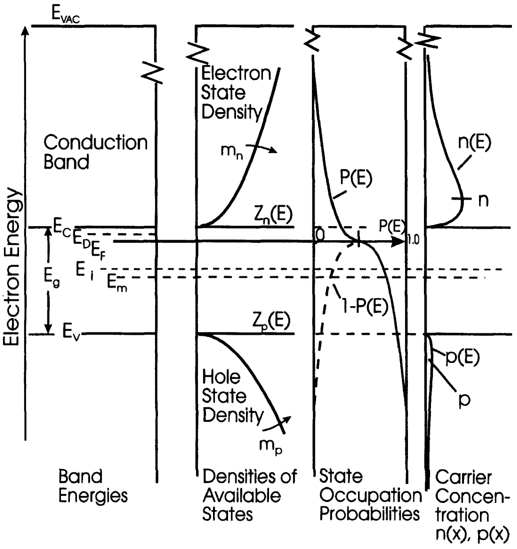

FIG. 1. Determination of electron concentration in terms of energy bands, densities of available states, and the Fermi–Dirac distribution function.

1.1 Energy Bands, Densities of States

A semiconductor energy-band diagram for a uniformly doped n-type material in thermal equilibrium is shown in Fig. 1. Unless otherwise stated, the material under discussion is crystalline silicon. Doping the (group IV) silicon up to about 0.1% with group V "donor" atoms, such as phosphorus (P) or arsenic (As), makes available up to one electron per atom that substitutes for silicon in its tetrahedral covalent bonding configuration, producing n-type silicon (n-Si). Doping with group III "acceptor" atoms makes available one hole per substitutional atom, producing p-type silicon (p-Si).

The four panels of Fig. 1, with energy levels aligned, show for n-Si

1. the valence band and its upper edge, E_V; the conduction band and its lower edge, E_C; the energy gap E_g between these levels; the midgap energy E_m; the electron "donor" energy level E_D; the "Fermi energy" E_F; and the "intrinsic" Fermi energy E_i;
2. a parabolic curve representing the quantum mechanically determined density of *available* electron states, $Z_n(E)$, in the (nearly empty) conduction band, and the corresponding density of available vacancy (hole) states, $Z_p(E)$ in the valence band;
3. the temperature-dependent Fermi–Dirac distribution function $P(E)$, centered on E_F, which gives the probability of any state of energy E in each band being occupied by an *electron*, and (dashed) $1 - P(E)$, the corresponding probability of any state of energy E being unoccupied by a *hole* in the valence band; and
4. the product of the available state densities in **2** and their occupation probabilities in **3**, which gives the energy distributions of state-occupying electrons in the conduction band, holes in the valence band, and their integrals n and p in units of numbers per cm^3.

1.2 Fermi–Dirac Occupation Probability

The Fermi–Dirac *electron* occupation probably for these states is given by the well-known Fermi–Dirac distribution function,

$$P(E) = \{\exp[(E - E_F)/kT] + 1\}^{-1}. \quad (1)$$

The product of $P(E)$ and the density-of-states function yields the densities of both holes and electrons with reasonable accuracy so long as the Fermi energy E_F remains within the energy gap. The Fermi energy is known as the "chemical potential" of the material, because a single electron added to the system in equilibrium resides (statistically) at the energy $E = E_F$. Joining two materials with two Fermi energies (measured from E_{vac}) produces a flow of electrons from the material with the higher Fermi energy to that with the lower. Removing a single electron from a material requires the energy $\phi = E_{vac} - E_F$, defined as the *work function.* The energy given up by an external electron at rest when dropping down to the conduction-band edge E_C is called the *electron affinity* χ, about 3.25 eV (electron volts) in silicon.

1.3 Carrier Concentrations

The energy gap E_g, an interband ionization energy, is about 1.1 eV. It takes much less energy to ionize a donor atom such as P or As, about 0.040 eV (40 meV), than to "ionize the valence band," i.e., to create an electron–hole (*e-h*) pair. Therefore, the donor energy level E_D shown in Fig. 1 lies 40 meV below the conduction-band edge. (Note that the figure is not drawn to scale.) The same can be said for ionizing group III atoms such as boron (B) and aluminum (Al), each of which "accepts" an electron from the valence band to complete the four silicon bonds required for it to "substitute" for silicon, thus creating a positively charged valence-band vacancy, or "hole," which is mobile in *p*-Si. Thus, an acceptor energy level E_A would be placed above the valence-band energy E_V by its ionization energy. A figure comparable to Fig. 1 for *p*-Si, and with the same acceptor ionization energy as that for the donor shown, can be constructed by simply rotating Fig. 1 about the midgap energy E_m.

In pristine silicon, with no dopants, the electron and hole densities are equal, $n = p$, since there are no other sources for either. The Fermi energy for this *intrinsic* semiconductor is written E_i and lies slightly above E_m in Fig. 1, because $Z_p(E)$ is larger than $Z_n(E)$ at every E, and when $E_F = E_i$, n must equal p.

The density of *ionized* donors is N_D and of *ionized* acceptors is N_A in the corresponding *n*-Si and *p*-Si. Thus in *n*-Si at equilibrium, with donor concentration N_D, $n_{n0} = N_D + p_{n0}$ with $p_{n0} \ll N_D$, and therefore $pn \approx p_{n0}N_D$. Correspondingly in *p*-Si, with acceptor concentration N_A, $p_{p0} = N_A + n_{p0}$ with $n_{p0} \ll N_A$ and $pn \approx n_{p0}N_A$. Thus, in equilibrium, taking $pn = n_i^2$, the minority-carrier concentrations are approximately

$$\begin{aligned} &\text{in } n\text{-Si}, \quad p_{n0} = n_i^2/N_D; \\ &\text{in } p\text{-Si}, \quad n_{p0} = n_i^2/N_A. \end{aligned} \tag{2}$$

For a sense of numbers, in silicon at room temperature, $n_i \approx 1.5 \times 10^{10}$ cm^{-3}, and $n_i^2 = 2.25 \times 10^{20}$ cm^{-3}. The atomic density is 5×10^{22} cm^{-3}. A normal doping level might be $N_D = 10^{18}$ cm^{-3}, or one dopant atom for 5×10^4 silicon atoms. On the assumption that all dopant atoms are substituted for silicon and are all ionized, the *majority-carrier* (electron) density, taking $n_i = 10^{10}$ cm^{-3} for simplicity, is

$$n_{n0} = N_D = 10^{18} \text{ electrons cm}^{-3},$$

and the *minority-carrier* (hole) density is

$$p_{n0} = 10^{20}/10^{18}, = 100 \text{ holes cm}^{-3}!$$

The ratio is $n_{n0}/p_{n0} = 10^{16}$, yet it is the diffusion of minority carriers that makes things happen in the bipolar junction transistor, which is also known as the "diffusion transistor."

In thermal equilibrium, *e-h* pairs are generated at a thermal generation rate G_{th}, usually involving defect and impurity states near midgap, without which G_{th} would be much smaller. This rate is matched by a recombination rate rnp, where r is a recombination rate constant. The rate is dependent on the simple product pn because the recombination process is assumed to be statistically independent. Given G_{th} and r, therefore, the product np must be independent of any specific value of n or p, established by local doping concentrations. One such situation is the intrinsic semiconductor where $n = p$ defined as n_i. Thus at fixed temperature and constitution of material $pn = n_i^2$ for any p and n.

Regardless of the shape of the density-of-available-states functions, the exponential character of the Fermi–Dirac function makes the integrated carrier concentrations n and p exponentially dependent on the displacement of E_F from E_C and E_V, respectively. This accounts for the analogy between the carrier concentrations in a potential gradient and an ideal gas, properties that are vital to the functioning of all junction and field-effect devices.

The electron or hole volume concentration n or p at any point in the crystal is given by a $P(E)$-weighted integral of the electron (hole) density of available states as indicated above. The results of these integrals, which are worked out in Kittel (1996) and Sze (1981), are

$$n = 2\left(\frac{2\pi m_n \kappa T}{h^2}\right)^{3/2} \exp\left(-\frac{E_C - E_F}{\kappa T}\right), \tag{3}$$

$$p = 2\left(\frac{2\pi m_p \kappa T}{h^2}\right)^{3/2} \exp\left(-\frac{E_F - E_C}{\kappa T}\right). \tag{4}$$

Putting $E_F = E_C$ for n and $E_F = E_V$ for p gives the special values $n = N_C$ and $p = N_V$, the upper-limit values for the electron and hole densities predicted by this model. In this terminology, the np product is found to be, with $E_g = E_C - E_V$,

$$n_i^2 = np = N_C N_V \exp(-E_g/\kappa T). \tag{5}$$

2. *pn*-JUNCTION FUNDAMENTALS

For simplicity, all of the basic ideas to be developed here are based on a one-dimensional model, i.e., an infinite plane structure with the carriers flowing normal to the plane. Uniform doping concentrations are used for analytical simplicity, except where doping gradients are essential to device design. Translation to realistic two- and three-dimensional structures and doping concentrations follows without conceptual difficulty, but requires complex computer modeling for quantitative analysis.

2.1 Junction Potential and Carrier Concentrations

Two moderately doped n-type and p-type silicon crystals have the same electron affinity χ but different work functions Φ as shown in Fig. 2. The work-function difference, $\Delta\Phi$, is equal to the Fermi energy difference between the two isolated crystals, typically about 1 V for moderately doped silicon.

When the two crystals are brought together, the key energies at the surfaces are joined as shown by the arrows in Fig. 2. Equilibrium of the new system is established by the flow of electrons from the n-Si to the p-Si, and the flow of holes in the opposite direction, with near annihilation of both by recombination. The resulting positive and negative fixed (ionized dopant) charge on either side of the junction, Fig. 3(a), creates an electric field [Fig. 3(b)] that grows until the potential-energy barrier V_0 (c) for both holes and electrons equals the original $\Delta\Phi$.

At this final stage, the Fermi energy is constant throughout the composite system, which is by definition the equilibrium state. The conduction-band edge, representing the rest energy of an electron in the system, is recognized as a plot of the electron potential energy through the junction. Divided by the electron charge $-q$, the conduction-band energy becomes the *electrostatic potential* function $\phi(x)$ through the junction region, except for an arbitrary zero point, as shown in Fig. 3(d), which shows this equilibrium potential. A similar argument identifies the valence-band edge as the potential energy of a hole, with energy measured *downward.* Therefore the potential $\phi(x)$ is a common potential representing the potential energy for both holes

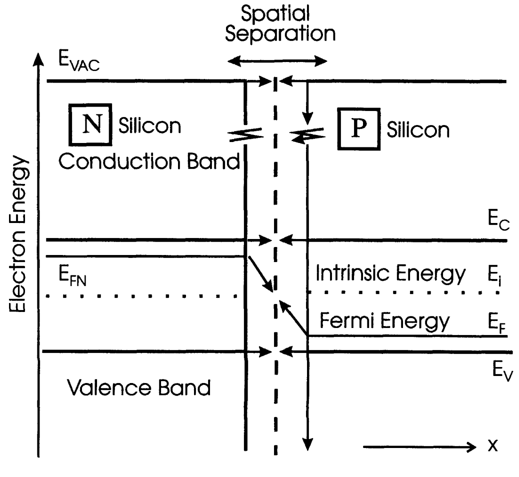

FIG. 2. Joining n-type and p-type semiconductors at a junction.

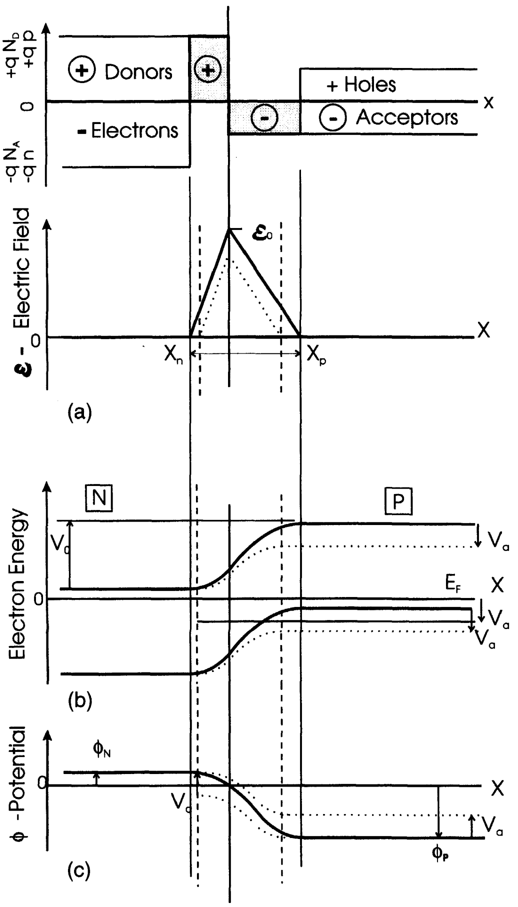

FIG. 3. (a) Uniform dopant, and depleted carrier concentrations around *pn* junction with corresponding electric field in equilibrium; (b) corresponding conduction- and valence-band edges; (c) junction potential. Dotted curves: shifts with forward bias applied, with two potentials in (c).

and electrons in the region where it is defined. It can easily be shown that

$$\phi(x) = E_F - E_i(x). \tag{6}$$

At equilibrium, the difference between the extreme values $\phi_N - \phi_P = V_0$, a potential barrier sometimes referred to as the "built-in voltage." Also shown in Fig. 3(c) is an example of the two *quasi-equilibrium* potentials ϕ_n and ϕ_p, separated by a "forward" applied voltage V. These determine both carrier concentrations in forward bias through the depletion region, in quasi equilibrium with their sources, $+qN_D$ and $-qN_A$.

It is convenient to take the zero point for the potential at the point where $n = p = n_i$, the *intrinsic* carrier concentration, defined in Eq. (5). With reference to the intrinsic point, the concentrations for electrons and holes throughout the space-charge region in equilibrium are written in terms of the potential difference measured to that point, behaving like the densities of ideal gases:

$$n(x) = n_i \exp[+q\phi(x)/\kappa T], \tag{7}$$

$$p(x) = n_i \exp[-q\phi(x)/\kappa T]. \tag{8}$$

These densities typically vary by factors of 10^{12} to 10^{16} from one side to the other. The potential *energies* of the holes and electrons increase to the left and to the right, respectively, at any point in the common electric field $\epsilon(x)$. The proper potential function and the charge distribution are found by solving Poisson's equation simultaneously with the equations for $n(x)$ and $p(x)$, Eqs. (7) and (8). This is a complex process even for the simplified model under discussion here. Finding the approximation to the potential is greatly simplified, however, if one adopts the "depletion approximation" (Shockley, 1949). In this approximation, it is assumed that all of the free electrons are removed from the depleted *n*-Si layer back a length X_n and all the holes are removed from the *p*-Si layer back a length $X_p = (N_D/N_A)X_n$, a "space-charge layer" that is overall electrically neutral. Having found a potential by this depletion approximation, the potential can be used to make a second approximation to the carrier concentration, inconsistent with the depletion approximation, of course, but remarkably useful for the purpose of physical reasoning. The results yield figures similar to Fig. 3(c), with the further assumption that doping concentrations are constant (but not equal) and the host semiconductor is the same on each side of the junction.

2.2 Voltage Control of Minority-Carrier Boundary Values

Given this model (Shockley, 1949), with the electron concentration on the *n* side of the depletion layer given as $n_{n0} = N_D$, and $p_{p0} = N_A$, the electron concentration at the *p*-Si boundary and the hole concentration at the n-Si boundary of the depletion layer are, respectively,

$$n_{p0} = N_D \exp(-qV_0/\kappa T),$$
$$p_{n0} = N_A \exp(-qV_0/\kappa T). \tag{9}$$

With a positive battery voltage V applied to the p-Si with respect to the n-Si, the chemical potential between the n-Si and the p-Si that has to be balanced by the space-charge potential difference becomes $V_0 - V$. This requires that the integral of the electric field $\epsilon(x)$ (Fig. 3) be reduced by positive V, requiring that the junction width be correspondingly reduced. The flow of majority carriers into the two sides of the junction corresponding to this inward boundary displacement permits one to calculate a "junction" capacitance per unit area as the dielectric constant divided by the thickness of the depletion layer (Sze, 1981).

It is assumed that in this process, the majority-carrier concentrations at the n-Si and p-Si boundaries, even as they move, are unchanged when V is applied, and that the carrier concentrations within the junction remain in equilibrium with their sources on opposite boundaries. Thus, with a voltage applied there are two quasi-equilibrium potential functions, obtained by integrating the common electrostatic field within the junction, one anchored at ϕ_N on the n-Si side and the other at ϕ_P on the p-Si side, separated by the applied voltage V, which determine $n(x)$ and $p(x)$ within the junction, including the boundary values for the minority-carrier concentrations in the nondepleted, "charge-neutral" regions on the opposite sides, as they do in equilibrium.

Correspondingly, each of these boundary concentrations is increased by the factor $\exp(qV/\kappa T)$. At the p-Si boundary, the minority-carrier electron concentration becomes, in equilibrium,

$$\begin{aligned} n_p(0) &= N_D \exp[-q(V_0 - V)/\kappa T] \\ &= n_{p0} \exp[+qV/\kappa T], \end{aligned} \tag{10}$$

and the corresponding *excess* electron concentration n' at the boundary is just

$$n'(0) = n_p(0) - n_{p0}.$$

Analogous relations establish the minority-carrier hole concentration at the n-Si boundary. The *excess minority-carrier* concentrations that appear at the boundaries of the charge-neutral n-Si and p-Si regions are therefore, on the p-Si side,

$$p'(0) = p_{n0}\{\exp(qV/\kappa T) - 1\}, \tag{11}$$

and on the n-Si side,

$$n'(0) = n_{p0}\{\exp(qV/\kappa T) - 1\}. \tag{12}$$

These famous exponential relationships (Shockley, 1949) are found over and over again in semiconductor device physics (Sze, 1981).

2.3 The Continuity Equation and Carrier Transport

The junction potential through the space-charge layer establishes carrier *concentrations* within the space-charge region and at its boundaries where they become minority-carrier boundary conditions in the charge-neutral n-Si and p-Si regions. The continuity equation, which is applicable everywhere, is used in this model to determine how the carriers flow inside these quasineutral regions.

For a given carrier type, the continuity equation simply sums up the mechanisms by which the concentration of that carrier type can increase with time. For electrons and holes independently, continuity at any point in space and time is expressed as follows:

$$\frac{\partial n}{\partial t} = G_{\mathrm{Th}} + g_0 - rnp - \nabla \cdot \boldsymbol{F}_n, \tag{13}$$

$$\frac{\partial p}{\partial t} = G_{\mathrm{Th}} + g_0 - rnp - \nabla \cdot \boldsymbol{F}_p, \tag{14}$$

where G_{Th} is the thermal generation rate of electron–hole (e-h) pairs, g_0 is the sum of all other e-h pair generation rates, r is a recombination rate constant, and $\boldsymbol{F}_n$ and $\boldsymbol{F}_p$ are the flow flux density vectors for the indicated carriers.

In equilibrium, all terms are zero except for the thermal generation and the recombination terms:

$$\text{Equilibrium: } 0 = G_{\mathrm{Th}} - rnp, \tag{15}$$

$$np = G_{\mathrm{Th}}/r = n_i^2. \tag{16}$$

It is assumed for simplicity that G_{Th} and r are constants throughout the system. Thus, the product np is constant everywhere. Therefore in the quasineutral p-Si with majority-carrier density $p_{p0} = N_A$, the recombination rate, consisting of four terms (with the x dependence removed to reduce clutter), is

$$r(np) = rn_i^2 + r[N_A n' + (n_i^2/N_A)p' + n'p'].$$

The first term must balance G_{Th} by Eq. (16). Next, the high conductivity and approximate charge neutrality of this p-Si region require $n'(x) \approx p'(x)$, with the result that the second term is much larger than the third term. With rN_A, the "minority-carrier lifetime," defined as the constant τ_n on dimensional grounds, the recombination rate becomes, in one dimension,

$$rnp(x) = n'(x)/\tau_n + rn'^2(x). \tag{17}$$

The nonlinear term is one that arises under conditions of "high injection," which is important at relatively high forward voltage. The condition for "low injection," for which this term can be neglected, is therefore $n'(0) \ll N_A$. Solution of Eq. (13) for an initial uniform $n'(x)$ shows that $n'(t)$ decays exponentially with the time constant τ_n. Thus the term "minority-carrier lifetime."

For the present purpose we take g_0 (the basis for phototransistors, solar cells, video cameras, avalanche detectors, etc.) to be a constant to indicate its presence in some cases.

Anywhere in the pn-junction system, the electron and hole carrier-flow flux densities F_n and F_p, which go into Eq. (13), are accounted for by an electric-field "drift" or "conductivity" term and the simplest diffusion term:

$$F_n(x) = -n(x)\mu_n\epsilon(x) + D_n \frac{\partial}{\partial x} n(x), \tag{18}$$

$$F_p(x) = p(x)\mu_p\epsilon(x) + D_p \frac{\partial}{\partial x} p(x). \tag{19}$$

These equations are most useful in describing carrier flow outside the depletion region.

2.4 Diffusion Equation for Minority Carriers

It may be shown that at normal, uniform doping levels and low injection, the nonlinear, ϵ-driven majority-carrier flow is much less than the carrier-density–gradient diffusion flow. Using this convenient assumption, putting the pieces back into the continuity equation for the excess minority electron concentration, and assuming that the spatial and time-dependent derivatives of $n_{p0}(x,t)$ are zero yields, in one dimension,

$$\frac{\partial n'}{\partial t} = -\frac{n'(x)}{\tau_n} + D_n \frac{\partial^2}{\partial x^2} n'(x) + g_0. \tag{20}$$

This is the famous time-dependent diffusion equation, which is used for modeling device dynamics. It is simply a specialized statement of the original continuity equation under the conditions stated. The time-independent diffusion equation (TIDE), which describes steady-state behavior, is

$$0 = -\frac{n'(x)}{\tau_n} + D_n \frac{\partial^2}{\partial x^2} n'(x) + g_0. \tag{21}$$

In cases where the above sequence of assumptions cannot be made, the field components in Eqs. (18) and (19) must be retained (Kroemer, 1985; Sze, 1981), and other consequences of alloying and dopant gradients, discussed in Sec. 4, must be used to correct the illustrative treatment of this section.

The solution of the above TIDE, in one Cartesian coordinate, is of the form

$$n'(x) = A^+ \exp(+x/L_n) + A^- \exp(-x/L_n) + g_0, \tag{22}$$

in which $L_n^2 = D_n\tau_n$ is the minority-carrier "diffusion length," the average distance that a diffusing excess carrier travels in the neutral p-Si region before it recombines with a majority hole.

The coefficients A^+ and A^- are determined by two boundary conditions on $n'(x)$. In the "long junction," where the p-Si extends far beyond L_n, the physical boundary condition at $x = \infty$ (or $x \gg L_n$) requires that $A^+ = 0$ and $A^- = n'(0)$. Thus, in the neutral p-Si region, and correspondingly in the neutral n-Si region, the excess minority-carrier concentrations are, using x_p and x_n as defined in Fig. 4 for symmetry,

$$n'(x_p) = [n'(0) - g_0\tau_n]\exp(-x_p/L_n), \tag{23}$$

$$p'(x_n) = [p'(0) - g_0\tau_p]\exp(-x_n/L_p). \tag{24}$$

These excess-carrier concentrations are electrically compensated by majority-carrier concentrations that accumulate during the transients between steady states by majority-carrier drift in the field created by the excess minority carriers. The result is a compensating hole and electron population in a "diffusion capacitance" each side of the junction in which the charges of opposite sign are separated by statistical improbability of their recombining instead of an insulator. Each capacitance per unit junction area is given by the excess-carrier charge per volt, which can be calculated by inspection of Fig. 4. These two "diffusion capacitors" are in parallel with the junction capacitor defined in Sec. 2.2. All are voltage dependent, a very useful property especially in reverse bias.

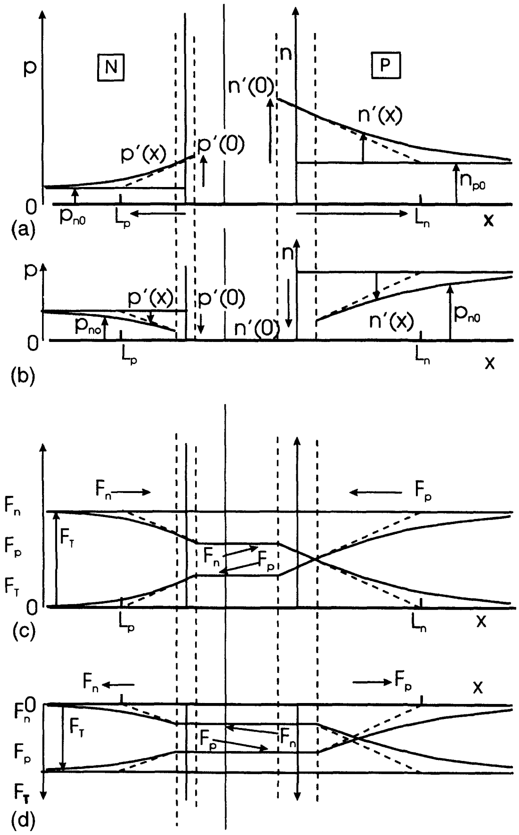

FIG. 4. (a) Minority-carrier concentrations near junction in forward bias; (b) same for reverse bias; (c) electron and hole flux densities near junction in forward bias; (d) same for reverse bias.

The corresponding minority-carrier flow rates are defined in terms of the carrier flux densities, using the diffusion component of Eq. (18) and its equivalent for holes on the p-Si and n-Si sides of the junction, respectively:

$$F_n(x_p) = D_n\frac{[n'(0) - g_0\tau_n]}{L_n}\exp\left(-\frac{x_p}{L_n}\right), \tag{25}$$

$$F_p(x_n) = D_p\frac{[p'(0) - g_0\tau_p]}{L_p}\exp\left(-\frac{x_n}{L_p}\right). \tag{26}$$

The above two minority-carrier concentrations and current densities for a long junction for forward and reverse biases illustrate the role of optical generation rates in the pn junction. For example, a voltage input controls $F_n(x_p)$ through $n'(0)$. Optical generation g_0 controls $F_n(x_p)$ through $g_0\tau_n$. But these two input quantities drive the electron flux density in opposite directions. The first is the normal semiconductor rectifier, and the second is the pn-junction solar cell. Having made this point, we set g_0 equal to zero for simplicity until it is needed.

The above electron and hole flux densities are plotted in Fig. 4. In the depletion layer, which is exaggerated here, the carrier flux densities are shown constant, meaning that $G_{\text{Th}} - rnp$ in this layer is assumed to be zero.

Along a common x coordinate the two minority-carrier flow components above have opposite signs. Electrons flow to the right, holes to the left. The corresponding carrier flux densities are multiplied by charges of opposite sign. Thus, the two current components are in the same direction, in this case to the left. If we assume, for simplicity, that $N_D \gg N_A$, then the electron current density dominates. With a diode area A, the electron current density in the $-x$ direction is

$$I = I_0\{\exp(qV/\kappa T) - 1\}, \tag{27}$$

$$I_0 = qA(D_n/L_n)n_{p0}. \tag{28}$$

This expression is plotted in Fig. 5. In gen-

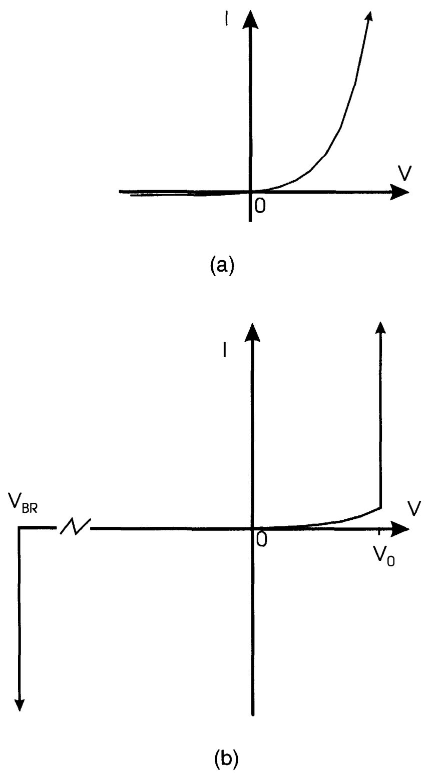

FIG. 5. (a) "Ideal" electron current vs voltage for $p^{++}n$ junction. (b) Observed *IV* characteristics, with the "ideal" component reduced to show the practical "reverse-breakdown" and "flat-band" breakdown components.

eral, the hole component would simply add to I_0.

It should be emphasized that in this model, the details of recombination and carrier transport in the depletion region have been bypassed. The carrier concentrations obtained by quasi-equilibrium potentials as outlined simply supply boundary conditions, or "injection" concentrations at the boundaries. However, the carrier flux densities can always be described in terms of field- and gradient-driven components even if the transport model is not as simple as Eq. (8) and its hole equivalent. In equilibrium, each carrier population at each position in the same field, but in its own gradient, adjusts its own concentration and gradient for zero net flow, and the product is n_i^2 even though n_i^2 may be a function of position. In forward bias, the field is reduced, and the diffusion flow overbalances the field-driven component. In reverse bias the unbalance reverses sign and favors the field over the diffusion flow.

When a forward voltage approaching V_0 is applied, the "low injection" approximation fails, and the analysis above fails. When the voltage reaches V_0, the space-charge layer disappears, the potential barrier, which controlled the minority-carrier boundary values, disappears, and the recombination process still required to maintain junction current is confined to a continuously thinning layer. At $V = V_0$ the current rises abruptly with V, giving rise to the rectifying property that has so many practical uses. Compared with normal operating forward currents, the current $I(V)$ expressed in Eq. (27), represented by Fig. 5(a), is essentially negligible, although the concepts are vital in the BJT. Commonly encountered I–V characteristics of "diode rectifiers" are shown in Fig 5(b).

In reverse bias, the field ϵ_0 at the center of the junction increases until the energy gained between inelastic collisions is large enough (about 1.8 eV) to cause impact ionization. When the *e-h* pair creation rate per collision exceeds unity, there is again a sharp rise in the device current. Under controlled conditions, this phenomenon can be used to advantage, such as multiplication in the collector of a transistor or as a very efficient photon detector (Sze, 1981, Chap. 13). Many useful functions can be performed by designing *pn*-junction devices with a variety of doping levels and gradients, and operating in various voltage ranges (Sze, 1991; Streetman, 1995).

2.5 The *pn* Junction as a Generation/Recombination Device

It should be clear that in *forward bias*, electrons flow into the junction area from the *n*-Si region, but no electrons flow out of the *p*-Si region. Correspondingly, holes that flow in from the *p*-Si region do not flow out through the *n*-Si region. Since the charge carried by each carrier type is the same except for the sign, all electrons and holes flowing into the junction *recombine* in the diffusion regions on either side of the junction as well as in the junction depletion region, as shown schematically in Fig. 6. Each of the recombination processes is represented by a circled *R* in the figure. At the

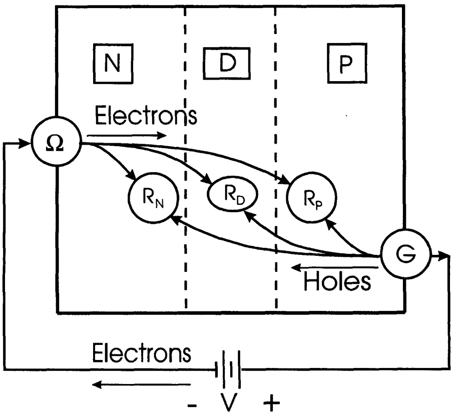

FIG. 6. *pn*-junction diode recombination (*R*) and generation (*G*) centers in forward bias.

boundary between the *p*-Si and the metal contact, a generation process, equal to the sum of all of the recombination process, is shown as a circled *G*. The junction of the *n*-Si with the metal contact is assumed to be Ohmic and is represented by a circled *Ω*. The recombination processes generate heat in most cases and generate photons in others, such as LEDs and lasers. The generation processes absorb heat, in some designs used for electronic cooling. Reversing the voltage polarity changes all the directions of flow and interchanges all the *R* and *G* centers. In Fig. 7 an n^+p "short diode," with the *n*-Si side very heavily doped, is shown. On the *p*-Si side, at a distance *W*, much shorter than L_n, from the depletion layer, the doping concentration N_A increases abruptly by, say, a hundredfold. The solution to the diffusion equation within the length *W* from the depletion edge is approximately a straight line. The electron flow at the boundary is therefore

$$F_n(0) = D_n n'(0)/W, \tag{29}$$

and the recombination rate within *W* is

$$R_{P1} = n'(0)W/2\tau_n. \tag{30}$$

Since $W \ll L_n$, the flow due to the gradient almost all flows through the layer *W* into the heavily doped region, where it is consumed by the recombination rate R_{P2}. Therefore the ratio of the two recombination rates is approximately

$$R_{P2}/R_{P1} = 2(L_n/W)^2. \tag{31}$$

Such "short diodes" store relatively little diffusion charge and therefore have a relatively short response time. Further, for a given forward bias, the current flow is increased by a factor of L_n/W over the long diode, in both directions.

In the BJT we separate these two current components and use the small one to control the other.

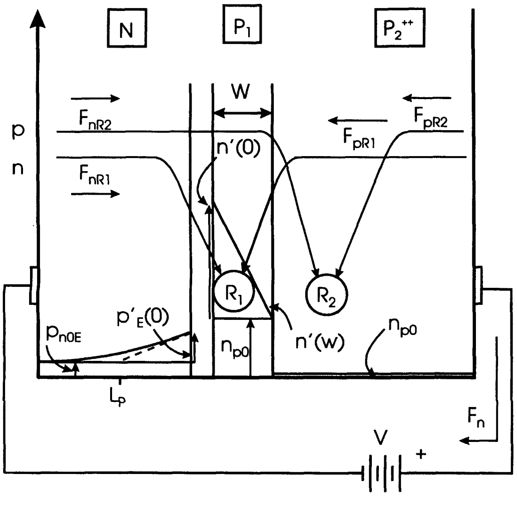

FIG. 7. Modification of *pn* junction of Fig. 7 with light and heavy doping on the *p*-Si side.

3. BIPOLAR TRANSISTOR PHYSICS

The original "semiconductor triode" consisted of a block of *n*-type germanium (the base), with two closely spaced wire "points" on the surface, as shown in Fig. 8. By pass-

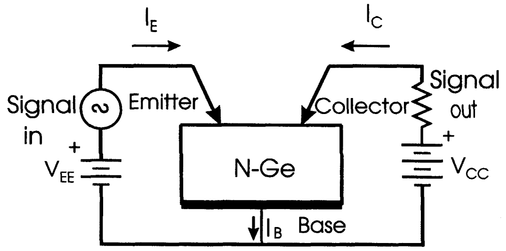

FIG. 8. The original Bardeen and Brattain (1948) germanium point-contact type-A transistor.

ing electrons at high density from the wire "points" into the base, atoms from the metal wire (tungsten or phosphor bronze) were diffused into the germanium base, forming a hemispherical *p*-Si shell under each contact. Figure 9(a) shows the popular schematic representation of the *pnp* and the *npn* transistors. Figure 9(b) shows the *pnp* and *npn* transistors arranged in the two-port circuit configurations corresponding to common-base and common-emitter connections. A readable history of the technology development during the early years of the transistor and its antecedent semiconductor devices can be found, along with copious references, in the valuable book by Shive (1959). Probably the first major compilation of transistor technology was published about this time by Western Electric (1958).

The fundamental physics of the planar BJT follows simply from the *pn*-junction physics discussed in Sec. 2, on the basis of uniform doping in the emitter, base, and collector. This is not a quantitatively adequate representation of the most advanced high-frequency structures in use today, but the concepts are fundamental to all transistors, and the mathematical formulation is more tractable than the computer simulations now in common use. The earliest comprehensive texts (Gärtner, 1960; Lindmayer and Wrigley, 1965) treat the essential physics in a more cumbersome way and have a heavy emphasis on circuit models. There are a great many books that have made it to the marketplace in recent times, some quite readable (e.g., Streetman, 1995). Other fairly recent texts deal with transistors and modern technology in more complex detail (Warner and Grung, 1983; Muller and Kamins, 1986; Wolf 1986, 1990, 1993).

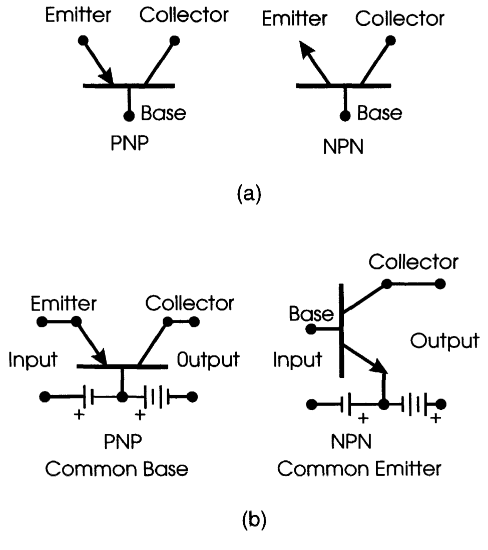

FIG. 9. (a) Standard symbols for *pnp* and *npn* transistors. (b) Two-port connections for common-base and common-emitter configuration.

3.1 Minority-Carrier Current Flow, and Current Gain

Figure 10 shows an illustrative minority-carrier profile of a planar *npn* transistor under three conditions. The thin *p*-Si region sandwiched between the two *n*-Si regions is the functional equivalent of Bardeen and Brattain's "base" as shown in Fig. 8. As such, it is similar to the npp^{++} structure of Fig. 7, except that the minority-carrier concentration at the end of the thin *p* layer is voltage controlled by a second junction rather than the transition to a heavily doped p^{++} layer.

The base is much thinner than the minority-carrier diffusion length in the material, L_n

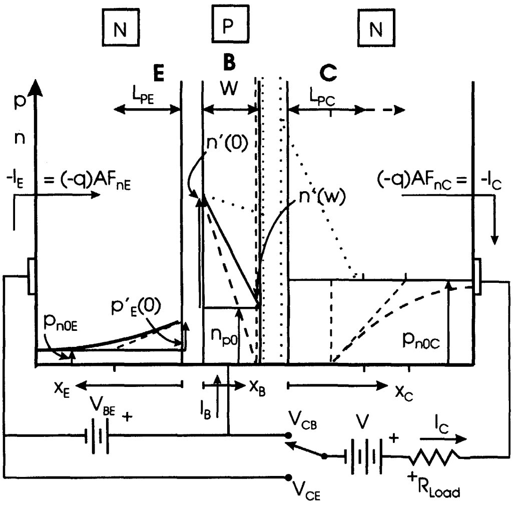

FIG. 10. Schematic diagram of equilibrium minority carrier connections and voltage dependent boundary conditions for the *npn* bipolar transistor for forward biased emitter-base junction, zero-biased, $V_{CB} = 0$, (solid); and both forward (dotted) and reverse (dashed) biased collector-base junction. Switch converts from common-base to common-emitter configuration. Transistor area is A.

= $\sqrt{d_n\tau_n}$. The two n-Si regions differ in that the emitter is typically doped much *greater* than the base, to keep the diffusion capacitance and recombination rate low on that side of the junction. The collector on the right is typically doped much *less* (i.e., much higher minority-carrier concentration) than the base so that when the reverse-bias voltage across the collector–base junction varies, most of the accompanying variation in the depletion-layer thickness takes place in the collector. This reduces the negative feedback resulting from normal signal variations in the load current. The same doping ratio puts most of the depletion layer between collector and base and also permits higher operating voltage before the depletion layer in the base is pushed all the way through to the emitter, a condition known as base "punchthrough."

Consistent with the above, a high doping concentration in the base compensates the geometrical resistance increase, due to the thin base layer, through which the base-emitter current flows, perpendicular to the currents in the plane of the cross section of Fig. 10. The low-resistivity subcollector, which returns the transistor current, is not shown.

The essential physics of gain in the *npn* transistor is illustrated by biasing the electrodes as shown in Fig. 10, with the switch in the common base (CB) position, and both R_{Load} and $V_{\mathrm{CB}} = 0$. The emitter–base (EB) junction is forward biased, V_{EB}, as shown in Fig. 4. The EB space charge region narrows slightly on both sides, but we eliminate this detail in this and related figures. The excess minority-carrier boundary conditions shown, $p'_E(0)$ and $n'(0)$, rise exponentially with V_{BE}. Thus, at only 0.1 V, these concentrations are over 50 times the equilibrium concentrations. On the scale of $n'(0)$ the equilibrium concentrations n_{p0} and p_{n0C} would be difficult to see, and on the scale of p_{n0}, n_{p0} would be difficult to see. To cover the full range, therefore, it is normal to represent concentrations on a logarithmic scale. Nevertheless, to describe minority-carrier diffusion, carrier concentrations are measured on linear scales, which accounts for schematic diagrams such as Fig. 10, which, even though they are quantitatively unrealistic, are convenient for discussing the physics. In particular, to illustrate the physics of current gain, it is convenient to assume that the excess carrier concentration on each side of the CB junction is zero, which is the condition $V_{\mathrm{CB}} = 0$ illustrated by solid lines in Fig. 10.

The excess-carrier concentrations on each side of the EB junction are established by the respective equilibrium minority-carrier concentrations and the voltage V_{EB}. On the emitter side of the junction, as demonstrated in connection with Fig. 4, and with

$$p_{n0E} = n_i^2/N_{PE},$$

we have

$$p'_E(0) = p_{n0E}\{\exp(qV_{\mathrm{EB}}/\kappa T) - 1\}, \tag{32}$$

and at the boundary on the other side of the junction in the p-Si base,

$$n'(0) = n_{p0}\{\exp(qV_{\mathrm{EB}}/\kappa T) - 1\}. \tag{33}$$

The excess minority-carrier concentration in the base, a decaying exponential solution of the diffusion equation, Eq. (23), is almost a straight line, because the diffusion length L_n is much greater than the width of the neutral base region, W. Actually, the solution sags slightly below the straight-line approximation shown, giving a small positive second derivative, which by the continuity equation tracks the local recombination rate, expressed by Eq. (21). The gradient of the straight line is used to calculate the diffusion flow of electrons from emitter to collector, and the integral of the line divided by τ_n gives the essential base recombination rate required to support this flow. Their ratio gives the highest possible current gain, the "ideal β" of the transistor. In summary, the following relations are written in terms of the conventional characteristic lengths and times, and also the corresponding materials parameters in order to emphasize their equivalence.

Base diffusion rate (cm^{-2} K^{-1}):

$$\begin{aligned} F_{nD(\mathrm{EC})} &= D_n n'(0)/W \\ &= D_n \frac{n_i^2}{N_A}\frac{1}{W}\left\{\exp\left(\frac{qV}{\kappa T}\right) - 1\right\}. \end{aligned} \tag{34}$$

Base recombination rate (cm^{-2} K^{-1}):

$$\begin{aligned} R_B &= n'(0)W/2\tau_n \\ &= \tfrac{1}{2} r_n n_i^2 W\{\exp(qV/\kappa T) - 1\}. \end{aligned} \tag{35}$$

Ratio = ideal β:

$$\beta_{\text{ideal}} = I_{\text{collector}}/I_{\text{base}} = 2(L_n/W)^2 = 2D_n/(r_B N_A)W^2. \tag{36}$$

This base-limited current gain is the ideal. Recombination in the base is the minimum price to pay for the diffusion flow through the base. In the early transistors with a thick base, it was the dominant price.

Another price to pay is the corresponding diffusion flow from the base into the emitter, established by the same V_{EB}. However, although V_{EB} (with N_{DE}) establishes the minority-carrier boundary value adjacent to the base, the carrier flow and ultimate recombination that takes place in the emitter depends on the emitter structural details, discussed in Sec. 5.2. In the simplest example of the long emitter, the gradient is determined by L_{pE}, i.e., by the electron diffusivity D_{pE}, and the minority-carrier (hole) lifetime τ_{pE}. The excess hole concentration at the emitter side of the junction is

$$p'(x_E) = p'(0)\exp(-x_E/L_{pE}). \tag{37}$$

The corresponding hole diffusion flux density ("hole injection") from base into emitter is

$$F_{pD(E)}(0) = -D_p \left|\frac{\partial p'(x_E)}{\partial x}\right|_{x_E=0} \tag{38}$$

regardless of where this flow is consumed by recombination. Continuity for the long, uniformly doped emitter requires that the diffusion rate at the boundary be equal to the recombination rate in the emitter:

$$F_{pD(E)}(0) = D_{pE}\frac{p_E'(0)}{L_{pE}} = \frac{p_E'(0)L_{pE}}{\tau_{pE}} = \left(\frac{D_p r}{N_{DE}}\right)^{1/2} n_i^2\left\{\exp\left(\frac{qV}{\kappa T}\right) - 1\right\}. \tag{39}$$

This flow rate, regardless of its description, is another component of the total majority-carrier flow rate into the base and adds another term to the denominator in the expression for β. The "actual" β becomes, allowing for different values of n_i^2 in the base and emitter,

$$\beta_{\text{actual}} = \frac{\dfrac{D_n}{W}}{\dfrac{W}{2\tau_n} + \left(\dfrac{n_{iE}}{n_{iB}}\right)^2 \dfrac{N_A}{N_{DE}}\dfrac{L_{pE}}{\tau_{pE}}} = \frac{\dfrac{D_n}{W}}{\dfrac{W}{2} r_B N_A + \left(\dfrac{n_{iE}}{n_{iB}}\right)^2 \dfrac{N_A}{N_{DE}}\sqrt{D_{pE} r_E N_{DE}^+}}. \tag{40}$$

An equivalent transit time may be determined using the above relations. The base diffusion flow rate is equated to the average minority-carrier concentration in the base times the effective velocity of the average carrier density, a numerically equivalent, but physically different, *drift* conductivity process. From this, one can calculate the *effective diffusion-transit velocity,* $\mathcal{V}_{\text{eff}}$:

$$D_p\frac{p'(0) - p'(W)}{W} = \frac{p'(0) + p'(W)}{2}\mathcal{V}_{\text{eff}},$$

from which, for $p'(W) = 0$, is just

$$\mathcal{V}_{\text{eff}} = (2/W)D_p. \tag{41}$$

But by definition, the effective diffusion transit velocity is related to the mean-carrier transit time τ_t by

$$\tau_t = W/\mathcal{V}_{\text{eff}}. \tag{42}$$

The number of carriers that make it through the base between recombination events is the current gain of the device:

$$\frac{\tau_p}{\tau_t} = 2\frac{D_p\tau_p}{W^2} = 2\left(\frac{L_p}{W}\right)^2, \tag{43}$$

which is in agreement with the ideal β, Eq. (36), not the actual β, because it depends upon the base transport process only. Since the transport mechanism of the useful current in the device is by diffusion of minority carriers through the base, many authors refer to this generic structure as the "diffusion transistor." In designs where substantial electric fields are built in, a "drift" component may be added in the "high-injection" range, which complicates the details of the analysis. Whatever the transport mechanism, it is the minority-carrier flow in the base that carries the useful device current *between regions in which they are majority carriers.*

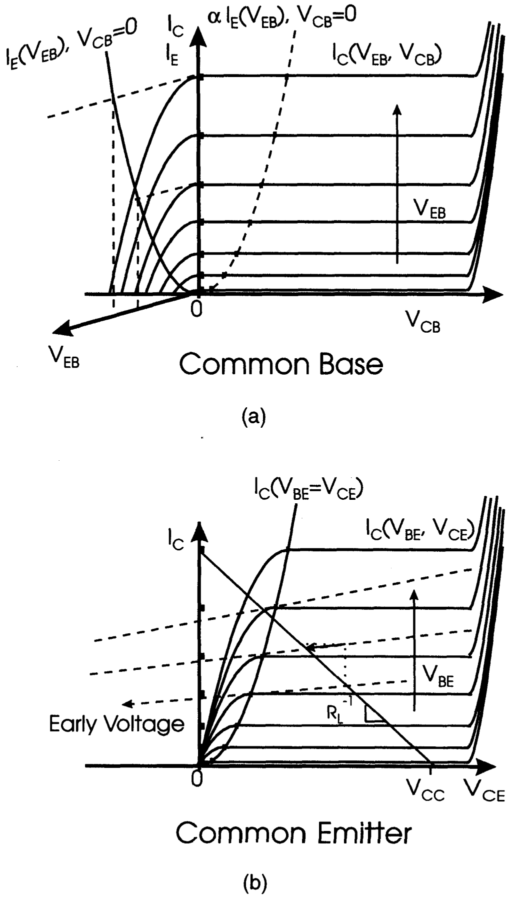
Modern technology has produced manufacturable BJTs with high current gains and very high cutoff frequencies. The implications are that the base is very thin—1,000 Å or less—with little recombination taking place there; that the minority-carrier concentration in the emitter is extraordinarily low; that the recombination rate constant r is abnormally high, and the corresponding n_i^2 is low; that most of the recombination is taking place in the emitter; and that the minority-carrier transport in the base is significantly assisted by the electric field. The details, which are difficult to confirm experimentally, are discussed further in Sec. 4.

3.2 Common-Base and Common-Emitter Characteristics

The above discussion is based on the *common-base* (CB) configuration, in which the two junction voltages that control the two minority-carrier boundary values in the base are specified independently for conceptual simplicity. Whatever the circuit configuration, the collector/emitter current ratio, α, is a little less than one. In that configuration, however, the low-voltage emitter-circuit *current* essentially replicates itself in the high-voltage collector circuit with a consequent power gain. However, the *common-emitter* (CE) configuration is the one most commonly used in communications, control, and computer circuits because the current gain is much higher, namely, the β derived above. In addition, the "output" current I_C is approximately linearly related to the "input" current I_B over a large part of the normal operating range.

The two (*npn*) circuit configurations, CB and CE, are shown in one diagram in Fig. 10, to emphasize their relationship. Minority-carrier concentrations in the base and collector for three cases are illustrated by solid lines for the case $V_{\mathrm{CB}} = 0$; dashed lines for the normal reverse-biased CB junction; and dotted lines for the forward-biased CB junction required to shut off the collector current. Given zero net recombination in the BC depletion layer, minority electrons and majority holes diffuse into the quasineutral collector where they recombine to give zero net collector current.

The three-terminal properties of the two circuit configurations are shown in Figs. 11(a) and 11(b). For the CB configuration, with the $V_{\mathrm{CB}} = 0$ switch setting in Fig. 10, increasing V_{BE} raises $n'(0)$ in the base exponentially as indicated above in Eq. (33), and the electron diffusion through the base increases proportionally, neglecting base width change. This is shown schematically in Fig. 11(a), where F_{nC} has been converted to iI_C, and F_{nE} has been converted to $-I_E$. The emitter current is shown on a perpendicular fold as a function of V_{EB}. It is then projected back on the common I_B-I_C axis, although $I_C = \alpha I_B$, with α typically close to 1.0. The two currents are shown equal along this axis for convenience. The I_B curve is multiplied by α



(a)

(b)

FIG. 11. Transistor current–voltage characteristics for (a) common-base and (b) common-emitter connections, with I_C vs $V_{\mathrm{CB}} = 0$ superimposed for both cases.

and swung around on the $I_C(V_{EB},V_{CB})$ coordinates.

With increasing V_{CB} above zero, the collector current shown as horizontal lines in Fig. 11(a) slopes upward as shown by the dotted lines in Fig. 11(b). This increase of current, known as the "Early effect," is due to a depression of $n'(W)$ at the collector boundary of the base and to a corresponding narrowing of the base, as shown in Fig. 12, both of which increase the gradient of the minority-carrier concentration in the base and add generation processes either side of the CB junction, which are illustrated in Sec. 3.3. The Early voltage for a given bias is the point where the corresponding dotted line intersects the negative V_{CE} axis.

Reversing the polarity of V_{CB} moves the characteristics into the northwest quadrant of Fig. 11(a). With given V_{BE} and $n'(0)$, $n'(W)$ is raised, reducing the minority-carrier gradient in the base eventually to zero, at which point the collector carrier flow is reduced to zero.

In the CE structure, V_{BE} is still an independent variable, but the voltage supply V_{CB} is reconnected from collector to emitter, and is labeled V_{CE}. In this case, to keep $V_{CB} = 0$ while raising V_{BE} requires maintaining V_{CE} equal to V_{BE}. In effect, the F_{nC} axis of Fig. 11(a) bends over and becomes congruent with the dotted exponential curve in that figure, and the shutoff curves to the left of that boundary all correspond to a forward-biased CB junction, as in Fig. 11. All turnoff curves go through zero together, because both junctions have the same forward bias when emitter and collector are tied together.

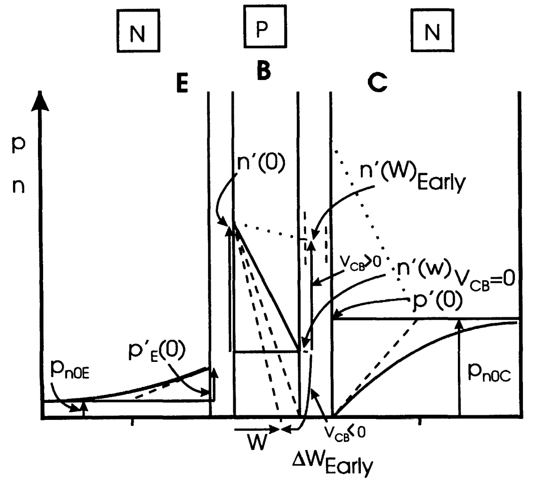


FIG. 12. Effect of collector reverse-bias voltage on base narrowing and ultimate punchthrough preceded by sharp current rise, and the forward "Early voltage" bias required to bring I_c to zero.

The *I–V* characteristics in this figure are voltage parametrized for convenience of discussing the device physics, and are thus exponentially spaced. Using input current as the parameter would result in linear spacing of the horizontal, "saturation" current lines. Since both I_B and I_C are exponential functions of V_{BE}, it is common practice to plot them on logarithmic plots of V_{BE}. The transistor properties approach the ideal if the two curves run parallel to each other, in which case the current gain is constant over the range. Such curves, which are shown as exponentials in Fig. 11, are known as Gummel plots, and are found in almost every report on transistor research.

Operating conditions in which the CB junction becomes forward biased shut off the diffusion escape of minority carriers in the base when trying to switch off the transistor with the BE junction. Discharging the stored charge in the base depends then on recombination of the excess minority carriers in the base, which depends on the minority-carrier lifetime in the base, τ_n. This limitation can sometimes be avoided by means of the "Schottky clamp," which for the *npn* structure is an extension of the aluminum metal connection to the base or a platinum deposit that overlaps the collector. The aluminum makes Ohmic contact to the *n*-Si base, but makes a Schottky-barrier diode with the *n*-Si collector. The resulting Schottky diode, the equivalent of an abrupt one-sided *pn* junction, is polarized the same as the base-collector junction it parallels. But the Schottky-barrier diode is much more conductive than the base-collector junction, which prevents any significant forward voltage from appearing across either. In the normal polarity, both junctions are reverse biased, and the Schottky-barrier diode can be considered to be an open circuit.

3.3 The BJT as a Generation/Recombination Device

A helpful exercise to elucidate the fundamentals of BJT operation is to carry out the generation- and recombination-rates accounting in detail for specific examples.

As indicated in Sec. 3, each of the generation (*G*) and recombination (*R*) processes essential or peripheral to BJT operation involves equal and opposite electron and hole flows into (*R*) or out of (*G*) these centers. Each such center is therefore associated with a continuous charge-flow loop.

Figure 13 shows all the closed flow loops for a *pnp* BJT under normal bias conditions, for a long emitter. Loops passing through the base are grouped all together for the common-emitter connection and in pairs for the common-base connection illustrated in Fig. 11. Alteration of device parameters to give "abnormal" bias conditions and/or a "short, inhomogeneous, composite" emitter does not alter this picture. Such changes affect only the values associated with each of the *R* or *G* processes. All electron-flow components into the collector are *R* processes that correspond to *G* processes elsewhere, as identified in the figure. *R* and *G* processes interchange when external voltages reverse. The base components are all electrons with continuity through Ohmic contacts. From the physical description of each of these processes, simple mathematical expressions for the characteristics of the BJT under all conditions can be written down.

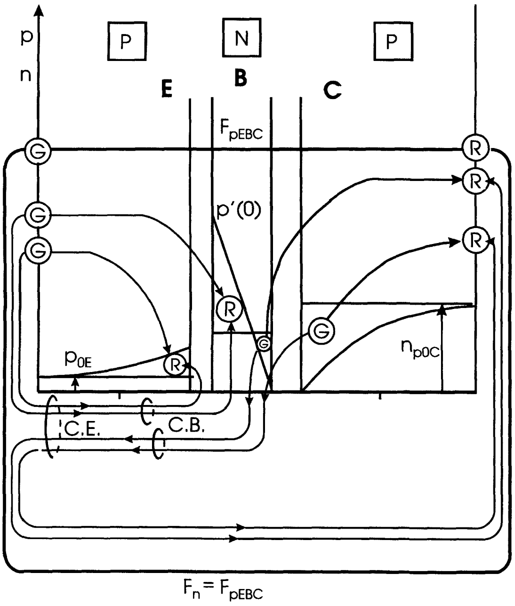

FIG. 13. Normal BJT bias conditions, showing continuity in terms of generation and recombination centers and all closed charge-flow loops.

The "useful current density" flow in this structure is the outer loop, $F_{pD(EC)}$, in which holes generated in the metal–emitter interface recombine again at the collector–metal interface unchanged in flow rate, which is controlled by diffusion transport through the base as minority carriers. All of the other closed flow components exist solely to support this hole-diffusion flow component. The reader should repeat Fig. 12 for the *npn* transistor to establish fully this vital concept.

3.4 Other Related Structures

There are many other application-inspired device structures that have been devised. Most of them are covered in Sze (1981), which in addition is an excellent index to the literature. All of them build on concepts developed in the preceding sections. Power semiconductor device design is in a class by itself, but there are three important structures that deserve mention here because they relate closely to the material developed in this article: the drift transistor, the *npnp* switch, and the photodiode and transistor. First we treat the photodiode and transistor.

The description of carrier transport in the base in Sec. 3 was limited to minority-carrier diffusion in the uniformly doped base. It is possible to achieve nearly uniform doping by the epitaxial growth technology referred to in Sec. 4, but traditional diffusion and implantation processes result in strongly graded, nearly Gaussian dopant profiles. The result is a strong rate of majority-carrier density *decrease* in the base between emitter and collector variation of majority-carrier concentration through the base, by as much as 100/1. The diffusion of majority carriers toward the collector in the overall charge-neutral base comes to an equilibrium value at every point, as it does in the depletion of the *pn* junction, when a large enough electric field, created by uncompensated charged dopant atoms, develops to balance it, Eq. (18) or Eq. (19). This same field drives *minority* carriers toward the collector, balancing, of course, the equilibrium minority-carrier *diffusion* in the "wrong" direction. When minority carriers are injected from the emitter, diffusion is incremented in the direction of the collector, as expected, but the large electric "drift" field (say, 20 meV over 100 nm = 2000 V/cm) contributes significantly to their velocity toward the collector, decreasing the net base transit time. The details of this "drift transistor" transport process are discussed in Kroemer (1985) and Sze (1981).

The BJT operates by means of a forward bias V_{EB} raising the minority-carrier concentration at one end of the base while holding the other end down with a reverse V_{CB}, and pouring minority carriers into the collector by diffusion. The same carrier gradient in the base can be achieved by removing the emitter and allowing the minority-carrier concentration to rise with photon absorption, the result of the $g_0\tau_n$ term in Eq. (24). That is essentially the photodiode, and the *pn*-junction solar cell in raw form (Sze, 1981, Chap. 4).

The phototransistor adds positive feedback to the photodiode above. The minority electrons generated in the lightly doped *p*-type base would normally flow to the collector, originating from the metal–semiconductor diode *R* contact. Instead, the *P* contact floats, and the photogenerated holes are drawn into the base of a subsidiary transistor at the edge of the structure. The emitter of that transistor is positively biased with respect to the collector, and so an electron diffusion from emitter to collector flows in response, and in parallel with the photogenerated electron flow from the photodiode.

A second device structure of special interest is the *npnp* switch. As noted in Sec. 3.3, the *G* center in the collector provides a minority-carrier diffusion flow into the transistor base, which reduces the base current required to support the base diffusion electron flow. Normally this quantity is essentially fixed because the junction is in reverse-bias saturation, as shown in Fig. 11. That component of diffusion current from collector back into the base could be increased, however, by *raising* the other end of the minority-carrier distribution in the collector.

The obvious way of doing this in the case of the photodiode was photogenerated minority carriers, the g_0 process. In the transistor, the means was to add a junction. In the present case, one simply adds a junction after the collector in Fig. 11. The last three layers, then, form a *pnp* transistor, the input of which is the original diffusion flow of electrons, which places a negative charge in the collector, and the output of which is the forward-bias flow of minority holes through the (original) collector into the (original) base, which constitutes positive feedback. This so-called "hook collector" (Lindmayer and Wrigley, 1965) was one of the earliest transistor innovations, along with the "drift transistor." If the gain is greater than one, this device will be unstable and be switchable from one state to the other. The result is the *npnp* switch, which led to the silicon-controlled rectifier and the thyristor, key components in power-control technology. These are discussed in TRANSISTORS, POWER.

4. MATERIALS SCIENCE, TECHNOLOGY AND APPLICATION

From the beginning, the transistor—the BJT, field-effect transistor (FET), or any of its derivatives—has been a multidisciplinary effort. All disciplines involved have contributed to the engineering of smaller, faster, lower-power, more reliable devices, driving and being driven by systems objectives. The participating disciplines themselves have been enriched, in some cases completely reconstituted, and in others created altogether.

Astonishing developments announced in the past few years rest on a succession of ideas and exploratory studies embedded in this evolutionary process, in analogy with the precursor studies that led to the first transistor, except that the driving forces have been much more sophisticated design objectives. In particular, the market pressures for "personal assistant" electronics, starting with the pocket calculator and moving up to the organizers, notebooks, the cellular telephone, pagers, and the global positioning system, implied that the final stage would be the integration of all these units by means of radio communications, from the very short to the very long range, directly or though cellular links that extend seamlessly the wired internet.

4.1 Design Objectives

To accomplish this, it would be necessary to include dynamic random-access memory (DRAM), microprocessor, analog, nonvolatile memory, and radio-frequency circuits all on the same chip, and all manufactured by compatible processes, materials, and temperature/time profiles. The result would be the low-voltage, low-power "mixed signal" technology that forms the centerpiece of the enormous range of applications that microelectronics is only beginning to fill.

One of the key challenges was electronics that could operate in the communications band that extends up to 80 GHz. The range above about 2 GHz has been the province of gallium arsenide technology, a difficult technology to manage, and incompatible with silicon technology. The challenge, then, was to displace the gallium arsenide technology with one that could perform equivalent functions within the realm of developing silicon technology. Developments already taking place in silicon technology to achieve higher-speed, lower-power, and higher-yield digital circuits and memory have now made this possible.

The key to success was the evolution of a new concept of semiconductor device manufacturing: building the transistor *on top of* rather than *down inside of* the silicon wafer. In the traditional methodology, the BJT was made by means of a sequence of doped-glass deposition and thermal, diffusive drive-in, or alternative dopant-ion implantation steps, followed by an anneal at temperatures high enough to activate the dopants. The deepest of these doped layers (taking an *npn* transistor for example) must be a low-resistance *n*-Si buried "subcollector" layer below the collector for carrying the collected current back to the surface. Second comes the *n*-Si collector, at a much lower doping level, then the *p*-Si base at a higher doping level, and the *n*-Si at a still higher level, to minimize base-emitter injection current. All of these processes involve pushing the dopants through the silicon and through each other, involving some uncontrollable crystal-induced channeling, anisotropic diffusion, and attendant damage. These result in nonuniformity of the semiconductor and transport parameters, and often reliability problems. Even in the best case, the complementary error function and Gaussian doping profiles determined by the physics of the deposition and implantation properties are not those that the designer would wish to choose (Harame *et al.*, 1995).

4.2 Epitaxial Silicon/Germanium BJT

The latest strategy, at least for high-speed microelectronics, is (for the *npn* transistor) to grow the *n*-Si collector epitaxially on a heavily doped *n*-Si "subcollector," and, further, to design and implement accurately a variety of heterostructures (Kroemer, 1957, 1982, 1985). The reactor is a UHV/CVD system using silane for the silicon, phosphene and diborane for *n*- and *p*-type doping, and germane for growing silicon-germanium layers, all in a diluting hydrogen carrier gas. The subcollector, used to carry the current back to the surface through a low-resistance path, is first grown epitaxially on a lightly doped *p*-Si epitaxial layer, which can be used for a complimentary MOS transistor. This layer is first grown on a heavily doped, conductive *p*-Si wafer substrate. Such a layered structure also sets the stage for complete device isolation by means of surrounding trenches.

At the designed collector thickness, the phosphene is replaced by a programmed concentration of diborane, which provides a silicon base of controlled dopant-concentration profile. Simultaneously, more or less, a controlled flow of germane is abruptly added to the stream, growing a SiGe alloy base, starting typically at about 10% Ge. At the end of the approximately 100 nm of epitaxial base growth, the germane flow, which has been decreasing linearly toward zero, and the diborane, which has been rising toward its peak concentration, are terminated, and a moderately doped *n*-Si emitter "cap" of about 10 nm thickness is grown. On top of this is deposited a highly doped arsenic polysilicon contact that is annealed by rapid thermal anneal (RTA) enough to activate the arsenic dopants, and just about penetrate the "cap" by diffusion (Li *et al.*, 1987; Harame *et al.*, 1995; Crabbé *et al.*, 1993). There are many details to be understood about the effects of the profiles and their overlaps at the junctions, and even the option of placing an undoped silicon layer in the middle of each layer. The discussions in the literature are not easy to follow. However, there is no question that SiGe-BICMOS technology for telecommunications above 50 GHz has been established (Kermarrec *et al.*, 1994). Device designs up to 75 GHz, and perhaps higher, have been reported (for reference, 10 GHz corresponds to the popular 3-cm radar frequency) (Patton *et al.*, 1990; Kermarrec *et al.*, 1994).

The use of UHV/CVD has made it possible to grow the structures described with atomic-layer precision and repeatability. In such structures, current gain and current density have been increased, the Early voltage, Fig. 12, has been increased, junction capacitances have been reduced, frequency response has been increased, and collector breakdown voltage has been maintained. A significant advantage has been gained by means of the graded Si/Ge epitaxial base. Although the details are beyond the scope of this article, and some may not yet be fully understood, it can be said that the two salient properties of the structure derived from the graded Si/Ge base—the effect of the high germanium content near the collector, and the doping profile in the very thin base—are these:

1. The sharp discontinuity in germanium content near the collector, from zero to about 10% at the CB junction, sets the strain in the thin Si/Ge base to the thick-film–determined value. Estimates of the consequent reduction in the band gap E_g are between 30 and 75 meV. As illustrated in Sec. 3.4, this would result in an increase of n_i^2 of between 3 and 20. The high doping concentration at the base also produces a band-gap lowering, and a consequent additional increase in n_i^2, offsetting at least partially the decrease normally associated with high doping concentrations (Klaassen *et al.,* 1992).
2. Since the base layer is very thin, the recombination of base current in the base itself should be very small, leaving the emitter recombination rate to control the gain of the transistor, as indicated in the denominator of Eq. (41). The thin base, however, requires compensatingly high doping to maintain a reasonably high value of the punch-through collector voltage. The high doping level at the emitter interface presents a low resistance for the supply of base–emitter injection current, and with the low diffusion capacitance of the emitter, a low *RC* time constant.

4.3 Polysilicon Emitter

Perhaps the most interesting result of this new technology is the unique interface properties and dramatic current gain increase associated with the "Ohmic" polycrystalline silicon contact to emitter, which becomes a part of the emitter itself. In spite of many publications, there remains some doubt about the role played by the polysilicon, but no doubt about the factor of 7 or larger gain that results. It has been demonstrated that the high arsenic doping of the polysilicon diffuses out into the epitaxial, approximately 10-nm "cap" during the RTA process that activates the arsenic. Heavy doping of the emitter and consequent low n_i^2 guarantee low emitter charge storage and diffusion capacitance, but do not alone guarantee the observed low diffusion injection into the emitter, Eq. (38), which has been supposed to account for increased current gain (Patton *et al.,* 1988; Eltoukhy and Roulston, 1982; Ashburn and Soerowirdjo, 1981; Graul *et al.,* 1976).

In the manufacturing environment, the epitaxial growth step takes place at relatively low temperatures, which is less than optimum for defect-free epitaxy. Therefore, this technology, which is also much more costly and has fewer transistors per functional unit than microprocessors or memory, seems to be best suited for just the technology best suited for it.

INTRODUCTION

The field-effect transistor (FET) is an electronic device for modifying the flow of current in a material across two terminals, under the control of an electric field induced by a voltage applied at a third terminal. The use of the field effect in an electronic device was first described in the 1930s (Lilienfeld, 1930; Heil, 1935). Shockley (1952) published the first analysis of a practical electronic device based on the field effect. Figure 1 shows a diagram of the basic concept behind the field-effect transistor. Two terminals are attached to a block of conducting material (which in all further discussion we will assume to be semiconducting). Current flow is induced in the material by applying a voltage across the terminals, which are identified as the source and drain. Current flow from source to drain is altered by an applied transverse electric field from a third terminal, called the gate. The gate, or field plate, is separated from the material in which the current flows by a poorly conducting or nonconductive region. Thus, the input resistance of the device is high, and the device is considered to be voltage controlled, as opposed to current controlled as in a bipolar transistor. As the voltage on the gate is increased, the transverse field increases, and the current flow is modified. Depending on the polarity of the applied field, the current flow may be enhanced or reduced. Practical application of the field-effect transistor had to wait until the growth and processing of semiconductors was sufficiently reliable and clean so that the applied electric field was not overcome by other effects, such as uncontrolled charges along the surface of the semiconductor region. Engineering control of semiconductor devices has grown tremendously since the original concept of the field-effect transistor, such that as of the writing of this article (mid 1990s), it is commonplace to fabricate integrated circuits containing several million FETs on a single integrated circuit, with minimum feature sizes in the range of 0.50–0.35 μm.

1. JUNCTION FIELD-EFFECT TRANSISTOR (JFET)

The junction field-effect transistor (JFET) was realized early on (Dacey and Ross, 1953), since it was relatively easy to fabricate, but is now only used in specialized applications. Figure 2 shows the IEEE standard circuit schematic symbols for a JFET (IEEE, 1975). Figure 3 shows a schematic cross section of a JFET. The body consists of lightly doped *n*-type or *p*-type semiconductor, typically with a dopant concentration on the order of 10^{17} atoms/cm^3. A JFET with an *n*-type body is denoted an *n*-channel device, while a JFET with a *p*-type body is denoted a *p*-channel device. Highly doped regions of the same doping type as the body are then created, typically by solid-state diffusion of dopants at high temperatures, to form the source and drain contacts. Highly doped regions are required at the contacts to ensure that an Ohmic (nonrectifying) contact is formed between the semiconductor and any subsequent metal used for supplying voltage to the device. A *p-n* junction is formed at the surface of the semiconductor, between the source and drain. In consequence of a balance of diffusion of free carriers and electrostatic attraction between the carriers and their ion cores, a region relatively free of carriers (the so-called "depletion region") is formed under the *p-n* junction. The extent of the depletion region can be modified by applying a bias voltage to the *p-n* junction. For an *n*-channel device, with a *p*-type gate region, negative (reverse) bias is applied to increase the depletion region under the junction. For *p*-channel devices, the opposite sign bias is applied.

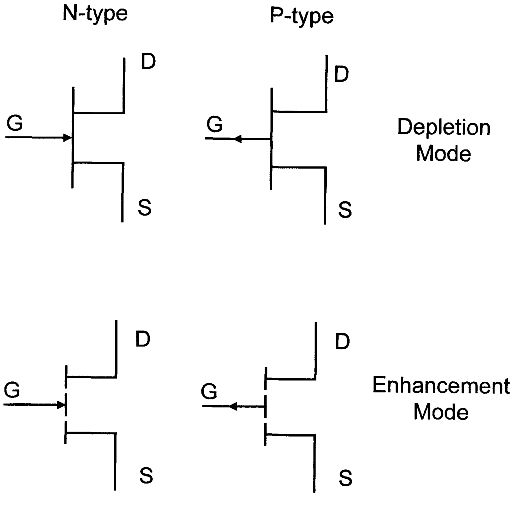

FIG. 2. IEEE standard schematic symbols for JFETs.

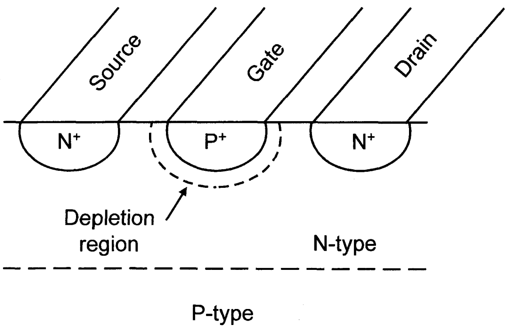

FIG. 3. Cross section of a junction field-effect transistor.

Consider the case where a very small voltage is applied to the drain, so that the potential from source to drain is essentially uniform [Fig. 4(a)]. For pedagogical reasons, we consider the device to be constructed so that there is a symmetry plane parallel to the channel. The device is assumed to be uniform in the third (width) dimension. We assume that the potential reference is at the source contact; thus all voltages are referred to the source, e.g., the gate-to-source voltage V_{gs}. As the reverse bias is increased on the gate, the current flow between the source and drain is constricted, and the resistance of the device increases. At some point, enough bias is applied so that the channel is completely constricted, and very little current flows between the source and drain. Un-

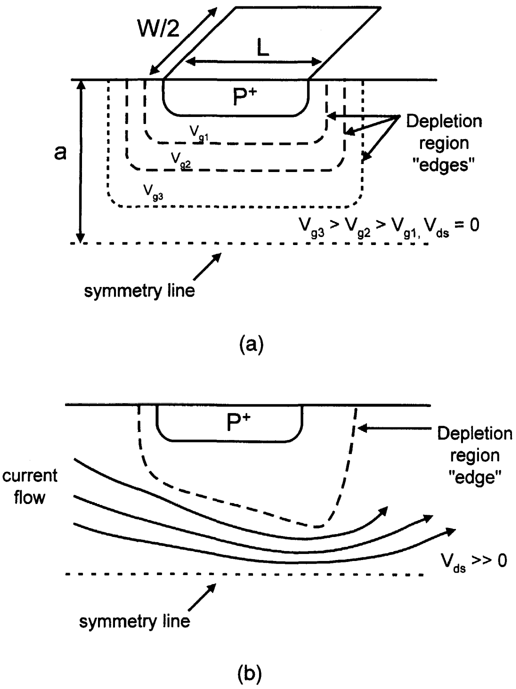

FIG. 4. Cross section of a JFET showing the depletion region under small drain bias (linear region) and under high drain bias (saturation region).

der these conditions, the device acts like a voltage-controlled variable resistance. This is the *linear* region of device operation, so named because the device acts like a linear resistance under these bias conditions. The voltage at which the device passes little current is called the *pinch-off voltage,* V_p. Furthermore, since this device operates by *depleting* the channel of carriers, it is called a depletion-mode FET. The equation for the drain current in the linear region of an n-channel depletion mode JFET is given by (Sze, 1981)

$$I_{ds} = I_p[3V_{ds}/V_p - 22[(V_{ds} + V_{gs} + V_{bi})^{3/2} - (V_{gs} + V_{bi})^{3/2}]/V_p^{3/2}] \quad (1)$$

The built-in potential of the junction V_{bi} is given by

$$V_{bi} = (kT/q)\ln(N_d/n_i), \quad (2)$$

where k is Boltzmann's constant, T is the absolute temperature, q is the electronic charge, N_d is the doping concentration in the channel, and n_i is the concentration of carriers in undoped semiconductor (intrinsic concentration). The pinch-off voltage V_p is given by

$$V_p = qN_d a^2/2\epsilon_s, \quad (3)$$

where a is the thickness of the JFET channel and ϵ_s is the permittivity of the semiconductor. The pinch-off current I_p is given by

$$I_p = W\mu q^2 N_d^2 a^3/6\epsilon_s L, \quad (4)$$

where W is the width of the device, μ is the carrier mobility, and L is the channel length.

Now consider the case where bias is applied to the drain terminal, with the gate at a zero bias condition [Fig. 4(b)]. As the drain bias increases, the current flow through the device increases, since the device is in the linear operating region. The drain voltage is dropped across the channel region. As the drain voltage increases, the gate-to-channel potential near the drain side of the p-n junction becomes increasingly reverse biased. This, in turn, causes the depletion region under the p-n junction to become larger near the drain end of the device. The effective channel resistance now increases, because the amount of nondepleted semiconductor in the channel is less. Eventually, the drain bias becomes so large that the depletion region from the p-n junction "touches" the depletion region from its mirror image. At this point, the incremental resistance of the channel to further increases in drain voltage is very high, and the so-called "pinch-off" voltage is reached. In reality, the channel never can pinch off entirely, as then no current would be able to flow in the device, and there would be no current to induce the voltage drop along the channel of the FET. Instead, the carrier density drops to a low value, and the drain current tends to remain constant as further drain bias is applied. This region of operation is thus called the *saturation region.* The equation for the drain current in the saturation region is given by (Sze, 1981)

$$I_{ds,sat} = I_p\left[1 - 3\left(\frac{V_{gs} + V_{bi}}{V_p}\right) + 2\left(\frac{V_{gs} + V_{bi}}{V_p}\right)^{3/2}\right]. \quad (5)$$

In the derivation of this equation, it was assumed that the carrier mobility is a constant independent of dopant atom density or electric field and that the potential drops gradually along the channel so that the Poisson's equation,

$$\frac{dE_x}{dx} + \frac{dE_y}{dy} = \frac{\rho}{\epsilon_s} \qquad (6)$$

(where E is the electric field and ρ is the space charge), can be simplified by dropping the term due to dE_x/dx. These assumptions will be revisited later.

JFETs were among the first FETs to be manufactured because they could be built using semiconductor processing steps that were originally developed for bipolar transistors. The modern use of JFETs is limited, since other types of FETs, notably the MOSFET, are superior in most respects.

2. METAL-SEMICONDUCTOR FIELD-EFFECT TRANSISTOR (MESFET)

The metal-semiconductor field-effect transistor (MESFET) is similar to the JFET, with the exception that the *p-n* control junction is replaced by a rectifying metal-semiconductor (Schottky) contact. It was first proposed by Mead (1966). It is typically used for fabricating FETs in semiconductors other than silicon, such as GaAs or InP. JFETs are not easily fabricated in compound semiconductors, because *p-n* junctions are difficult to form because of lack of suitable *p*-type dopant atom species, while metal-oxide-semiconductor FETs (MOSFETs) are difficult to build because of the lack of a suitable native oxide to insulate the gate from the semiconductor. Silicon MESFETs can also be manufactured, although they are seldom used commercially. Since the Schottky-barrier junction can only be operated in reverse bias without causing current to flow into the gate, MESFETs are typically operated as depletion-mode devices.

A cross section of a MESFET is shown in Fig. 5. Most MESFETs built in compound semiconductors start with a semi-insulating substrate. A thin layer of *n*-type semiconductor is grown, using epitaxy techniques (such as liquid-phase epitaxy or molecular-beam epitaxy). The gate metal is deposited and then etched to pattern the gate region. Source and drain junctions are formed by bombarding the semiconductor with accelerated *n*-type dopant ions (ion implantation). The channel region must be prevented from having source and drain dopants introduced; in addition, some space must be maintained between the gate and the source and drain regions. This can be done, for example, with a masking material over the gate. A short, high-temperature annealing (e.g., 700–800 °C) is used to diffuse the dopant atoms onto substitutional sites in the semiconductor lattice, thus allowing them to become electrically active. Since the gate dimensions of MESFETs are commonly well below 1 μm, lithographic techniques that are highly controllable, such as electron-beam lithography, are often used. Finally, Ohmic contacts to the source and drain regions are formed, usually by depositing a series of thin metal layers.

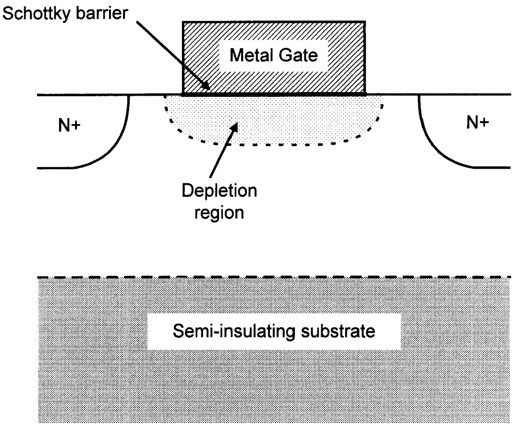

FIG. 5. Cross section of a metal-semiconductor FET (MESFET).

The physical operation of MESFETs is essentially similar to the JFET, with the built-in voltage V_{bi} of the JFET *p-n* junction replaced by the Schottky-barrier potential. Two important physical considerations must be added to the simple model presented in the earlier section: velocity saturation and nonequilibrium transport effects. In the previous formulas for the drain current, the carrier mobility was assumed to be constant. In reality, the mobility of electrons and holes in semiconductors is dependent on both the density of dopant atoms and the electric field. In the channel, the dopant density is relatively uniform. Although extra dopants may be incorporated to modify the pinch-off voltage, the channel dopant density is approximately uniform to an order of magnitude. Thus, the mobility can be adjusted by using various formulas fitted to experimental measurements, such as Arora *et al.* (1982). The effect of electric field along the direction of the current flow, however, cannot be ignored. At gate lengths typical of practice (below 1 μm), the electric field along the channel direction induced by the drain voltage becomes sufficiently high that the carriers can achieve high enough energy to emit optical phonons, which effectively drain off excess energy to the underlying lattice (Jacoboni *et al.,* 1977). This causes the carrier velocity to saturate at approximately 10^7 cm/s. For GaAs, velocity saturation can occur at fields as low as 15–20 kV/cm. Figure 6 plots the carrier velocity vs lateral electric field for electrons and holes in silicon, and for electrons in GaAs. The derivative of these curves is the mobility. The nonmonotonic behavior of the electron velocity in GaAs is due to the complicated nature of the electronic-band structure of this compound semiconductor, where electrons can occupy states with different effective masses, depending on their energy. Velocity saturation reduces the amount of drain current, compared to what is predicted by Eq. (5). The drain current is now increased linearly with gate voltage, as opposed to the square-law dependence of Eq. (5).

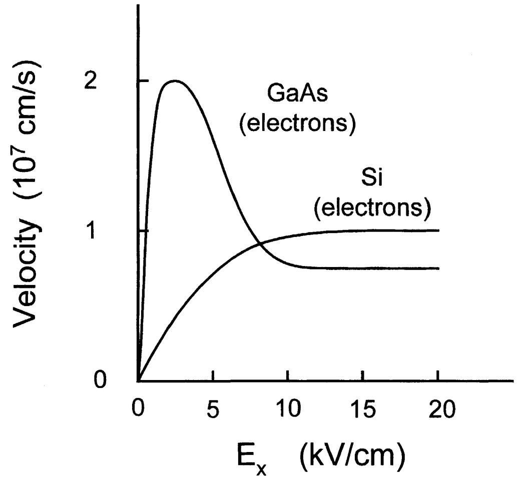

FIG. 6. Carrier velocity vs lateral electric field for electrons and holes in silicon, and electrons in GaAs (after *Physics of Semiconductor Devices,* 2nd ed., S. M. Sze, Copyright © 1981, John Wiley & Sons, Inc. Reprinted with permission of John Wiley & Sons, Inc.).

At very short channel lengths, the electric field at the drain end of the channel becomes sharply peaked, and the electrons may not have time (or distance) to achieve equilibrium between the energy gain from the electric field and energy-loss mechanisms, such as optical-phonon emission. This nonequilibrium state can allow the carrier velocity to exceed temporarily the equilibrium saturation velocity ("velocity overshoot"). Such effects are difficult to quantify in analytical expressions, and sophisticated numerical analysis programs are needed to predict device behavior under such conditions.

Common applications for MESFETs are in high-frequency (microwave) communication electronics and in high-speed digital computation elements. MESFETs are highly competitive for communication applications, because the higher mobility of compound semiconductors compared to silicon allows them to pass more current for a given gate length. Higher mobility also reduces the resistance of the source and drain areas, thus reducing thermal noise, an important factor for low-noise amplifiers. The semi-insulating substrate also provides less parasitic capacitance, further improving performance. Compound semiconductors are also compatible with optoelectronic devices. Multiple MESFETs can be joined in parallel to form power microwave devices. In digital-circuit applications, MESFETs are used in very high-speed computational circuits, although their density and cost are not yet competitive with silicon MOSFETs. Drawbacks to using compound semiconductors include lower thermal conductivity (poorer dissipation of heat), lack of a complementary device (only *n*-channel devices), higher costs for starting materials, less mature manufacturing, and lower levels of integration.

A variant of the MESFET suitable for fast switching or communication applications is the high–electron-mobility transistor (HEMT), in which a superlattice structure is formed by layers of different compound semiconductors. The channel of the device is formed of a lightly doped region, sandwiched between regions of different materials that are highly doped. The material properties of the sandwich are such that electrons in the highly doped regions "fall" into the lightly doped channel. This *real-space transfer* of carriers results in a channel that is conductive, yet with few ion cores to induce scattering from ionized impurities. This results in a device with high carrier mobility, at least at low transverse fields.

3. METAL-OXIDE-SEMICONDUCTOR FIELD-EFFECT TRANSISTOR (MOSFET)

3.1 Introduction

The metal-oxide-semiconductor field-effect transistor (MOSFET) is the workhorse device of modern microelectronics. Microprocessors using 5–10 million MOSFETs, operating at frequencies of several hundred megahertz, and with costs in the range of a few hundred to a few thousand U.S. dollars, are typical for the mid-1990s. The enormous growth in personal computing, telecommunications, consumer electronics, and other areas, most using integrated circuits containing MOSFETs as their main active element, has led the global semiconductor industry to invest billions of dollars in semiconductor fabrication facilities around the world.

3.2 Basic MOSFET Operation

MOSFETs come in two varieties, depending on whether electrons or holes are used to conduct the current between the source and drain. When electrons are used, the MOSFET is called an n-channel device; when holes are used, it is called a p-channel device. n-channel devices are divided into two types: enhancement mode, or normally off [Fig. 7(a)], and depletion mode, or normally on [Fig. 7(b)]. The source and drain of an n-channel MOSFET consist of heavily doped (n^+) areas, separated by the channel region. The gate, which is typically made of polysilicon, is insulated from the channel by a thin layer of silicon dioxide. The gate material is very highly doped, so that it acts essentially like a metal.

In an enhancement-mode device in which no voltage is applied to the gate electrode, there is no path for electrons to flow from the source to the drain; hence the device is in the "off" state. When a positive voltage is applied to the gate, electrons are attracted to the channel region from the pool of electrons in the source and drain regions. When a sufficiently positive voltage is applied, electrons form a path for current to flow from source to drain. This "enhanced" conductivity region (hence "enhancement" mode) is called the *inversion layer,* since the field effect has caused the conductivity of the channel region to change from p-type to n-type. The inversion layer is exceedingly thin, on the order of 1–10 nm.

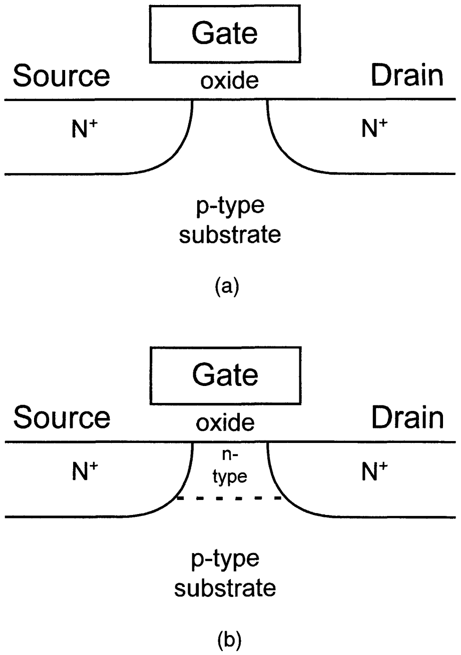

FIG. 7. Cross-section of n-channel MOSFETs. (a) enhancement mode, (b) depletion mode.

In a depletion-mode device, the channel region consists of lightly doped n-type material, on the order of 10^{17} dopant atoms/cm^3. Since there is a conductive path between the source and drain, this device is normally on, even when no voltage is applied to the gate. When negative voltage is applied to the gate, electrons are repelled from the channel, and a region depleted of electrons forms under the gate (hence "depletion mode"). With sufficiently large negative bias on the gate, all the electrons will be depleted from the channel, and the conductive path between the source and drain is disrupted. The device is now turned "off."

Figure 8 shows a cross section of both enhancement- and depletion-mode *p*-channel devices. The operation of *p*-channel devices is exactly the same as an *n*-channel device, except that the opposite sign voltages must be applied to the gate to attract or repel holes. In addition, the voltage applied to the drain is also negative, in order to get holes to flow from source to drain.

Figure 9 shows the IEEE standard circuit-schematic symbols for all four types of MOSFETs. Note that the MOSFET is a four-terminal device. Besides the source, drain, and gate, there is a terminal that allows direct electrical contact to the channel region. This is denoted the bulk or substrate contact. In analyzing MOSFET operation, the source contact is usually considered to be the potential reference; hence the applied voltages are gate to source (V_{gs}), drain to source (V_{ds}), and bulk to source (V_{bs}).

facturing process with both n- and p-channel devices on the same chip can consist of hundreds of discrete steps. Integrated-circuit manufacturers typically purchase silicon wafers from a vendor who refines the silicon from raw materials into large-diameter (e.g., 200 mm or larger) single-crystal boules [10(a)]. The boules are then sliced into thin wafers and are typically p type. The wafers may be grown lightly doped, or they may be grown highly doped, with a thin layer of lightly doped silicon grown on top, via epitaxial growth [10(b)]. The wafers are then processed to define regions where the MOSFETs will be formed. In between these regions, the MOSFETs must be electrically isolated from one another. This is typically done by creating regions of silicon dioxide between MOSFETs, either by treating selected regions of the silicon to an oxidizing atmosphere in a furnace (LOCal Oxidation of Silicon, or LOCOS) [10(c)] or by etching a trench in the silicon substrate and depositing oxide in the trench [10(d)]. If both n- and p-channel devices are to be formed on the same wafer, a region of n-type doping ("well" or "tub") is formed to hold the p-channel devices [10(e)]. In some processes, both n- and p-type wells are formed. Dopant atoms are introduced into the silicon wafer by the ion-implantation process, in which an electrostatic field is used to accelerate ionized dopant atoms, which are then embedded into the silicon wafer. By integrating the charge collected by the wafer, the number of dopant atoms per unit area (dose) can be monitored to high precision. The doping in the channel regions is adjusted to create enhancement- or depletion-mode transistors [10(f)]. The polysilicon gate material is then deposited and etched [10(g)]. The source and drain are then formed, again by ion implantation [10(h)]. The polysilicon gate acts as a masking layer, preventing the channel from being doped during source and drain formation. This *self-aligned* process is key to scaling MOSFET devices to submicron dimensions, since the source and drain are automatically aligned to the gate edges. In many processes, a refractory metal, such as Ti or Co, is deposited over the source, drain, and gate areas, and a metal-silicon compound is formed (silicide). This is done to reduce the resistance of these regions. Finally, a series of metal and silicon dioxide layers are deposited to allow connections to the MOSFET and to connect MOSFETs together [10(i)].

3.4 Physical Model of a MOSFET

3.4.1 MOS Capacitor Much of the basic physics in the MOSFET is contained in a simpler device, the MOS capacitor. Consider a region of lightly doped p-type silicon, covered by a thin layer of silicon dioxide, and capped with a layer of metal. The silicon region is connected to ground potential. For pedagogical purposes, consider the difference in work function between the metal and the semiconductor to be zero (the work function is the voltage necessary to raise an electron from the material's Fermi level to the vacuum level). Since the metal is electrically isolated from the silicon, a capacitor is formed. Any applied voltage on the metal induces a surface charge on the metal, which must be matched by an opposite charge on the silicon side. Figure 11 shows the energy-band diagram of the metal-oxide-silicon sandwich under various applied biases to the metal. With zero applied bias, there is no distortion of the energy bands, and the MOS capacitor is in the so-called *flat-band* condition. When a negative voltage is applied to the metal, the metal's energy bands are raised upward (energy $= -qV$). Part of the applied voltage drops across the oxide region, and the rest drops across the silicon region [Fig. 11(a)]. Holes, supplied from the large pool in the silicon bulk, are attracted to the negative potential and accumulate at the silicon/silicon dioxide interface. Thus, the MOS diode is said to be in *accumulation* bias. When positive voltage is applied to the metal, the energy bands are bent down [Fig. 11(b)]. The positive voltage repels holes from the silicon/silicon dioxide interface, and the holes are absorbed at the ground contact. The MOS capacitor is said to be in *depletion* bias, since the silicon region near the interface is depleted of holes. At higher positive voltage [Fig. 11(c)], electrons generated by random thermal excitation in the silicon bulk are attracted to the interface. At this point, the MOS capacitor is in *inversion* bias.

An analogous situation occurs in n-type MOS capacitors, with positive bias inducing accumulation of electrons and negative bias

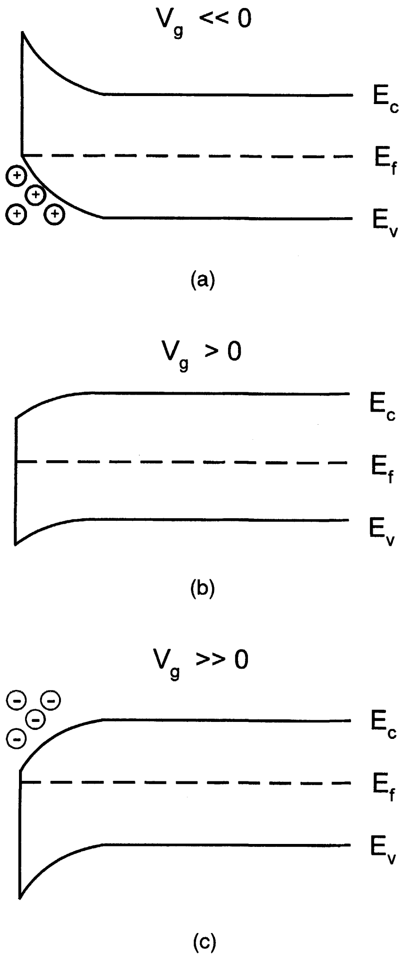

FIG. 11. Energy-band diagrams for a MOS capacitor under (a) accumulation, (b) depletion, (c) inversion bias.

inducing depletion of electrons and finally hole inversion.

3.4.2 Threshold Voltage One can express the change in electron and hole density with applied bias quantitatively by introducing the formulas for the electron and hole concentration as a function of the electrostatic potential ψ (defined as the potential at the midgap of the semiconductor and rigidly shifting with the edges of the semiconductor bands) (Sze, 1981):

$$n = n_0 \exp(q\psi/kT), \tag{7}$$

$$p = p_0 \exp(-q\psi/kT), \tag{8}$$

where n_0 and p_0 are the equilibrium electron and hole concentrations, q is the electronic charge, k is Boltzmann's constant, and T is absolute temperate. Again, consider a p-type MOS diode. As the metal, or gate, is positively biased, the hole concentration in the silicon decreases. This leaves behind the ionized dopant atoms, which serve to terminate field lines emanating from the gate. Since the p-type region is relatively lightly doped (e.g., 10^{16}–10^{17} cm^{-3}), a relatively large region of silicon must be depleted of charge to balance the surface charge induced on the gate metal. As the gate bias becomes more positive, the electron concentration becomes appreciable. At some point, the electron concentration becomes high enough to balance any additional charge induced on the metal gate. In fact, since the electron concentration increases exponentially, the potential at the silicon surface becomes *pinned* and need vary only slightly to provide all the charge needed to balance the induced charge on the metal gate. At this point, the MOS diode is said to cross its *threshold voltage,* in which the inversion channel is strongly formed. Unfortunately, there is no definitive definition for the threshold voltage. One common definition of threshold voltage is when the surface potential reaches twice the Fermi potential $\phi_b = q/kT \log(N_a/n_i)$, where N_a is the doping concentration in the silicon and n_i is the intrinsic carrier concentration. This leads to the following expression for the threshold voltage (Sze, 1981):

$$V_{th} = \sqrt{2q\epsilon_{Si}N_a(2\phi_b)}/C_i + 2\phi_b, \tag{9}$$

where V_{th} is the threshold voltage, ϵ_{Si} is the silicon permittivity, and C_i is the capacitance of the oxide layer. The first term represents the voltage dropped in the silicon bulk during the depletion phase, and the second term, the voltage dropped in establishing strong inversion. In practical MOSFETs, a third term is added due to differences in the work function between the gate material and the silicon bulk, and any fixed charges at the Si/SiO$_2$ interface.

When a MOS capacitor is transformed into a MOS transistor by the addition of a source and drain, the threshold voltage denotes the voltage at which the conducting channel forms. By varying the gate material and/or the doping concentration or type (p

or n), one can create MOSFETs with both positive and negative threshold voltages. This allows the formation of enhancement- or depletion-mode transistors.

3.4.3 Linear Bias Region We now consider the situation where source and drain contacts have been added to the MOS capacitor, so that a proper MOSFET has been formed. By convention, the source contact is considered the reference contact for all voltages and currents. In the following discussion, all equations are given for n-channel devices. The equations for p-channel devices are essentially the same as for n-channel, with the signs of the voltages changed. Figure 12(a) shows a cross section of an n-channel MOSFET under small drain bias. Using the gradual channel approximation discussed in Sec. 2 on MESFETs, an expression for the drain current, I_{ds}, in an n-channel MOSFET in the linear region ($V_{ds} \ll V_{gs} - V_{th}$) is given by (Sze, 1981)

$$I_{ds} = (W/L)\mu_n C_i(V_{gs} - V_{th})V_{ds}, \qquad (10)$$

where W is the gate width, L is the gate length, μ_n is the electron mobility, V_{gs} is the gate-to-source voltage, and V_{ds} is the drain-to-source voltage. The threshold voltage V_{th} is given by an expression similar to that given previously for the MOS capacitor, with the addition of a term that accounts for any bias applied to the substrate, V_{bs} (Sze, 1981):

$$V_{th} = 2\phi_b + \sqrt{2q\epsilon_{Si}N_a(2\phi_b + V_{bs})}/C_i. \qquad (11)$$

This bias region is called the "linear" region because the drain current I_{ds} is linearly proportional to the drain voltage V_{ds}. In this bias regime, the MOSFET acts like a voltage-controlled resistance. Figure 13 shows a plot of I_{ds} vs V_{ds}, with V_{gs} as a parameter. Note that for low V_{ds}, the drain current is linearly proportional to V_{ds}.

It should be noted that the mobility used in the expression for I_{ds} is not the bulk mobility of electrons (or holes) in silicon, but a mobility that accounts for additional scattering due to the proximity of the Si/SiO$_2$ interface and two-dimensional gas effects due to the quantum well formed by the sharp band bending near the interface. This inversion-layer mobility is a function of the applied

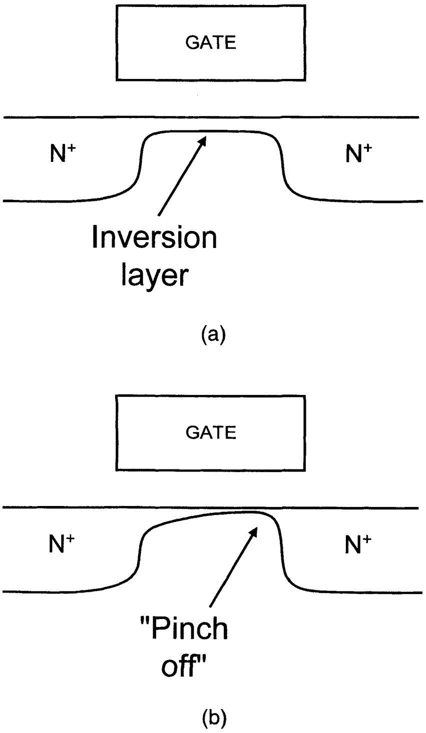

FIG. 12. Cross section of an n-channel enhancement-mode MOSFET under small drain bias (linear region) and high drain bias (saturation region).

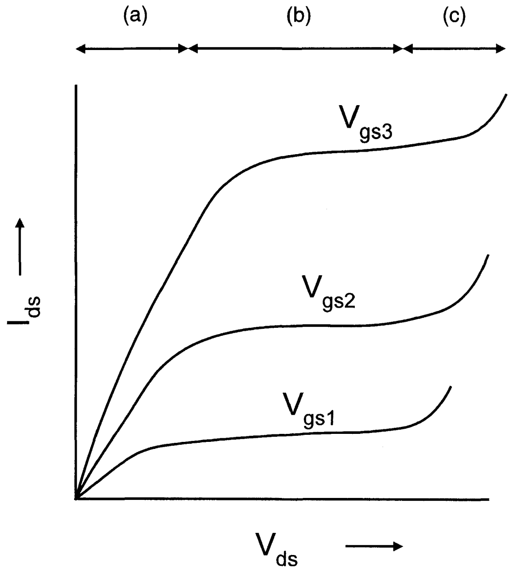

FIG. 13. Drain-current vs drain-voltage characteristics for an n-channel enhancement-mode MOSFET, with gate voltage as a parameter. (a) Linear region, (b) saturation region, (c) breakdown.

transverse field in the silicon; hence the mobility is a function of the gate voltage. If the measured mobility is plotted against the effective transverse field (defined as the electric field averaged over the electron distribution in the inversion layer), one can discern a so-called "universal" mobility curve, which is largely independent of channel doping concentration, as long as the effective field is sufficiently large enough to form a strongly inverted channel. Figure 14 shows a plot of the inversion mobility vs effective field (Sabinis and Clements, 1979).

3.4.4 Saturation Bias Region As the drain voltage is increased, the voltage drop along the MOSFET channel length can no longer be neglected. The gate-to-channel potential, which gives rise to the inversion layer, decreases as one approaches the drain, as shown in Fig. 12(b). This leads to a flattening of the I_{ds} characteristic, as given by the following expression for long n-channel devices (Sze, 1981):

$$I_{ds} = (W/L)\mu_n C_i\left\{\left(V_{gs} - 2\phi_b - \frac{V_{ds}}{2}\right)V_{ds} - \frac{2}{3} \times \frac{\sqrt{2q\epsilon_{Si}N_a}}{C_i}\left[(V_{ds} + 2\phi_b)^{3/2} - (2\phi_b)^{3/2}\right]\right\}. \quad (12)$$

As the drain voltage increases further, the gate-to-channel potential at some point near the drain is reduced sufficiently that an inversion channel can no longer be maintained. This is the so-called "pinch-off" point, similar to that in MESFETs. The electron concentration in the pinch-off region is greatly reduced compared to the inversion layer but is sufficient to conduct the drain current. At this point, further increases in drain voltage have only a small effect on I_{ds}. The expression for the drain current in saturation is (Sze, 1981)

$$I_{ds,sat} = (W/L)m\mu_n C_i(V_{gs} - V_{th})^2, \quad (13)$$

where m is a function of doping, with a value on the order of $\frac{1}{2}$. Note that the drain current in saturation varies with the square of the gate drive $V_{gs} - V_{th}$. As is discussed later, in modern devices with submicron gate lengths, velocity saturation reduces this to a linear dependence on gate drive. Note that in practice, the drain current does increase slightly as the drain bias increases, as shown in Fig. 13. In long-channel devices, this can be attributed to a small increase in the pinch-off region as the drain bias increases ("channel length modulation").

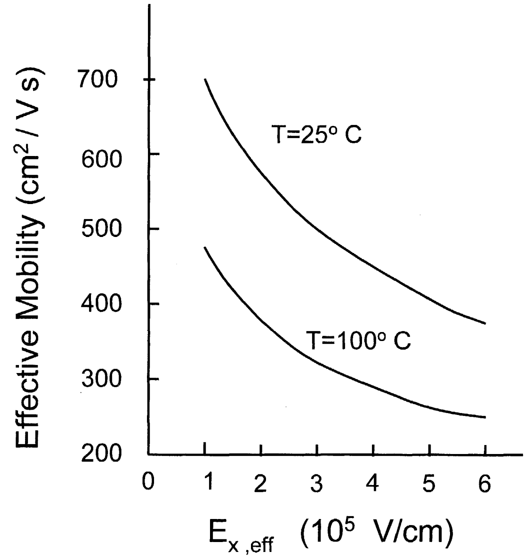

FIG. 14. Effective electron inversion layer mobility vs effective transverse field (Sabinis and Clements, 1979) (after *Physics of Semiconductor Devices*, 2nd ed., S. M. Sze, Copyright © 1981, John Wiley & Sons, Inc. Reprinted with permission of John Wiley & Sons, Inc.).

The saturation region is an important bias region for both analog and digital circuits that use MOSFETs. In analog amplification circuits, the MOSFET is biased in saturation, with the signal to be amplified placed on the gate. The amount of amplification, or *transconductance*, is given by differentiating the expression for I_{ds} with respect to V_{gs}:

$$g_m = 2m(W/L)\mu_n C_i(V_{gs} - V_{th}). \quad (14)$$

Again, note that for modern devices with velocity saturation, the transconductance will be almost independent of the gate drive.

In digital applications, the MOSFET is typically paired in series with another MOSFET, either an n-type depletion mode device, to form NMOS logic, or a p-type inversion-mode device, to form complementary MOS logic (CMOS); see Fig. 15. These transistor pairs form an inverter, in which a high bias

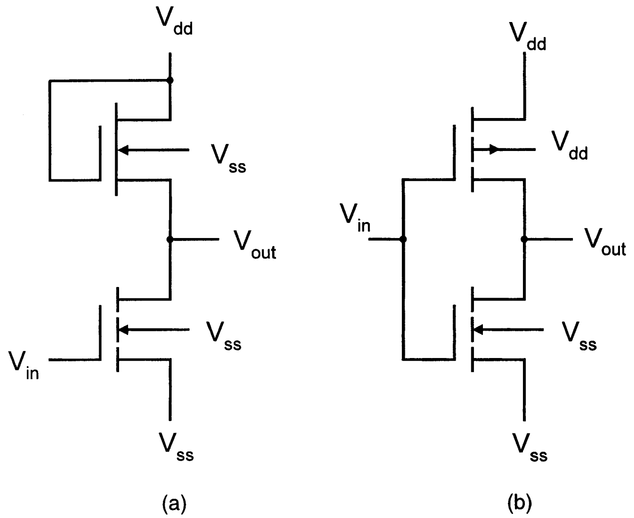

FIG. 15. MOS transistors configured as digital logic inverter gates. (a) NMOS logic (*n*-channel enhancement mode plus *n*-channel depletion mode), (b) CMOS logic (*n*-channel enhancement mode plus *p*-channel enhancement mode).

(logic "1") applied to the input of the inverter (gate) causes the output (drain) to switch to a low bias (logic "0"). The output of the inverter typically feeds other circuitry or interconnect lines, which are capacitive loads, and must be charged up or down. The amount of current available during the switching cycle for this charging is determined by the saturation-region current. Thus, a key parameter in increasing the speed of digital circuitry is the saturation current. The major lever to increasing the saturation current is reducing the dimensions of the gate length; hence the drive toward smaller and smaller dimensions.

3.4.5 Subthreshold Bias Region The third bias region of importance in the MOSFET is the subthreshold region, which may be loosely defined as the bias where the surface potential is between one and two Fermi potentials, ϕ_b. This region is also called "weak inversion." In this region, the drain current is formed by diffusion of carriers between the source and drain, rather than Ohmic conduction. In this bias regime, the drain current is exponentially dependent on the gate voltage (Fig. 16). In digital applications, a sharp subthreshold behavior is desirable, since this provides a more ideal "switch." In addition, poor subthreshold characteristics lead to higher currents in the "off" state, which lead to higher current and power consumption. It can also upset certain types of digital logic by allowing stored charge on circuit nodes to leak away. A measure of the "goodness" of the subthreshold characteristic is the amount of gate voltage required to increase the drain current by a decade, denoted the subthreshold swing (measured in mV/decade).

3.4.6 Breakdown Phenomena At sufficiently high drain biases, the electric field at the drain junction of the MOSFET can impart enough energy to carriers near the drain

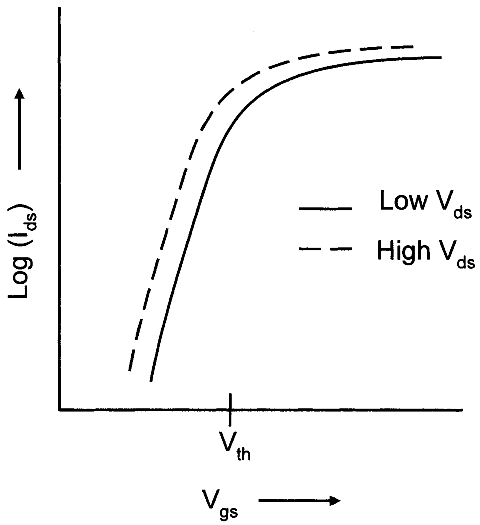

FIG. 16. Logarithm of drain current vs gate voltage for an *n*-channel MOSFET. Solid line: small drain bias. Dashed line: large drain bias.

that they can emit that energy as an electron–hole pair (the impact ionization process; Chynoweth, 1958). One can think of this crudely as an electron colliding with a lattice atom, and ejecting an electron, leaving behind a hole. The electrons are swept into the drain contact, and the holes are emitted into the bulk (assuming an *n*-channel device). As the drain voltage increases, more energy is available to impart to carriers, and the impact ionization rate increases. At high enough drain voltage, this can cause considerable current to flow between the drain and substrate, and may permanently damage the drain junction by localized heating. In short-channel MOSFETs, another type of breakdown phenomena may occur earlier. The generated holes that are swept into the substrate can cause a localized voltage drop between the channel region and the deep bulk. This drop is such that it causes the source junction to become forward biased. This causes more electrons to be injected from the source, increasing the drain current. Larger drain currents increase the amount of carriers available for impact ionization, thus providing more carriers to participate in impact ionization. This positive feedback mechanism can eventually cause the drain current to increase sharply and possibly cause catastrophic failure.

3.4.7 Temperature Effects The main temperature effect in the MOSFET is the change in carrier mobility vs temperature. The inversion layer mobility has a T^{-2} power relation (Sabinis and Clements, 1979). The saturation velocity has a slight dependence on temperature, ranging from 10^7 cm/s at 20 °C to approximately 9×10^6 cm/s at 100 °C for electrons (Canali *et al.*, 1975; Cooper and Nelson, 1981). The saturation velocity for holes is slightly lower (8×10^6 cm/s at 20 °C). Both these effects lead to lower drain currents at higher temperatures. The threshold voltage decreases with increasing temperature, on the order of a few mV/°C. The subthreshold swing is directly proportional to temperature. Temperature effects are important to consider in practical designs, since even with heat sinks or active cooling, the actual operating temperature may be 50 to 75 °C higher than the ambient temperature.

3.5 Small-Device ("Short-Channel") Effects

During the initial development of MOSFETs, the channel length was many microns long, and the device could be designed using the simple formulas presented in the previous sections. These formulas assume that the source and drain regions are sufficiently far from the channel so as not to affect the device behavior. In addition, the channel length was assumed long enough that the current flow in the device could be considered one-dimensional and that the gradual-channel approximation was valid. As MOSFET channel lengths became smaller, and especially in the regime of channel lengths below 1 μm, these assumptions were violated. The following section discusses some of the important effects that modify the behavior of small-dimension MOSFETs.

3.5.1 Threshold Voltage In a long-channel enhancement-mode MOSFET, the threshold voltage is achieved solely by the applied gate potential, which alters the surface potential so that the inversion layer of electrons or holes is formed. Now consider a short-channel MOSFET, where the source and drain junctions are in close proximity to the channel, as in Fig. 17. The source and drain junctions are surrounded by regions depleted of carriers, even at zero source or

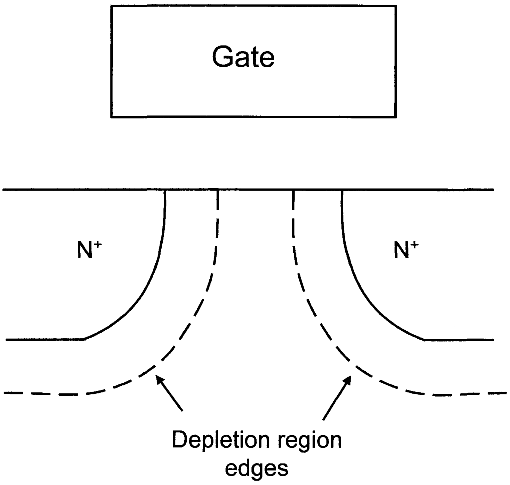

FIG. 17. Cross section of a short-channel MOSFET, showing encroachment of source and drain depletion regions into the channel.

drain bias. When the device length becomes smaller, these depletion regions intrude into the channel, and "predeplete" it. Since part of the channel is already depleted at zero gate bias, it takes less applied voltage to form the inversion layer, and thus the threshold voltage is lowered. This "roll-off" of the threshold voltage is worsened as the channel length decreases. In fact, at some point, the gate loses control over the channel, and the device is considered to be in *punch-through.* A related problem is the so-called drain-induced barrier lowering (DIBL). This effect is the lowering of the device threshold when the drain is biased in saturation. It is an extension of the short-channel roll-off previously discussed. At high drain biases, the depletion region around the drain junction extends farther into the channel. This "predepletes" more of the channel and lowers the threshold voltage further.

Because these effects lower the device threshold voltage, these two effects also increase the amount of current passed by the device when in the "off" state. Recall that in the subthreshold region, the drain current is logarithmically dependent on $V_g - V_{th}$. Even a small decrease in the absolute value of the threshold voltage will cause a large increase in the "off" current. The off current is a critical concern in digital electronics. Besides increasing the amount of current, and hence power, used by devices when they are off, excessive amounts of off current can even cause certain types of circuits to fail to operate properly. Therefore, control of device threshold is a major concern of MOSFET designer engineers.

3.5.2 Velocity Saturation A significant deviation in MOSFET behavior in the saturation bias regime occurs at short gate lengths as a result of carrier velocity saturation. This effect becomes important for micron- and submicron-length devices. As mentioned in the previous discussion on MESFETs in Sec. 2, velocity saturation is the failure of carriers to maintain a linearly increasing velocity with applied electric field and is due to the emission of optical phonons, which are very efficient at transferring energy from carriers to the lattice. Since velocity saturation occurs at high electric fields, which implies high V_{ds}, this effect is noticed in the saturation bias regime. Besides delivering less drain current than expected, velocity saturation also tends to make the saturation current linearly dependent on gate voltage, as opposed to a square-law dependence. It should be noted that the performance of short-channel MOSFETs is not limited entirely by velocity saturation. The carrier mobility at low drain biases is also still important in determining the drain current in saturation. In fact, *p*-channel devices show less velocity-saturation effects than *n*-channel devices (for a given gate length) because the mobility of holes is considerably less than that of electrons (Fig. 6). The higher the low-field mobility, the "faster" the carriers reach their saturated velocity, and the sooner velocity-saturation effects are seen in the drain current.

3.5.3 Hot Carriers and Reliability Another issue that must be considered in short-channel MOSFET design is the effect that high fields have on long-term reliability. We have seen that high electric fields in the MOSFET channel cause the carrier velocity to saturate. These fields are not uniform but are sharply peaked at the drain junction. The carriers gain energy from this field, and some fraction of the high-energy tail of the distribution ("hot" carriers) can acquire enough energy to cause a variety of effects. One effect is impact ionization, where an energetic carrier interacts with the lattice and transfers its energy into creating an electron–hole pair. The newly created electron adds to the drain current, while the hole is swept down into the substrate and adds to current flowing out of the substrate. If a carrier has even more energy, it can surmount the barrier between the silicon and the silicon dioxide and be collected as gate current. These hot carriers can cause damage to the gate oxide in a number of ways. For example, they can induce charges in the oxide, or create traps at the Si/SiO_2 interface that can be occupied by electrons or holes, depending on the available carriers in the channel (Fig. 18). If enough damage occurs to the oxide, it can cause shifts in the threshold voltage or other effects that degrade device performance over time. Typically, the gate currents are very small and thus difficult to measure; however, the substrate current, a close cousin of the gate current, can be used as a proxy to monitor gate current. Accelerated

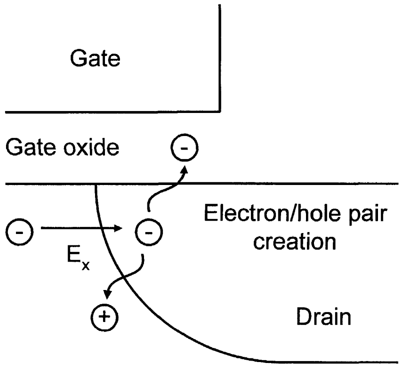

FIG. 18. MOSFET degradation due to hot-carrier injection into the gate oxide.

testing at higher voltages is also used to look at effects that might take years to occur under normal operating conditions. The main tool that MOSFET designers use to reduce hot-carrier effects is modifying the dopant concentration at the source and drain junctions to try to equalize the voltage drop across a larger area, thus reducing the electric field that drives hot-carrier generation. MOSFET designers also have the option of using modified gate oxides (oxynitrides) that are more robust to hot-carrier damage but tend to produce MOSFETs with lower mobility, because of larger amounts of fixed charge at the silicon–oxide interface. The trend toward lower operating voltages (3.3 V and below) reduces the lateral electric fields in the device, although this is counteracted by the continuous trend toward smaller channel lengths, which raise them.

3.6 MOSFET Variants

3.6.1 Silicon-on-Insulator (SOI) MOSFET There are several advantages to fabricating MOSFETs on an insulating substrate, rather than a conducting substrate as is commonly done in industrial practice. Figure 19 shows a cross section of such a device. Earlier SOI MOSFETs were fabricated using thin silicon films grown on completely insulating material that had a close match to the lattice constant of silicon, such as sapphire. The resulting films were prone to defects, and the mobility in the films was not comparable to that in bulk silicon. Recently, interest has grown in using SOI material grown by the silicon implanted oxide (SIMOX) process, where normal silicon wafers are implanted with a high dose of oxygen to form a buried insulating layer. These wafers have better electrical quality than previous silicon on insulators, although maintaining control over the thickness of the upper silicon film is still problematic. The main advantages of SOI over bulk silicon are the reduction in parasitic capacitances under the source and drain junctions due to the source and drain areas butting against the insulating layer, improved resistance to operational upset due to high-energy radiation (important for space applications, for example), immunity to catastrophic interaction between n- and p-channel devices when used together in an integrated circuit (CMOS latch-up), and improved subthreshold characteristics. Disadvantages include less controllable manufacturing, due to difficulties in control-

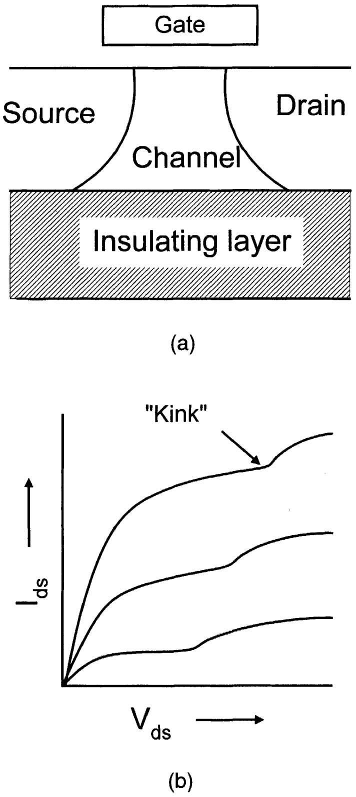

FIG. 19. Cross section of a silicon-on-insulator (SOI) MOSFET. Inset: drain-current vs drain-voltage characteristics, showing the "kink" effect.

ling the silicon film thickness (resulting in changes in threshold voltage), less ability to dissipate heat generated by the device due to the buried oxide, higher wafer costs, and the lack of a contact to the body of the MOSFET. Without this contact, the body of the MOSFET is not tied firmly to any potential and can "float." In particular, any carriers generated by impact ionization at the drain cannot be easily collected and cause the body of the MOSFET to rise to a higher potential, causing a "kink" in the MOSFETs I_{ds}–V_{ds} characteristics (see inset, Fig. 19). Many of these problems are technological, rather than absolute, and may be resolved in the future. SOI MOSFETs remain an area of intense research.

3.6.2 Nonvolatile Memory It is possible to produce MOSFETs whose threshold voltage can be altered electrically by injecting charge onto a gate that is not connected to any other potential ("floating"). In particular, enough charge can be stored on the gate so that the sign of the threshold voltage changes, and the device turns from normally off to normally on. With proper design, the charge can remain on the floating gate for years. Such transistors can be used as a memory device. There are many possible configurations of nonvolatile memory cells. Figure 20 shows one possible configuration, using two levels of polysilicon. The lower level is the floating gate and is separated from the MOS channel by a thin oxide. The second polysilicon layer (control gate) is used to program the device. A large positive voltage is applied to the control gate, which induces a large electric field between the floating gate and the MOS channel. The bands of the silicon substrate are bent sufficiently to allow electron tunneling between the channel and the floating gate, thus storing electrons on the gate. These electrons will make it more difficult to form an inversion channel in the MOSFET, on account of electrostatic repulsion, thus increasing the threshold voltage. The device is now turned off. The floating gate can be discharged by applying a voltage of the opposite sign to the control gate, or, in some designs, by shining ultraviolet light through a window on the device package.

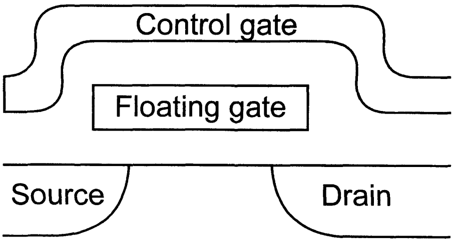

FIG. 20. Cross section of nonvolatile memory, using MOSFET technology.

The obvious benefit of nonvolatile memory is that the memory state is retained, even if the power supply for the device is turned off, unlike traditional semiconductor memory chips. In addition, such memories require less power than traditional semiconductor memory, an important attribute for low-power and portable electronics. At the time of this writing, some industry observers suggest that nonvolatile memory chips may rival traditional semiconductor memory chips in the future.

4. ADVANTAGES AND DISADVANTAGES OF FETs

The two main families of active semiconductor devices are the bipolar transistor family and the field-effect transistor family. The following is a brief comparison of the two:

- Field-effect transistors can be formed in many types of semiconducting materials, since only one type of carrier, usually *n* type, is required. Many compound semiconducting materials, such as GaAs, can only form *n*-type material. Bipolar transistors require both *n*- and *p*-type regions.
- Field-effect transistors can take advantage of advances in lithography to scale their gate dimensions. Since the FET current is proportional to *W/L*, smaller gate lengths improve performance. The current passed by bipolar transistors is proportional to their area ($W \times L$), so scaling dimensions alone do not improve device performance. Bipolar transistors must also rely on advanced processing to create thin layers of different type semiconductor (e.g., base region) to improve performance.
- Bipolar transistors can generally deliver more current for a given area than field-effect transistors, since their current scales

with their area. To generate large currents, field-effect transistors must increase their width, while keeping their length small.

- Field-effect transistors can generally operate at higher and lower temperature ranges than bipolar transistors and do not suffer from thermal runaway effects as bipolar transistors do.
- *n*- and *p*-type silicon MOSFETs can be combined in complimentary digital circuits (CMOS) such that current flows (and power is consumed) only when the circuit is switching. This can lead to lower power consumption than logic circuits implemented with bipolar transistors.
- Bipolar transistors have certain advantages in analog circuits. They have greater linearity than field-effect transistors and can have higher gain in amplifying circuits.
- Bipolar transistors are generally more complex devices than MOSFETs, have more parasitic elements, and are harder to model for computer-aided design.
- Although bipolar transistors have been traditionally used in analog circuitry, MOSFETs can be used to implement a variety of important analog circuits, such as switched capacitor filters and analog-to-digital converters, in an inexpensive and efficient manner.

GLOSSARY

Analog Circuit: An electronic circuit that performs a useful function by representing a quantity, e.g., speech, by an infinitely variable electronic quantity, such as a voltage or current. Examples of analog circuits are amplifiers, modulators and demodulators, and oscillators.

Bipolar Transistor: A three-terminal semiconductor electronic device that operates by modulating the current flow of carriers between two regions of like dopant type (termed the emitter and the collector) separated by a third region of opposite dopant type (denoted the base). The emitter-to-collector current is modulated by the injection of current into the base region. The bipolar transistor relies on the interaction of both carrier types (electrons and holes) to operate.

Compound Semiconductor: A semiconductor that is based on more than one elemental atom. Examples of compound semiconductors are GaAs, InP, and AlGaInAs.

Digital Circuits: An electronic circuit that performs a useful function by representing a quantity, e.g., speech, by a discrete set of electronic quantities, such as voltage or current. Most typical digital circuits have two levels (a binary system), in which one voltage or current level represents a 0, and another a 1.

Dopant Atom: An atom added to a semiconductor crystal that is able to modify the conductivity of the semiconductor by donating an electron (donor atom) or accepting an electron and thus creating a hole (acceptor atom).

Effective Mass: An approximation used to describe the mass of an electron or hole when moving in a crystal lattice. The mass of the carrier appears to change because of the interaction between the carrier and the periodic potential imposed by the crystal lattice.

Energy Bands: A description of the allowed energy states that electrons and holes may have in a crystal.

Heat Sink: A mechanical device that is used to remove generated heat from a semiconductor device. Most heat sinks are made of highly conductive metal, constructed so that they have a high surface area to promote heat transfer.

Hole: The absence of an electron in a material's filled valence band. The motion of a hole can be thought of as the motion of an electron from the sea of electrons in the valence band into the gap. Holes are positively charged. Although holes and electrons are often thought of as identical, except for charge, this is only an approximation. A hole's properties are controlled by the valence band(s), which can be very different from an electron's conduction band(s).

Intrinsic Carrier Concentration (n_i): The number of holes or electrons that are present in a semiconductor through thermal generation only, i.e., in a pure crystal.

Inversion Layer: A thin conductive layer that forms when the surface potential of a MOS device is raised (or lowered) so that a layer of electrons (holes) is formed at the semiconductor–insulator interface.

Inverter (logic gate): The basic binary digital circuit, which transforms one binary state at the input to the other binary state at the output.

Ion Implantation: A technology that takes an ionized impurity atom and accelerates it by means of an electric field and bombards it into a semiconductor target. This technique is used to introduce dopant atoms into the semiconductor. It is used in all modern IC processing because of its ability to control the amount of dopant introduced, as well as its depth in the semiconductor.

Lithography: A technology for transferring patterns from a predrawn mask onto the surface of a semiconductor wafer. Typically, the pattern is formed in a layer of photosensitive material (photoresist) that changes chemically when selectively exposed to light or electron bombardment. The chemically altered photoresist is either hardened or made easier to remove.

Mobility: The proportionality factor between an applied electric field and the resulting velocity of an electron or hole. The mobility is not a constant but depends on the number of dopant atoms, the temperature, and even the electric field itself.

Optical Phonon: A mechanical vibration quantum in a crystal that has energy in the range of an electron volt.

Schottky Barrier: A contact between a metal and a lightly doped semiconductor, such that a rectifying (non-Ohmic) contact is formed. A rectifying contact readily passes current in one direction but blocks current flow in the opposite direction.

Semiconductor: In a semiconductor, a gap of approximately 1 eV occurs between the energy states of the tightly bound, or valence, electrons and the outer, conduction electrons. Thermal energy can excite a limited number of electrons from the valence band into the conduction band, thus producing a poorly (semi)conducting material.

Superlattice: A semiconductor structure that is formed by repeated layers of different composition, such that the electronic properties are altered for a useful purpose.

INTRODUCTION

Microwave is any electromagnetic wave with a frequency in a range commonly regarded as extending from 300 MHz to 300 GHz, covering the spectrum lying between the radio frequency and the far infrared. The part of the spectrum higher than 30 GHz is also regarded as the millimeter-wave band, as the corresponding wavelength in free space is comparable to or shorter than a millimeter. Microwave is widely used to carry voice and data signals over the air and into deep space. Beginning in the World War II era, the microwave spectrum has also been segmented and labeled into many sub-bands: *L*-band (1.12–1.70 GHz), *R*-band (1.70–2.60 GHz), *S*-band (2.60–3.95 GHz), *H*-band (3.95–5.85 GHz), *C*-band (5.85–8.20 GHz), *X*-band (8.20–12.4 GHz), *Ku*-band (12.4–18.0 GHz), *K*-band (18.0–26.5 GHz), *Ka*-band (26.5–40.0 GHz), *Q*-band (33.0–50.5 GHz), *U*-band (40.0–60.0 GHz), *V*-band (50.0–75.0 GHz), *E*-band (60.0–90.0 GHz), *W*-band (75.0–110.0 GHz), *F*-band (90.0–140.0 GHz), *D*-band (110.0–170.0 GHz), and *G*-band (140.0–220.0 GHz).

Microwave transistors are widely used in many instrumentation and wireless communication systems: they provide the essential function of generating, amplifying, and modulating current source at microwave frequency. Various materials such as semiconductors, superconductors, or metal-based systems have been experimented with to realize microwave transistors. Nevertheless, almost all of today's microwave transistor functions are implemented on semiconductors for any practical applications. This article first reviews figures of merit of basic microwave applications and then surveys a few key semiconductor microwave transistor technologies based on these factors.

1. EQUIVALENT-CIRCUIT MODELS AND FIGURES OF MERIT

In order to link the physical transistor behaviors to the microwave characteristics, the equivalent-circuit model and a few figures of merit are introduced in this section for several applications.

1.1 Small-Signal Transistors

For small-signal excitations, the complex current–voltage characteristics of a microwave transistor can be simplified and linearized for a given dc bias condition. For example, a *p-n* junction can be modeled as a capacitor and a resistor in parallel for microwave signals, where its resistance value represents the slope of the diode's exponential voltage–current characteristics and its capacitance value reflects both the diffusion capacitance and the capacitance from the depletion layer under a steady-state bias condition. By exercising this technique to simplify physical carrier-transport equations, a set of equivalent-circuit models assembled from a set of simple linear lump elements such as capacitors, resistors, and dependent current sources would describe the small-signal microwave characteristics of the intrinsic part of a microwave transistor adequately.

To describe accurately the transistor frequency response at microwave frequencies, the contribution from the extrinsic parasitic elements in the microwave transistor, such as interelectrode capacitors, contact resistors, and bonding-wire inductance, is significant and should be included in the equivalent circuit. Unlike the equivalent-circuit elements of the intrinsic part of the transistor, the value of these extrinsic parasitic elements is independent of the operating bias of the transistor. At higher end of the microwave band, for example, in the millimeter-wave bands, the physical dimensions of a microwave transistor and its interconnection leads would be as large as a fraction of the wavelength, and distributed effects should be incorporated into the equivalent-circuit model. Because of this distributed nature at microwave frequencies, both the amplitude and the phase of the instantaneous voltage and current wave forms of the transistor are highly sensitive to the external impedance presented to the transistor terminals, and it is very difficult to determine them precisely. Therefore, it is common to use the incident and reflected power wave forms and scattering matrices from a known termination reference impedance to characterize the transistor at microwave frequency rather than using the instantaneous current and voltage wave forms at dc or low frequency. Nevertheless, the instantaneous current and voltage can be derived from the scattering parameters if the terminating impedance at the transistor terminals is known (Vendelin *et al.*, 1990).

Once the equivalent circuit of the transistor is determined and verified by experimental data, the frequency response can be predicted by circuit theory for any external termination conditions. The amplifier gain of the transistor usually rolls off at high frequency because of the long transit delays of the carriers and the charging time of capacitive elements. When the gain is reduced to unity, the corresponding frequency is called the cutoff frequency of a transistor. Figure 1 shows the frequency dependence of commonly used transistor gain characteristics. Hybrid current gain (h_{21}) is defined as the output-to-input current gain of the transistor, when the output of the transistor is short-circuited. The short-circuit current gain cutoff frequency, f_T, is widely used to monitor the intrinsic transport properties of the charge carriers. Unilateral power gain (U) is defined as the maximum power gain

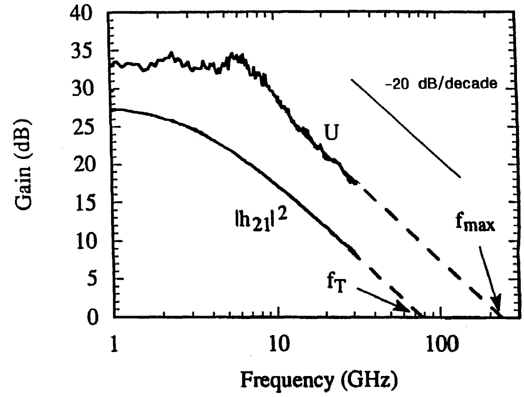

FIG. 1. Frequency dependence of the unilateral power gain, U, and current gain, h_{21}, of a microwave transistor. The gain rolls off at a slope of −20 dB/decade under the influence of a dominant time constant.

of the transistor when both input and output of the transistor are connected to an impedance conjugate matched to the internal impedance of the transistor and the internal feedback in the transistor is nullified by an external feedback circuit. The *U* represents the highest power gain a transistor can produce theoretically for a given frequency and bias condition. When *U* rolls off to unity, the corresponding frequency is defined as the maximum unilateral power-gain cutoff frequency, $f_{\max}$, which is the highest frequency at which a transistor can still produce gain, usually in an oscillator circuit.

In most cases, the frequency response of a microwave transistor is limited by a dominant time constant. This exhibits a dominant pole in the frequency response, and the linear gain of the transistor reduces at a rate of -6 dB/octave or -20 dB/decade with the rise of frequency. For a transistor with an $f_{\max}$ of 100 GHz, we may expect a maximum gain of 20 dB at 10 GHz [i.e., $20 \log_{10}(f_{\max}/f)$]. The actual amplifier gain will be less than 20 dB because of the mismatches between external impedance and the input and output impedances of the transistor. The mismatches on the external impedance are necessary in many cases to enhance the amplifier noise figure, to obtain a broad and flat frequency response, or to avoid instability of the amplifier.

1.2 Microwave Low-Noise Transistors

Many microwave amplifiers are designed to boost very weak signals. However, a microwave transistor also generates noises and adds it to the amplified signal. The noise figure, *F*, is a measure of the output signal quality, defined as the ratio of the input signal-to-noise ratio to that of the output:

$$F = \frac{(S/N)_i}{(S/N)_0}. \tag{1}$$

There are many internal noise sources in a microwave transistor such as low-frequency generation–recombination noise, broad-band current shot noise, current fluctuation noise, and thermal noise. The output noise of a transistor is the ensemble average of the amplified input noise plus this internally generated noise. These internal noise sources, depending on their physical origins, are added to the output of the transistor through a web of equivalent-circuit elements.

From the quantum-mechanical fluctuation and dissipation theory, the internally generated noise will be minimized once these noise sources can be dissipated through an optimal external impedance. For a given set of frequency and bias conditions, the noise figure of a transistor reaches its minimum value $F_{\min}$ when its input is connected to an optimal admittance Y_{opt} to dissipate the internally generated noise power effectively. Given this input termination of Y_{opt} and a conjugate matched-output matching network, the maximum available gain of this transistor is called associated gain, G_A. Together with the equivalent internal noise resistor R_n, $F_{\min}$, G_A, and Y_{opt} completely describe the noise and gain characteristics of a microwave transistor. The gain can be increased by connecting another value of admittance *Y* to the transistor. However, the noise figure of this new amplifier will be degraded from its lowest value to

$$F = F_{\min} + [R_n/\mathrm{Re}(Y)]|Y - Y_{\text{opt}}|^2. \tag{2}$$

To obtain a desirable signal level, cascading of multiple stages of transistors is necessary. The gain and noise figure of a multiple-stage amplifier is related to that of each amplifying stage by

$$G = G_1G_2G_3 \ldots \tag{3}$$

and

$$F = F_1 + (F_2 - 1)/G_1 + (F_3 - 1)/G_1G_2 + \ldots, \tag{4}$$

where F_i's and G_i's are the noise figure and associated gain of each amplifying stage, respectively. It is important to note that both the noise figure and the associated gain of the first couple of stages dominate the overall amplifier performance. A low-noise microwave transistor located at the forefront of the amplifier should have a very low noise figure and a very high power-gain cutoff frequency to produce enough gain margin at the operating frequency. The excess gain is needed to compensate the loss from the impedance mismatch Y^*_{opt} presented at the input of the transistor for $F_{\min}$ and to discount the noise contribution from the following stages. For many satellite microwave receivers operating at a few gigahertz frequency, it is common to use low-noise transistors with cutoff frequency more than 100 GHz so that the transistor in the first stage will have the lowest noise figure while it still provides plenty of gain so as to minimize the noise contributions from the rest of the stages.

1.3 Microwave Power Transistors

In many applications, microwave transistors are utilized to handle large signal swings. For example, in the mixer circuit, a transistor is driven into the nonlinear operation regime such that it mixes two input signals to produce desirable higher-order harmonic contents at the output. For power-amplifier applications, the signal level is also strong enough that the characteristics of a microwave transistor can no longer be described by its small-signal model, and a complete description of the transistor device model should be used.

Power amplification is a very common application for microwave transistors. Many figures of merit of power amplifiers, such as saturated output power, power-added efficiency, and available power gain, are linked to the transistor characteristics. Power transistors are biased in one of three modes: class A, B, or C. The class A operation offers the best linearity, while the class B and C configurations provide better peak power and efficiency.

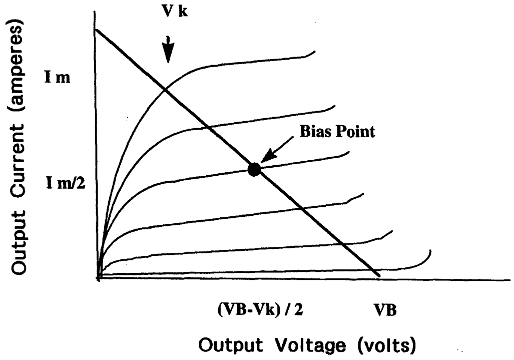

FIG. 2. Bias point of a microwave transistor for class-A linear amplification. The knee voltage V_K, breakdown voltage V_{BK}, and maximum current I_m of the transistor determine the maximum output power of the transistor.

As shown in Fig. 2, the bias point for class A operation is chosen in the middle of the peak voltage and current swing such that the peak output current and voltage will not reach the nonlinear region of the transistor. The maximum power level and maximum power-added efficiency are approximated by

$$\text{Maximum Output Power } (P_{\max}) = (V_{BK} - V_K)I_{\max}/8 \quad (5)$$

$$\sim V_{BK}I_{\max}/8, \quad (6)$$

and

$$\text{Power-Added Efficiency (PAE)} = P_{\max}/(P_{dc} + P_{\max}/G) \quad (7)$$

$$\sim 1/(2 + 1/G) < 50\% \quad (8)$$

with the voltage and current of the transistor biased at $(V_{BK} - V_K)/2$ and $I_{\max}/2$, respectively. V_K is the output knee voltage at the maximum output current $I_{\max}$, V_{BK} is the output breakdown voltage, P_{dc} is the dc power consumption, and G is the associated microwave gain of the transistor amplifier. In order to provide the desired current and voltage at the output, the resistance of the output load line is approximately $V_{BK}/I_{\max}$, which is usually much less than the output resistance of the transistor for the optimal matching for gain. Assuming a mismatch loss of α to the maximum available gain of the transistor at an operating frequency f, the associated gain and the power-added efficiency can be rewritten as

$$\text{Associated Gain} \sim \alpha f_{\max}/f, \quad (9)$$

$$\text{Maximum Power-Added Efficiency} = 1/(2 + f/\alpha f_{\max}). \quad (10)$$

For high output power, high gain, and good efficiency, it is clear that we need transistors with large V_{BK}, $I_{\max}$, and $f_{\max}$.

For class B and C operations, the transistor is biased near the cutoff region at $V_{BK}/2$ in order to obtain a full peak current swing of $I_{\max}$. It relies on the external filter circuit to remove the nonlinear distortion. For example, the maximum saturated power and power-added efficiency of an ideal class B power amplifier can be expressed as

$$P_{\max,B} = (V_{BK}/2 - V_K)I_{\max}/2 \quad (11)$$

$$P_{\mathrm{dc,B}} = (\pi/4)(V_{\mathrm{BK}}/2 - V_{\mathrm{K}})I_{\mathrm{max}} \qquad (12)$$

$$\begin{aligned}\mathrm{PAE}_{\mathrm{max,B}} &= P_{\mathrm{max,B}}/P_{\mathrm{dc}} \\ &< 2/\pi = 63.6\%. \qquad (13)\end{aligned}$$

The maximum power-added efficiency of a class C power amplifier is even higher when the amplifier is driven more into the saturation regime. The value will be close to 100% when the output voltage and current wave forms look like a square wave with one at its peak and the other one at zero. However, in practical applications, a significant filtering network will be needed at the output of this nonlinear amplifier in order to remove higher-order harmonics and intermodulation products.

2. MICROWAVE BIPOLAR TRANSISTORS

Bipolar transistors are widely used to generate, amplify, and mix microwave signals because of their unique noise characteristics and current-handling capability. In this section, we review the microwave characteristics of both homojunction and heterojunction bipolar transistors. The general operation principles and dc characteristics of bipolar transistors can be found in other articles in this Encyclopedia, such as Transistors, Bipolar.

2.1 Homojunction Bipolar Transistors

2.1.1 Device Operation Homojunction bipolar transistors are configured in either *p-n-p* or *n-p-n* doped multilayers as emitter (E), base (B), and collector (C). The microwave signals are carried by the minority carriers such as holes in the *n*-doped base of *p-n-p* transistors or electrons in the *p*-doped base of *n-p-n* transistors, respectively. These minority carriers are injected from the emitter side of the forward-biased E-B junction into the base region. These minority carriers then drift and diffuse through the heavily doped base region. Some minority carriers will recombine with the majority carriers in the base and E-B junction as part of the base current. Those base minority carriers reaching the reverse-biased B-C junction will be accelerated by the high electric field and collected by the collector as part of the collector current.

The intrinsic frequency response of the bipolar transistor is determined by the total transit delay from the injection of carriers in the emitter till the collection of these carriers in the collector. This intrinsic delay consists of the charging delay of the E-B junction, the transit delay in the base and B-C space-charge region, and finally the charging delay of the B-C junction. The base doping level needs to be high to reduce the resistance of base current in the thin base.

2.1.2 Device Models The equivalent circuit of a bipolar transistor is shown in Fig. 3 when the bipolar transistor is operated

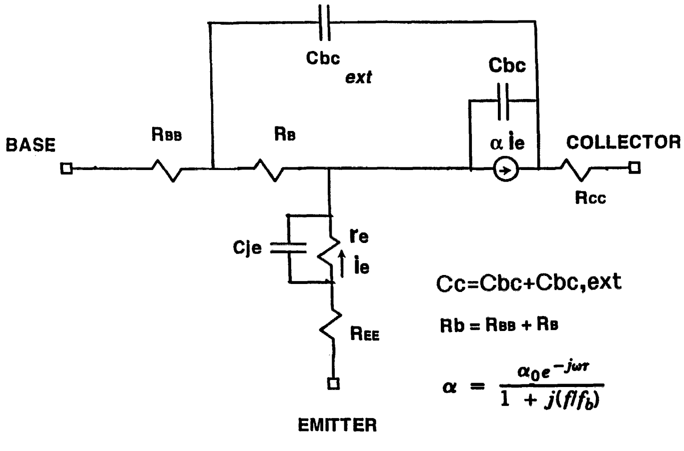

FIG. 3. Equivalent circuit of a microwave bipolar transistor.

in the active mode with a forward-biased E-B junction and a reverse-biased B-C junction. The total transit delay τ_T from the emitter to the collector is the sum of the emitter charging time (τ_E), base transit time (τ_B), collector transit time in the B-C space-charge region (τ_{SCC}), and collector charging time (τ_C), where

$$\tau_E = (R_E + R_B + Rcc + R_{EE})C_{be}, \tag{14}$$

$$\tau_C = (R_E + R_B + Rcc + R_{EE})C_{bc}, \tag{15}$$

$$\tau_B = W_B^2/2D, \tag{16}$$

$$\tau_{SCC} = t_C/2V_c, \tag{17}$$

and W_B, t_C, D, and v_c are the thickness of the neutral base, the thickness of the collector space-charge region, the diffusion constant of minority carriers in the base, and the carrier velocity in collector, respectively.

From this intrinsic delay, many figures of merit such as cutoff frequencies can be derived. The common-emitter current-gain cutoff frequency f_T and the maximum power-gain cutoff frequency $f_{\max}$ can be expressed as

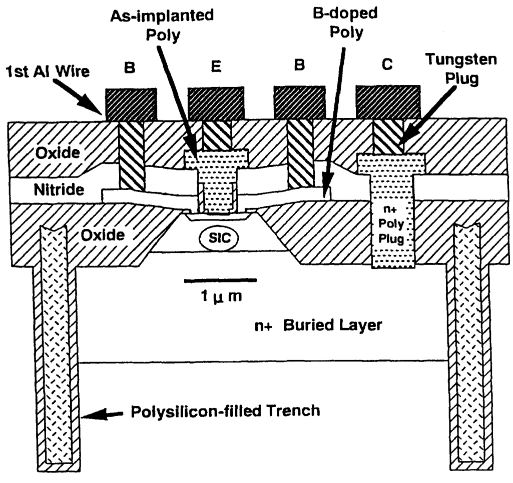
$$f_T = 1/2\pi\tau_T \tag{18}$$

$$\begin{aligned} &= 1/2\pi[C_{be}(R_E + R_B + Rcc + R_{EE}) \\ &\quad + C_{bc}(R_E + R_B + Rcc + R_{EE}) \\ &\quad + \tau_B + \tau_{SCC}] \end{aligned} \tag{19}$$

and

$$f_{\max} = \sqrt{\frac{f_T}{8\pi C_{bc}R_B}}. \tag{20}$$

Both f_T and $f_{\max}$ are dominated by the emitter charging time $R_E C_{be}$ at low operating collector current, while they are limited by the transit time at high current. The power-gain cutoff frequency $f_{\max}$ is also limited by the external parasitic elements such as R_B and C_{bc}. For microwave applications, special attention in the IC processing has to be addressed on how to reduce the base resistance and collector capacitance, and these transistors are usually operated at high current density to reduce the emitter charging time. Figure 4 shows the cross-section diagram of a state-of-the-art silicon bipolar transistor with a super self-aligned process (Ugajin and Fossum, 1994). A super self-aligned process is needed to reduce the parasitic base resistance and collector junction capacitance.



SIC = Selectively Ion-implanted Collector

FIG. 4. Cross section of a high-performance silicon bipolar junction transistor fabricated with self-aligned implantation technology. The process is carefully designed to minimize base resistance and collector feedback capacitance to achieve high cutoff frequency.

2.1.3 Noise Characteristics There are many noise sources in a bipolar transistor. The dominant noise sources are generation–recombination noise in the emitter space-charge region, shot-noise sources in the emitter junction and collector junctions, thermal (or Johnson) noise from the base resistance, recombination noise in the extrinsic base region, multiplication noise in the high-field collector space-charge region, etc. These noise sources can be introduced into an equivalent circuit such as Fig. 3. The collective terminal noise characteristics of a bipolar transistor result from the interplay of these sources with the rest of the device equivalent circuit.

The frequency dependence of the spectral density of the collector noise current is illustrated in Fig. 5. The noise-current spectrum shows three regions:

1. $1/f$ rolloff characteristics at low frequency,
2. a flat noise floor over a very broad bandwidth, and
3. a steep rise ($\sim f^2$) at high frequency.

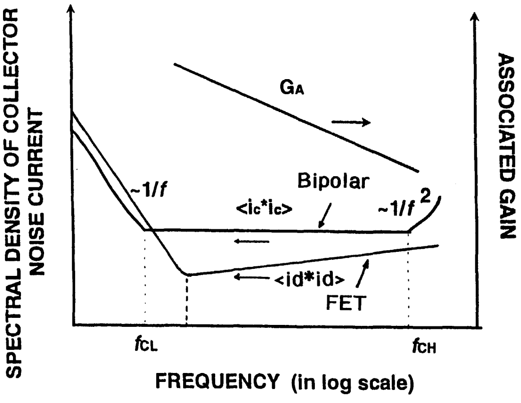


FIG. 5. Illustration of current-noise power spectrum of a bipolar transistor and a FET.

The shot noise, thermal noise, and multiplication noise in the collector depletion region make up the broad-band noise floor. The generation and recombination noise in the emitter-base depletion region and the surface states dominates the low-frequency noise spectrum. At very high frequency, those two shot-noise sources in the emitter junction and collector junction are no longer correlated by the transit delay, and total noise current increases substantially.

The low-frequency noise is very important to many applications, such as high-precision analog-to-digital converters, ultrastable microwave oscillators, etc. The low-frequency current fluctuations in the oscillating transistor will be up-converted to the microwave frequency, and the stability of the oscillating frequency (or the resultant phase noises) will significantly deteriorate. In the field-effect transistors (FETs) based on lateral carrier transportation parallel to the surface of the semiconductor, the generation and recombination current from the buffer layer and substrate is the major source of low-frequency current noise. As a result, the low-frequency noise-current density is high in FETs. Devices based on vertical carrier transport, such as emitter-up bipolar junction transistors (BJTs) or heterojunction bipolar transistors (HBTs), are less sensitive to the electronic defects and imperfections in the buffer layer and substrate material. The dominant carrier-transport mechanism in the emitter and base of bipolar transistors is effectively shielded from noise sources in the substrate by the high electric field in the collector as well as the highly doped and quasineutral n^+ region of the subcollector contacting layer.

The high-frequency noise of bipolar transistors is dominated by the broad-band thermal and shot noises. Therefore, the minimum noise figure can be calculated from the macroscopic equivalent-circuit model using the approximation from Hawkins (1977):

$$F_{\min} = \frac{a(R_b + R_{\text{opt}})}{r_e} + \frac{(1 + f^2/f_F^2)}{\alpha_0}, \tag{21}$$

where

$$R_{\text{opt}} = \left[(R_b^2 - X_{\text{opt}}^2) + \frac{(1 + f^2/f_F^2)r_e(2R_b + r_e)}{a\alpha_0}\right]^{1/2}, \tag{22}$$

$$X_{\text{opt}} = 2\pi f C_{je} r_e^2 (1 + f^2/f_F^2)/a\alpha_0, \tag{23}$$

and

$$a = [(1 + f^2/f_F^2)(1 + f^2/f_e^2) - \alpha_0]/\alpha_0, \tag{24}$$

with $f_e = 1/2\pi\tau_e$, $f_F = 1/2\pi\tau_F$, and dc common-emitter current gain $\beta_0 = \alpha_0/(1 - \alpha_0)$. Here we replace the base transit-time cutoff frequency f_b by the total transit-time cutoff frequency f_F.

An optimal microwave low-noise bipolar transistor requires very low base resistance and very small forward transit delay. Low base resistance and high associated gain can be realized with a submicron emitter stripe width and high base doping density. The shot noise would be significantly reduced by operating the transistor at a small collector current. The microwave gain is preserved by the high collector current density in the small active area.

2.1.4 Power Characteristics Bipolar transistors have been a very popular choice for microwave power applications because of their large current-driving capability and thin vertical structure for high-frequency performance. The maximum power that can be delivered by a bipolar transistor is limited by its voltage swing and current swing. The output voltage swing is dominated by the breakdown voltage of the collector junction. In order to obtain a high collector breakdown voltage, a very thick and lightly doped collector depletion region is used. However, the lightly doped collector depletion region also limits the space-charge current density and, therefore, the maximum current that can be driven through the transistor. This collector-current density places a limit on the charging time constant of the emitter–base junction and the cutoff frequency of the bipolar transistor. For a silicon bipolar transistor, the product of the current-gain cutoff frequency f_T and the collector breakdown voltage VB_{CEO} is a constant typically less than 120 GHz-V (Nanba *et al.,* 1993). The low cutoff frequency of a microwave transistor means a low power gain and poor power-added efficiency. The microwave gain is degraded even further when ballast emitter resistors are added to the emitter to improve the linearity and thermal stability.

In order to deliver high current, many active emitters are connected in parallel to form a power transistor. Because of the nonuniform temperature distribution and the potential drops along the interconnection lines, the base–emitter junction voltage may be different by a few multiples of thermal voltage kT/q from one part of the transistor to another. This slight variation in the base potential in one cell will amplify the collector current of this cell exponentially. The increase of the collector current heats this weak cell even hotter and leads to thermal runaway. This is the major reliability problem of power bipolar transistors. In order to desensitize the variations in the turn-on potential and thermal distribution of massive parallel emitter–base junctions in a power transistor, a ballast resistor is usually added in series with each emitter. This ballast resistor also acts as a negative feedback to linearize the output collector current such that the output current is no longer responding to the input voltage in an exponential way (Yamada *et al.,* 1996).

2.2 Heterojunction Devices

Kromer (1982) first suggested that the high-frequency performance of transistors may be improved by replacing the heavily doped homojunction emitter with a lightly doped heterojunction emitter made of a material with the same lattice constant but with a higher band-gap energy than the base material. The high band-gap energy of the emitter of a heterojunction bipolar transistor (HBT) effectively suppresses the back-injected carriers from the base to preserve the dc current gain. Therefore, a lightly doped emitter can be used to lower the base–emitter junction capacitance, and the high-frequency power gain is improved by the high base doping. With the advances of the modern epitaxial growth technologies, such as molecular-beam epitaxy (MBE), organometallic vapor-phase epitaxy (OMVPE), and low-pressure chemical vapor deposition (LPCVD), high-frequency microwave HBTs with more than 100-GHz cutoff frequency have been realized using many III–V compound semiconductor materials (Ishibashi and Yamauchi, 1988; Chen *et al.,* 1989) as well as traditional silicon materials with a strained narrow–band-gap base with a small germanium composition (Crabbe *et al.,* 1993). The heavily doped base also alleviated some problems in designing traditional homojunction bipolar transistors such as base width modulation from the collector bias [a.k.a. Early effect (Early, 1952)] and gain suppression at high injection level.

Most microwave HBTs are implemented with one heterojunction and typically as *n-p-n* configuration to utilize the high mobility and high velocity of electrons. A large valence-band offset between the emitter and base (ΔE_V) is desirable to suppress the back-injected holes from the heavily doped base. The dc current gain β can be expressed as

$$\beta \approx \frac{N_{D,E}}{N_{A,B}} \exp\left(\frac{\Delta E_v}{kT}\right) \tag{25}$$

where $N_{D,E}$ and $N_{A,B}$ are the donor density in the emitter and the acceptor density in the base, respectively. It can be seen that high current gain and a high emitter-to-base doping ratio is possible even with a small valence-band discontinuity.

Double heterojunction HBTs are also used to enhance the breakdown voltage for high-power applications by employing wide–band-gap material at both emitter and collector. However, care should be taken to minimize the conduction-band spike of the base–collector heterojunction, which may block the transport of base minority carriers into the collector depletion region. Table 1 lists some

Table 1. Commonly used heterostructures for microwave heterojunction bipolar transistors (HBTs).

Substrate	Emitter	Base
Silicon	Si	$Si_{(1-x)}Ge_x$
GaAs	AlGaAs	GaAs
	InGaP	$In_xGa_{1-x}As$
	AlGaP	InGaP
InP	AlInAs	InGaAs
	InP	
	InGaP	
GaSb	AlSb	InAs
SiC	AlGaN	SiC
Sapphire	GaN	GaInN

of the popular material selections to build HBTs.

Despite the difference of carrier-transport dynamics between the HBT and BJT, the ac equivalent-circuit model and the frequency response are dominated by the carrier transit time as well as charging-time delay from the junction and contact parasitic. Both the microwave frequency response and the noise properties of HBTs are limited mainly by the base resistance and base–collector junction capacitance. By reducing the base thickness for short carrier transit time and increasing its doping concentration to reduce the excess base resistance, microwave HBTs with greater than 100-GHz frequency response and excellent microwave noise characteristics are realized in many material systems.

3. MICROWAVE FIELD-EFFECT TRANSISTORS

The general operation principles of various field-effect transistors (FETs), such as MOSFETs, MESFETs, and HEMTs, are described in detailed in other articles in this Encyclopedia and will not be repeated here. Critical device parameters affecting microwave operation are examined in this section.

3.1 Equivalent Circuit and Its Frequency Response

In general, the current transport in the FET is by the majority carrier. The carriers are injected from the source contact into the conduction channel underneath the gate electrode. After the carriers are accelerated by the electric field in the channel, they are collected by the drain contact. The weak ac signal is typically applied to the gate electrode, and then amplified by the channel conductance modulation through the source-to-drain current.

The high-frequency small-signal equivalent-circuit model of a FET is depicted in Fig. 6. The high-frequency response of a FET is limited by the carrier transit time between the source and drain underneath the gate field:

$$\tau = 1/2\pi f_T = L_g/\langle v_s \rangle = 1/[g_m/2\pi(C_{gs} + C_{gd})], \tag{26}$$

where f_T is the current-gain cutoff frequency, L_g is the effective gate length, $\langle v_s \rangle$ is the average carrier velocity in the channel, g_m is the transconductance, and C_{gs} and C_{gd} are the gate-to-source and gate-to-drain capacitance, respectively. The maximum power-gain cutoff frequency f_{max} is limited by the parasitic resistive and capacitive elements:

$$f_{max} = f_T/[4(R_g + R_s + R_{in})/R_{ds} + 4\pi f_T C_{gd}(R_g + R_s + R_{in})]^{1/2}, \tag{27}$$

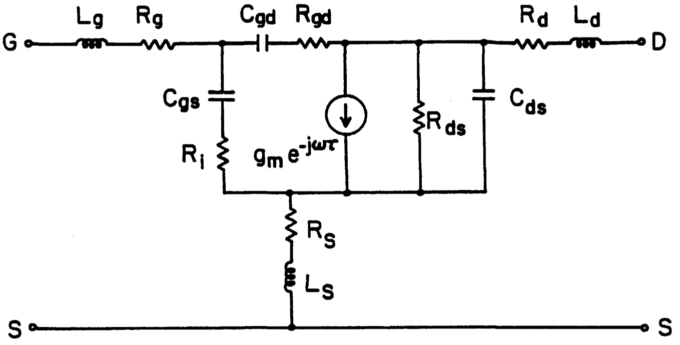

FIG. 6. Equivalent circuit of a microwave field-effect transistor.

where R_g, R_s, R_{in}, and R_{ds} are the gate resistance, source resistance, channel resistance, and source–drain output resistance, respectively, and C_{gd} is the gate–drain capacitance. For devices fabricated on a highly conductive substrate, the frequency response would be further degraded by the parasitic capacitance from the substrate.

To design a good microwave FET, it is necessary to increase the high-frequency gain by reducing the gate length as well as parasitic resistance and capacitance. However, the gate resistance increases with the reduction of gate length. The effective R_{gs} can be reduced by increasing the gate cross section using a T-shaped structure, which has a small footprint and large conductive overlay. A multiple-finger structure with shorter unit gate width per finger would also reduce the total gate resistance. To reduce the source resistance (R_s), one uses a self-aligned structure that places an ion-implanted source next to the gate as in metal-oxide-semiconductor field-effect transistors (MOSFETs) and Schottky metal-semiconductor field-effect transistors (MESFETs), or utilizes a high-mobility material as in a high–electron-mobility transistor (HEMT) structure.

With the high electric field forming under the short gate electrode, the hot-electron injection into the substrate will increase the transit delay and reduce the output resistance R_{ds}. The increase of output conductance from hot carriers will reduce the high-frequency power gain and the maximum power-gain cutoff frequency f_{max}. A higher barrier layer between the active channel and the substrate is needed to confine these hot carriers inside the channel using either a homojunction or a heterojunction. By taking all these into consideration, today's state-of-the-art microwave transistors with 0.1-μm T-shaped metal gate have demonstrated very high power-gain cutoff frequency f_{max}, up to 600 GHz using InP substrate (Smith *et al.*, 1995).

3.2 Noise Characteristics

The FET usually offers the best microwave noise performance of all types of microwave transistors. The physical reason behind this selection is that the intrinsic noise generators inside a FET are the mobility fluctuation (or velocity fluctuation) of the channel current and the thermal (or Johnson) noise from contact electrodes. For the same amount of operating current, the noise power from a resistive source is half that produced by the shot noise through a *p-n* junction. However, from the quantum-mechanical noise generation and dissipation theorem, these intrinsic noise reservoirs should be discharged through an optimal drainage impedance presented at the gate electrode at the operation frequency. Otherwise, when a nonoptimal termination impedance is connected to the gate electrode, the excess gate noise would be amplified by the gain mechanism (i.e., the transconductance) in the output drain current. Unfortunately, as shown in Fig. 7, the optimal input impedance for the lowest noise figure is not the same as the best impedance to obtain the highest gain. The selection of terminal impedance at the input is a trade-off between the noise figure and gain.

The minimum noise figure of a FET in a common-source configuration can be expressed by the widely used empirical Fukui's equation (Fukui, 1966):

$$F_{\min} = 1 + K_f 2\pi f C_{gs} \sqrt{\frac{(R_g + R_s + R_i)}{g_m}}, \qquad (28)$$

where C_{gs}, g_m, R_g, R_s, and R_i are the gate-to-source capacitance, transconductance, gate resistance, source contact resistance, and channel resistance, respectively. The constant

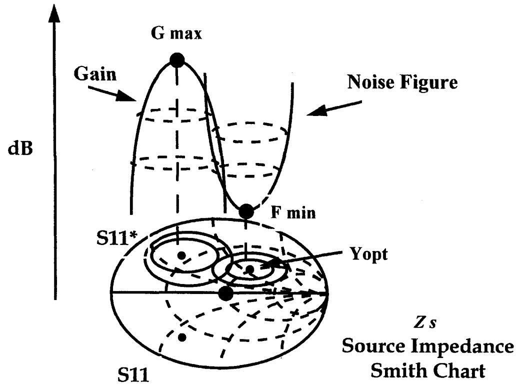

FIG. 7. Illustration of the influence of the input termination impedance on the microwave gain and noise figure of a transistor. Usually, the optimal impedance for gain is not the same as the optimal impedance for the lowest noise figure.

K_f is Fukui's constant, which has a value between 1 and 3. The value of Fukui's constant reflects the electron temperature of the drain current. It depends on the device structure as well as the carrier-transport dynamics in the channel.

The minimum-noise figure F_{min} is also a function of frequency and bias current, which is low at lower drain current and voltage. To build a low-noise microwave FET, it is important to keep the gate length short for small C_{gs}, to minimize the parasitic resistance for lower thermal noise, and to select a channel material and device structure to increase g_m and lower the electron temperature. In general, K_f is approximately 3 for the silicon *n*-MOSFET, 2.2 for a GaAs *n*-MESFET, 1.7 for GaAs HEMTs, and 1.1 for an InP *n*-HEMT. Nevertheless, the K_f factor varies quite a bit from device to device even with the same material system depending on the device structure and bias condition.

The low-frequency noise fluctuations in a FET channel are much worse than in the junction bipolar transistor. The large amount of low-frequency fluctuation, which is well below tens of megahertz, comes from the trapping and detrapping process from the deep states in substrate and surface, usually in the $1/f$ or Lorentzian form. This low-frequency noise current would significantly deteriorate the frequency stability, or the phase noise performance, of a microwave FET oscillator. To reduce the low-frequency noise current, a better surface passivation layer and better buffer layer (Hughes *et al.*, 1987), such as a superlattice or a *p-n* junction, should be introduced to isolate the FET channel from these noise sources.

3.3 Microwave Metal-Oxide-Semiconductor Field-Effect Transistors (MOSFETs)

Most of the high-speed MOS processes for digital integrated circuits use polycrystalline silicon gate electrode for logic gates with very small gate width of tens of microns. However, a large gate periphery, in the order of hundreds of microns, is needed to produce enough transconductance for most microwave applications. The large gate resistance from polysilicon material degrades the noise and power gain significantly. For microwave applications, low-resistance silicide and metal films are used for the gate electrode material.

The cross section of a typical microwave MOSFET is shown in Fig. 8. The lightly doped drain contact region, L_r, determines the breakdown voltage of the transistor. The source is connected to the substrate ground plane through a deep P^+-implanted sinker to reduce the inductance of the source contact. The turnon knee voltage at a high drain current is determined by the gate length, L_g. For applications requiring high power-added efficiency or running at low supply voltage, a submicron gate is needed to reduce this turnon voltage (Yoshida and Katsueda, 1995).

Because of the low mobility associated with a silicon MOSFET, a large gate perimeter is needed to obtain high voltage gain and large power density. The large transistor dimension suffers high microwave loss from interconnection metallization and large cross talk between devices fabricated on a highly conductive silicon substrate. The use of silicon-on-insulator (SOI) technology, where a very thin silicon epitaxial layer is formed on top of an insulating dielectric film or substrate such as sapphire, greatly reduces these parasitics. Submicron-gate microwave CMOS/SOI FETs have been demonstrated with excellent noise characteristics (de la Houssaye *et al.*, 1995). However, the defect density of the silicon epilayer on the insulators is still high (in the order of 10^6/cm^2 today) for practical integrated-circuit applications.

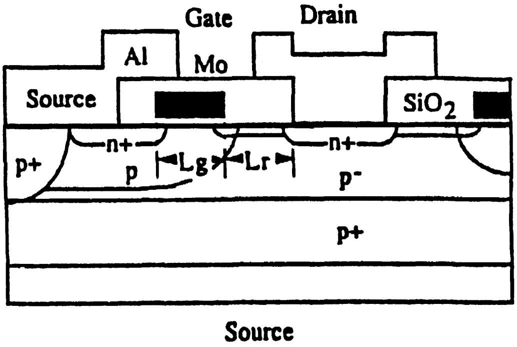

FIG. 8. Cross section of a microwave silicon MOSFET.

3.4 Microwave Schottky Metal-Semiconductor Field-Effect Transistors (MESFETs)

Since the 1970s, MESFETs (metal-semiconductor field-effect transistors) have dominated microwave transistors beyond 1 GHz because they are implemented with the high electron mobility and saturation velocity of the GaAs compound semiconductor. It is difficult to form a stable insulating layer on the GaAs surface to build GaAs MOSFETs or MISFETs. Instead, a Schottky junction is used to control the channel current by placing the metal electrode directly on a thin, doped semiconductor layer. The conductance of the channel is then modulated by the depth of depletion region formed underneath the Schottky metal. As more reverse bias is applied to the gate, eventually the whole channel is depleted and the transistor is turned off. The frequency response of a MESFET is determined, to the first order, by the single pole formed by this depletion capacitance C_{gs} and the transconductance g_m, and its rolloff frequency is $f_T = g_m/2\pi C_{gs}$. For MESFET transistors designed for high frequency, it is important to keep a small C_{gs} by shrinking the gate length and to obtain high dc transconductance by utilizing a thin and highly conductive semiconductor with high mobility and saturation velocity. The overall frequency response of the MESFETs would be further degraded by other parasitic elements, such as gate resistance, gate–drain capacitance, substrate capacitance, etc.

For most MESFETs made of compound semiconductors using GaAs or InGaAs, the channel current is limited by the saturated electron velocity rather than the low-field mobility as in silicon. In these GaAs FETs, electrons are injected from the source contact and accelerated under low electrical field in the channel toward the gate depletion region in the central valley of the conduction band with a high mobility. These electrons are then modulated by the gate potential and accelerated by the high electric field along the boundary of the gate–drain depletion region. However, as electrons acquire more energy, most of them are no longer confined in the high-mobility main valley (Γ valley) in the conduction band; instead, they are scattered into low-mobility satellite valleys (L and X valleys). This happens under a small drain bias, typically less than a volt. These electrons continue to drift toward the drain contact with the saturated velocity.

The threshold voltage V_T, where the channel current is cut off, is

$$V_T = \phi_B - \frac{1}{\epsilon}\iint \rho(x)d^2x \tag{29}$$

with a maximum channel current I_{max} of

$$I(V_{GS}) = qZv_s \int_{VT}^{VGS} \rho(x)dx, \tag{30}$$

where the $\rho(x)$ is the channel doping profile, ϕ_B is the Schottky barrier height, Z is the total gate width, and v_s is the saturated electron velocity. The channel doping, $\rho(x)$, can be introduced either by directly implanting the dopants into the semi-insulating substrate or by using epitaxial growth techniques. The threshold voltage can be made either positive for enhancement-mode devices or negative for depletion-mode devices by adjusting the doping and thickness of the channel material. However, significant gate current and even catastrophic damage will occur when the gate electrode is forward biased beyond the turnon voltage of the Schottky diode.

Figure 9 shows a typical GaAs MESFET structure with a double-recessed channel region for high-power applications. A short gate length and low parasitic source and channel resistance are needed to produce high power gain at microwave frequency. The metal gate is usually placed asymmetrically between the source and drain, which is

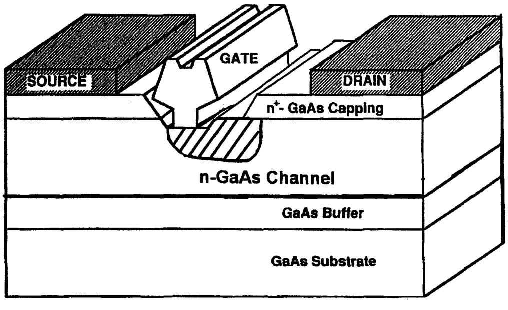

FIG. 9. Cross section of a microwave GaAs MESFET.

closer to the source to reduce the source resistance and away from the drain to obtain higher breakdown voltage. The source–drain breakdown voltage BV_{DS} equals $BV_{\mathrm{GS}} - V_{\mathrm{T}}$, where BV_{GS} is the gate–drain breakdown voltage and V_{T} is the threshold voltage. To increase the breakdown voltage, a low-doped semiconductor is placed under the gate metal, and a fully depleted and well-passivated surface layer is placed on top of the channel between the gate and drain contacts.

The transconductance $g_{\mathrm{m}} = \Delta I_{\mathrm{DS}}/\Delta V_{\mathrm{GS}}$ usually increases with the gate voltage. The nonuniform transconductance will affect the linearity of a high-power amplifier under large signal modulation. Special doping profiles, such as exponential or pulse shape, can be prepared by modern epitaxial growth techniques to obtain a constant transconductance over a wide bias range.

Combining the self-aligned implantation and a T-shaped metal gate, both the source resistance R_{s} and gate resistance R_{g} of a MESFET with a submicron gate length can be made very small. The MESFET structure will have a current-gain cutoff frequency f_{T} as high as that of a HEMT structure assuming the same gate length and saturated carrier velocity in the channel (Moll *et al.*, 1994) This also means that an optimized GaAs MESFET structure would deliver the similar minimum noise figure as a HEMT structure with the same gate length, gate resistance, source resistance, and transconductance, from Fukui's noise equation (Feng and Laskar, 1993).

However, for the same noise performance, the power gain of a GaAs HEMT or the power-gain cutoff frequency f_{max} is usually higher than that of a GaAs MESFET of the same gate length. The output resistance of a HEMT is also higher than that of a MESFET with similar gate length. This leads to a lower overall noise figure of a cascaded multistage amplifier where high gain in the first and second stages is essential to reduce effectively the noise generated from the later stages as shown in Eq. (4). This is the reason why HEMTs are widely used in commercial multistage microwave low-noise amplifiers to provide high gain with lower noise figure and fewer stages.

The output resistance of a short-channel MESFET is lowered by the injection of high-energy carriers into the buffer and substrate from the doped channel. For MESFETs with short gate length, a significant amount of electrons are injected into the substrate by the high electric field under the gate. The hot carriers in the substrate have a long transit delay, which is dephased from the carriers staying in the channel, and decreases the output resistance of the transistor. The low output resistance or high output conductance would reduce the microwave gain and increase the drain noise current. To reduce the output conductance of the short-channel MESFETs, the thickness of the doped channel should be reduced and a high–potential-barrier buffer layer such as a heterojunction or *p-n* junction is usually added between channel and substrate. With the reduced channel thickness, a higher channel doping density is needed to maintain a high transconductance. This may present a practical problem in fabricating an ion-implanted structure with gate length below 0.3 μm. It is difficult to control the thin depth and high dosage under a low implantation energy. Therefore, most short-channel MESFETs utilize an epitaxial structure with a thin, highly doped channel and a heterojunction energy barrier at the channel–substrate interface. This is usually done by incorporating a "pseudomorphic" or "lattice-strained" structure with a small fraction of indium added into the channel. The compressive strain energy as well as the indium-rich alloy effectively increases both the energy separation of the high-mobility center valley and low-mobility satellite valleys of the channel and the channel–substrate interface barrier. This results in a higher saturated carrier velocity and better output conductance, which have already been built into the quantum-well HEMT structure.

3.5 High-Electron-Mobility Transistors (HEMTs)

Esaki and Tsu (1969) first suggested the concept of utilizing a modulation doping technique to separate electrons spatially from their ionized parent donors by an abrupt heterojunction interface. Electrons from the donors in the wide-band-gap materials are transferred and confined in a two-dimensional potential well in the narrow-band-gap material forming a two-dimensional electron gas (2DEG). In the absence of scattering by the ionized donors, these electrons have high mobility and large carrier density confined within a thin layer. With the advancement of molecular-beam epitaxy (MBE) technology, this concept was first demonstrated by Stromer *et al.* (1979). In 1980, the first HEMT was demonstrated by Mimura *et al.* (1980). Combining the high electron mobility and the thin quantum-well structure for better charge confinement in a scaled FET, the HEMT has dominated low-noise applications from 10 to 100 GHz. When HEMTs are cooled down to cryogenic temperature, their microwave low-noise performance rivals that of microwave masers. Today, HEMTs have been used extensively in radars, satellite receivers, and high-speed optical-fiber communication systems.

Figure 10 shows a typical HEMT structure, and Fig. 11 shows the conduction-band diagram underneath the metal gate. By placing a metal gate on the wide-gap AlGaAs supply layer, the Schottky barrier depletes the doped AlGaAs and transfers the electrons into the GaAs quantum well to form the 2DEG. Other features of the HEMT active structure are the thin undoped AlGaAs "spacer" layer between the highly doped AlGaAs supply layer and the undoped GaAs channel, and the heavily doped GaAs "cap" region above the AlGaAs layers. The spacer layer further separates the 2DEG from ionized donors for high mobility at the cost of total charge transferred to the GaAs. The heavily doped GaAs cap layer facilitates formation of Ohmic contacts to the device.

For a typical heterointerface such as AlGaAs/GaAs, the conduction-band offset is about 0.3 eV and generally only two lower subbands are populated at room temperature. When the AlGaAs layer is totally depleted, the density of the 2DEG can be controlled by the gate bias as

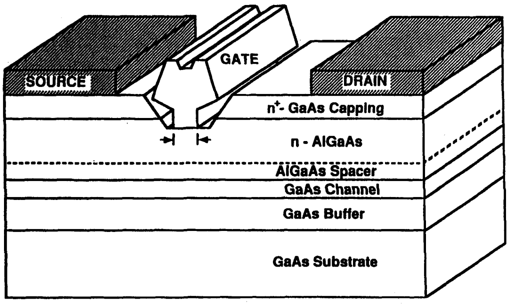

FIG. 10. Cross section of an AlGaAs/GaAs HEMT.

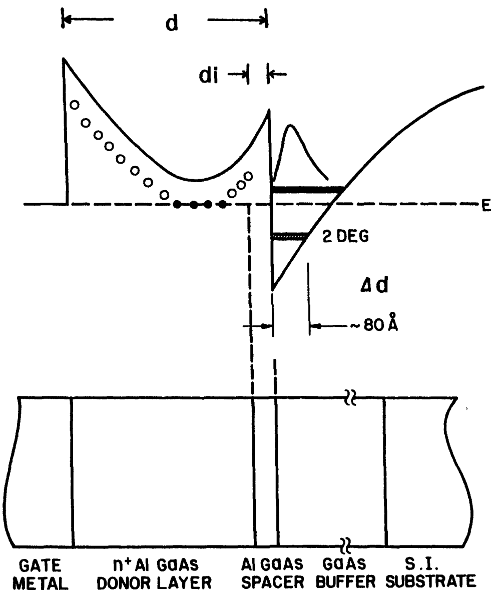

FIG. 11. Conduction-band diagram of an AlGaAs/GaAs HEMT at thermal equilibrium.

$$n_s = C_0(V_G - V_T)/q, \qquad (31)$$

where $C_0 = \epsilon\epsilon_0/(d + \Delta d)$ is the depletion capacitance between that gate and the 2DEG, $d + \Delta d$ is the average distance between the gate and the 2DEG, Vg is the gate bias, and V_T is the threshold voltage (Delagebeaudeuf and Linh, 1982). As the gate potential becomes more positive, the thickness of the depletion region is reduced, and eventually the low-mobility AlGaAs supply layer will start conducting and stop transferring electrons over the heterointerface. The maximum 2DEG density n_{s0} that can be provided by a heterointerface is approximated by

$$n_{s0} = \epsilon\epsilon_0(\Delta E_c - E_{F0})/(\alpha + q^2 d_i) \qquad (32)$$

through a self-consistent Poisson solver, where ΔE_c is the discontinuity of the conduction-band edge at the heterointerface, $\epsilon\epsilon_0$ is the specific dielectric constant of the supply layer, E_{F0} is the quasi-Fermi level in the 2DEG, d_i is the thickness of the spacer layer, and α is a constant.

The lateral-current transport mechanism in a HEMT from the source to drain can be modeled as a MESFET with two conductive layers, the low-mobility doped wide–band-gap supply layer and the high-mobility 2DEG in the undoped narrow-gap quantum well. It is important to design a HEMT structure such that all the lateral current flow is conducted by the high-mobility 2DEG layer. This is achieved by using a thin, heavily doped supply layer, which will be depleted by both the Schottky barrier potential and the potential spike from the conduction-band discontinuity. Under this condition, the maximum transconductance g_{m0} and maximum 2DEG channel current $I_{m,2DEG}$ are given by

$$g_{m0} = Zv_sC_0, \tag{33}$$

$$I_{m,2DEG} = qn_{s0}v_sZ, \tag{34}$$

where the average saturated velocity v_s is used for a HEMT with a total gate width of Z.

Because the carriers are traveling at the saturated velocity, the current-gain cutoff frequency is limited to $v_s/2\pi L_g$, which is similar to that of a MESFET of the same gate length. However, the microwave output conductance improved tremendously with the quantum confinement, and the high-frequency gain, or power-gain cutoff frequency, f_{max}, is higher than that of the conventional MESFET structure. The high mobility, thin supply layer, and quantum-confined layer structure are translated into low source resistance, high transconductance, and high output resistance for low-noise, high-gain, submicron-gate HEMTs. The processing steps for HEMTs are greatly simplified by the use of precise epitaxial growth techniques such as molecular-beam epitaxy (MBE) with an atomic-scale accuracy.

To enhance the current-handling capability of a microwave HEMT, it is important to select a heterostructure with a high conduction-band discontinuity and a narrow-gap material with high saturation velocity. A high conduction-band discontinuity helps suppress the back injection, or the real-space transfer, of the energetic 2DEG carriers into the supply layer by the electric field in the channel. The conduction-band discontinuity can be increased by introducing a lattice-strained (or pseudomorphic) quantum well at the heterointerface, such as adding a small fraction of indium into the GaAs quantum well. However, there is a limit on how much lattice mismatch the substrate material may tolerate, which is governed by the critical thickness of the strained epilayer, before the epilayer becomes unstable and relaxed. Another approach to increase the current-driving capacity is to incorporate multiple heterointerfaces. Special attention is needed in designing these structures to minimize the parallel conduction channels in the low-mobility supply layers.

To achieve good microwave performance, good process practice has to be exercised to reduce the gate resistance and source contact resistance. Usually, a T-shaped gate metal profile is fabricated with a submicron-gate footprint on the semiconductor and a thick and wide top-metal layer on the top to reduce the gate resistance. The source contact resistance is obtained by using a very heavily doped and sometimes lattice-strained narrow-gap cap layer. For higher gate-to-drain breakdown voltage, a pulsed-doped supply layer replaces the uniformly doped supply layer by an undoped wide-gap layer under the Schottky gate and a very highly doped thin supply layer in a few atomic layers.

Operating these HEMTs at cryogenic temperature enhances the mobility of the 2DEG and decreases the source resistance R_s by reducing the polar optical-phonon scattering. The noise figure is then improved significantly by the reduction of Johnson noise and by the increase of transconductance. The carrier confinement of the 2DEG is also improved at low temperature. However, the deep donors in the wide-gap supply layer may be frozen out at cryogenic temperature, and a LED is usually needed to activate these donors. Some emerging new material systems, such as AlInAs/InGaAs *n*-channel HEMTs on the InP substrate and Si/SiGe *p*-channel HEMTS on the silicon substrate, have demonstrated excellent microwave performance. Table 2 shows semiconductor material systems commonly used to fabricate HEMTs.

4. MONOLITHIC MICROWAVE INTEGRATED CIRCUITS (MMICs)

Mehal and Wacker from Texas Instruments demonstrated the first GaAs MMIC in 1968 (Mehal and Wacker, 1968). By the mid-

1970s, a great advancement of GaAs MESFET technology had been achieved, and researchers began to build MMICs. The MMIC is a microwave-integrated circuit that is built on a single semiconductor substrate and composed of both active microwave transistors and passive circuit elements such as capacitors, inductors, transmission-line elements, and bias and interconnection lines. During the cold war era through the end of 1980s, the early drive on MMICs was mainly by the instrumentation and military applications, which demand high performance, small size, and weight reduction. Not until the early 1990s were the real advantages of MMICs, in terms of low cost, high performance, small size, high reliability, reproducibility, and tolerance to environment changes, realized through mass consumer applications. Today, MMICs have been used to implement applications from simple microwave-radio building blocks such as low-noise amplifiers, oscillators, and power amplifiers to multifunctional subsystems such as integrated-frequency down-converters that integrate low-noise amplifiers, local oscillators, mixers, and intermediate-frequency amplifier all on a single chip. Many GaAs MMICs and silicon MMICs can be found in many popular items such as cordless phones, wireless mobile phones, and direct-broadcast satellite (DBS) receivers.

Figure 12 shows a microphotograph of a Lucent Technologies' broad-band dc–20 GHz 4-stage distributed amplifier using 0.25-μm HEMTs as active elements and on-chip integrated resistors, inductors, and capacitors to form passive low-loss matching networks.

4.1 Semiconductor Substrate for MMICs

Many semiconductor materials, such as gallium arsenide (GaAs), silicon (Si), and indium phosphide (InP) substrate, which are

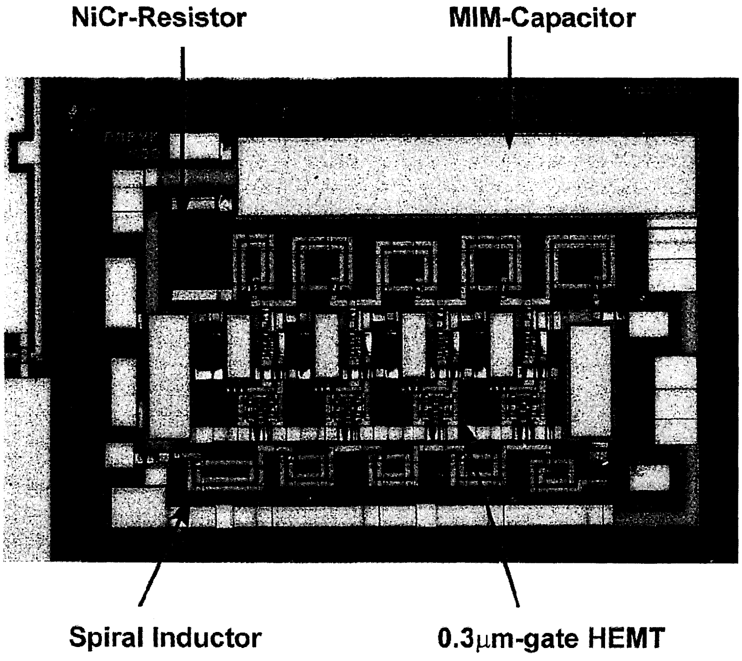

FIG. 12. Photomicrograph of a dc–15-GHz HEMT traveling-wave amplifier integrated circuit. Active HEMTs, metal-insulator-metal (MIM) capacitors, spiral inductors, and thin-film resistors are fabricated on the same chip. The dimensions of the circuit are 1 × 1.5 mm^2.

used to fabricate active microwave transistors, can be used to integrate passive elements as well. However, the Ohmic loss and dielectric loss of the substrate may impede the performance of low-loss transmission lines and high-quality inductors at microwave frequency. MMICs with operating frequency more than 100 GHz have been realized on semi-insulating GaAs and InP substrates. However, the high substrate leakage limits the operating frequency of silicon MMICs below 5 GHz using conventional highly doped substrates and less than 50 GHz on high-resistivity bulk silicon substrates or silicon-on-insulator substrates.

To control the characteristic impedance of the transmission lines on the substrate and improve the heat dissipation, the substrates are usually thinned down to a thickness of 50 to 100 μm with the back side metallized as heat sink and ground plane. To reduce the inductive interconnections to ground terminals, via holes are formed by selectively etching holes through the substrate and backfilled by metals to connect the top electrodes to the ground plane on the back side of the wafer.

4.2 Matching Networks

The overall circuit response of a MMIC is determined by both the microwave transistors and other circuit elements. As discussed in the previous sections, the gain of a microwave transistor decreases at high frequency. The noise figure and output microwave power of a microwave transistor are enhanced when specific input and output impedance are presented to its terminals. The optimal value of the impedance that a transistor would like to see may be quite different from the impedance provided by a microwave source and the load. Matching networks are introduced to transform the input impedance of a transistor, with no or little loss, to the source impedance of a generator, and its output impedance to a specific load (maybe the input of the next transistor). The frequency-dependent gain of the transistor is equalized by using a combination of high-pass and low-pass networks throughout the circuit. The matching network is also critical to eliminate the out-of-band instability and spurious response of the circuits by lowering the gain and impedance level outside the signal bandwidth with a frequency-selective filter.

The matching network may be implemented with both active microwave transistors and passive elements. The transistor is a very good broad-band impedance transformer up to about one-tenth of its cutoff frequency. When operated near its cutoff frequency, the frequency of this active transformer is loaded by many parasitic elements and is very difficult to handle. The use of the active matching network is further limited by the excessive noise generation and dc power consumption of transistors.

Most of the matching networks at microwave frequency are realized with passive circuit elements. For microwave frequencies below 10 GHz, low-loss passive lump elements such as spiral inductors, parallel-plate metal-insulator-metal (MIM) capacitors, and resistors can be used when their physical dimensions are much smaller than a quarter of a wavelength and the distributed effect is not dominating. Beyond 10 GHz, the use of distributed transmission-line circuit elements is necessary.

4.3 Passive Lump Elements

The quality factor (Q), that is, the ratio of the microwave energy stored to the energy dissipated in the network, directly affects the bandwidth, noise, and power performance of the MMIC. It is very important to select high-Q passive elements to implement the input, output, and interstage matching networks. For the lower microwave frequencies, less than 15 GHz, matching networks may be implemented using lumped passive elements such as capacitors, inductors, and resistors. Beyond 15 GHz, it is very difficult to utilize these lump elements because of the self-resonance, caused by many parasitics from the distributed effects and substrate ground plane.

Metal–insulator–metal (MIM) capacitors are commonly realized in the MMIC process for by-pass or coupling purposes. They use two metal layers separated by a thin dielectric material, typically silicon dioxide (SiO_s) or silicon nitride (Si_3N_4) with a thickness about 200 nm. The Q factor of a capacitor is

$$Q_C = 1/2\pi fRC, \qquad (35)$$

where f is the operating frequency, C is the capacitance, and R is the loss of the dielectric and metal plates. The use of MIM capacitors at high frequency is limited by the self-resonant frequency of about 12 GHz. At high frequency, the distributed effects are present on top and bottom electrodes. The self-resonant frequency is determined by these inductive elements and the distributed parallel-plate capacitance. For frequency beyond 10 GHz, capacitors are realized with interdigitated fingers or a small gap between two transmission lines.

Inductors are realized by multiturn spirals or rings. The inductance is determined by the self-inductance of each line segment and the mutual inductance among line segments. The Q factor of an inductor is

$$Q_L = 2\pi f L/R \tag{36}$$

where f is the operating frequency, L is the inductance, and R is the loss from metal lines and substrate. To build a low-loss inductor, it is essential to reduce the substrate loss and metal loss. The substrate loss may be reduced by using high-resistivity substrates, while the metal loss is dominated by the width, length, and conductivity of metal lines. At low microwave frequency, around 1 GHz, the metal loss is dominated by the skin depth of the metal, typically about 1 μm for gold and aluminum. It is important to deposit a very thick metal layer, at least three times the skin depth, to minimize the conductor loss for inductors and MIM capacitors at low microwave frequency. The self-resonant frequency of a spiral inductor is limited by the capacitive elements from the ground plane usually to 15 GHz on a semi-insulating GaAs substrate or 5 GHz on a doped bulk silicon substrate.

The resistors in a MMIC are realized by using a deposited thin resistive film such as nickel-chrome (NiCr) and tantalum nitride (TaN) or the doped semiconductor layer. The resistance R is determined by

$$R = \rho L/W, \tag{37}$$

where ρ is the resistivity of the film, L is the length, and W is the width. The deposited resistors are accurate and insensitive to temperature variation but low in resistivity and occupying a large chip area. The semiconductor film provides higher resistivity, but it is sensitive to temperature variations and parasitic junction capacitance from the buffer layer or substrate.

4.4 Passive Distributed Elements

Both inductive and capacitive elements at microwave frequency are realized using short transmission-line sections. It is also easy to implement any impedance matrices by adjusting length (L), width (W), and the characteristic impedance (Z_0) of the integrated transmission lines. Open, short, and impedance transformation can easily be implemented with the help of quarter-wavelength transmission lines. Transmission lines are very stable over the temperature variations, and their loss is very low. Disadvantages of the transmission-line matching network are its large size, frequency sensitivity, and narrow bandwidth.

Commonly used transmission lines for MMICs are microstrip (MS) and coplanar transmission lines. Both of them have very low propagation loss and frequency dispersion on a semi-insulating substrate, with cutoff frequency beyond 100 GHz. The microstrip transmission line consists of a top metal line on a substrate with a back-side ground plane. The characteristic impedance of a microstrip transmission line is determined by the width of the stripe and the thickness and dielectric constant of the substrate. The dependence of characteristic impedance on the width of a microstrip line on a GaAs substrate is illustrated in Fig. 13. The use of microstrip lines also requires substrate via holes to provide low-inductance ground connections to the circuit elements on the top of the wafer.

The coplanar waveguide (CPW) transmission line is a true TEM waveguide that consists of a central signal metal line separated by a gap from two adjacent ground planes on top of a semi-insulating semiconductor substrate. The characteristic impedance of the CPW lines is controlled by the width of the central conductor, the width of the gap, the substrate material, and the distance of the back-side ground plane. Usually, MMICs using CPW matching networks may avoid via holes and thinning of the substrate, which add extra processing cost. Higher characteristics can be realized on CPW lines than on

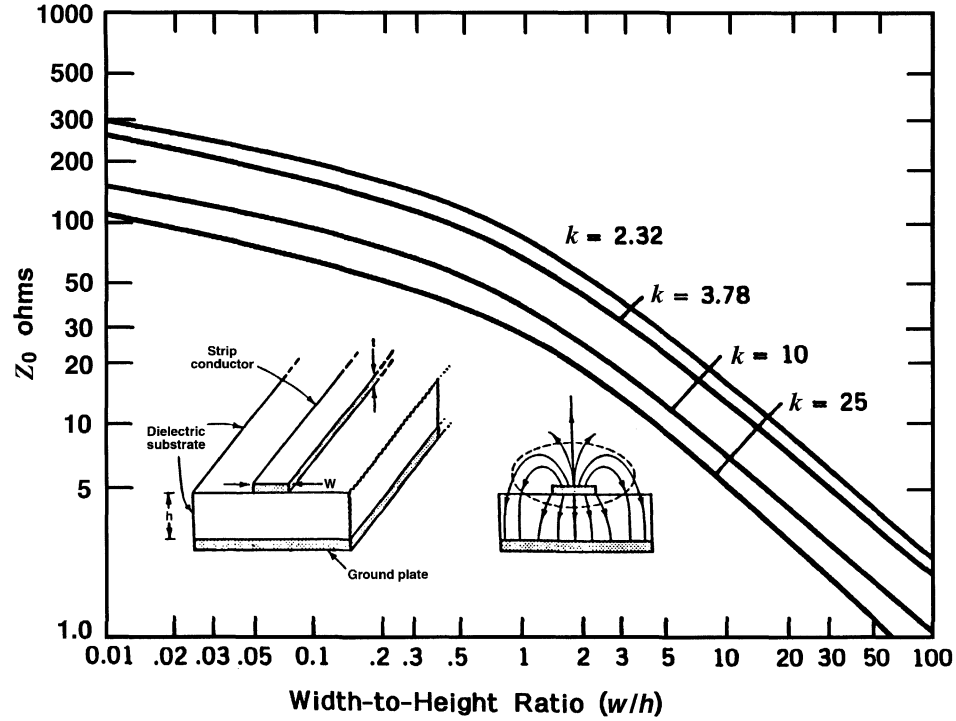

FIG. 13. Characteristic impedance of microstrip transmission line as a function of the width/height ratio, *w*/*h*, and effective dielectric constant, *k*.

MS lines. However, the propagation loss is slightly higher for CPW because of the strong coupling effects on the edges of the central conductor to ground planes. Additional connections between two ground planes are also needed along the transmission line to avoid possible unbalanced potentials between them.

4.5 Computer-Aided Design of MMICs

As the dimensions of circuit elements integrated on a MMIC are comparable to a fraction of the wavelength, many fringing fields will be produced near the intersections where different transmission lines, bias lines, and devices are connected together. These small field disruptions may affect the frequency response of matching networks and have to be accommodated by transmission-line design parameters. This is usually done by using a two-dimensional (2D) or three-dimensional (3D) finite-element electromagnetic (EM) wave computer simulator to predicate their behavior. Many high-performance circuits also require taking the large signal-time transient into the design process with the passive elements.

Thanks to the investments during the cold-war era in the late 1980s, many of these sophisticated time- and frequency-domain tools such as SPICE for time domain, harmonic balance simulators for frequency domain, and 3D EM simulator for complete MMIC layout are readily available and highly integrated into other circuit simulators. The signal integrity, interference, and cross talk of the microwave signals on the chip and between MMICs may now be analyzed and optimized. These CAD tools greatly eliminate much of the mystery of microwave and millimeter-wave design and shorten the design cycles significantly. These tools help realizing many sophisticated, multifunctional microwave integrated circuits and subsystems with high performance and low production cost.

GLOSSARY

Ballast Resistor: The resistor placed in series with each emitter when massive parallel emitter-base junctions are assembled to build a power bipolar transistor. This resistor is needed to desensitize the variations in the turn-on potential and thermal distribution among transistor cells.

Coplanar Waveguide Transmission Lines (CPW): A transmission-line structure that is a true TEM (transverse electrical and magnetic wave) waveguide, consisting of a central metal signal line separated by a gap from two adjacent ground planes on top of a semi-insulating substrate.

Equivalent-Circuit Model: The dynamics of physical carrier-transport properties of a transistor is simplified and modeled by a set of simple linear lump elements such as resistors, capacitors, and dependent current and voltage sources.

Heterojunction Bipolar Transistor (HBT): A bipolar transistor utilizing an emitter composed of a lighter doped and wider band-gap material than that in the base. A high current gain is realized by using the heterojunction barrier at the emitter–base interface to block the back-injected majority carriers from the base and subsequently to reduce the recombination current.

High–Electron-Mobility Transistor (HEMT): A transistor structure that utilizes a heterostructure to accumulate two-dimensional electron gas in the lightly doped high-mobility, narrow–band-gap channel and locate ionized donors from the highly doped wide–band-gap layer. The separation of electrons and ionized donors results in high electron mobility and low access resistance.

Johnson Noise: See **Thermal Noise.**

Matching Network: A circuit network that matches the impedance between its source and its load. It may be implemented with either active or passive elements.

Maximum Unilateral Power-Gain Cutoff Frequency (f_{max}): The frequency at which the unilateral power gain U decreases to unity, when both input and output of the transistor are matched and internal feedback is also nullified by an external tuning element. This is also known as the **maximum oscillation frequency** at which a microwave oscillator circuit can operate using this transistor.

Metal-Insulator-Metal (MIM) Capacitor: An integrated capacitor structure on a semiconductor that uses two metal layers separated by a thin dielectric material, usually silicon dioxide (SiO_2) or silicon nitride (Si_3N_4).

Metal-Oxide-Semiconductor Field-Effect Transistor (MOSFET): A transistor structure that utilizes the electrical field between the metal gate electrode and the semiconductor surface, separated by a thin oxide layer, to modulate the conductivity of the semiconductor channel.

Metal-Semiconductor Field-Effect Transistor (MESFET): A transistor structure that utilizes the Schottky barrier of the metal–semiconductor interface to modulate the conductivity of the semiconductor channel.

Microstrip Transmission Lines: A transmission-line structure that is a quasi-TEM (transverse electrical and magnetic wave) waveguide, consisting of a metal signal line on top of a semi-insulating substrate with a back-side ground plane.

Microwave: Any electromagnetic wave in a frequency range commonly regarded as extending from 300 MHz to 300 GHz, covering the spectrum lying between the radio frequency and the far infrared.

Millimeter Wave: The part of the spectrum higher than 30 GHz is regarded as the millimeter-wave band, as the corresponding wavelength in the free space is comparable or shorter than a millimeter.

Minimum Noise Figure (F_{min}): The noise figure of a transistor reaches its minimum value F_{min} when its input is connected to an optimal admittance set by the quantum-mechanical fluctuation and dissipation theory.

Molecular-Beam Epitaxy (MBE): A nonequilibrium epitaxial growth technique utilizing molecular beams in a high-vacuum chamber to form thin films lattice-matched on single-crystal semiconductor substrates.

Monolithic Microwave Integrated Circuit (MMIC): A microwave circuit that integrates both active and passive circuit elements on a single semiconductor substrate.

Noise Figure (F): A measure of the output signal quality, defined as the ratio of the input signal-to-noise ratio to that of the output.

Organometallic Vapor-Phase Epitaxy (OMVPE): An equilibrium epitaxial growth technique that utilizes atoms from organometallic vapors in a high-temperature reactor to form thin films lattice-matched on single-crystal semiconductor substrates.

Quantum-Mechanical Fluctuation and Dissipation Theory: A theory stating that the internally generated noise will be minimized once these noise sources can be dissipated through an optimal external impedance.

Scattering Parameters: A representation of a two-port network that utilizes incident and reflected power wave forms from a known termination reference impedance to characterize the transistor at microwave frequency.

Shot Noise: A broad-band noise source produced by the random scattering of carriers passing through a semiconductor junction. Its magnitude is proportional to the current. The upper frequency limit of the shot noise is determined by the mean scattering time of the charged carrier in the depletion region.

Short-Circuit Current-Gain Cutoff Frequency (f_T): The highest frequency at which the current gain of a microwave transistor can reach unity with a short-circuit load.

Thermal (or Johnson) Noise: A broad-band noise generated by a resistive element. Its magnitude depends on the operating temperature and the value of the resistance.

Two-Dimensional Electronic Gas (2DEG): Electrons that are confined in a two-dimensional quantum well to form an electron gas. The quantum well can be formed by using a thin-surface inversion layer on a metal–oxide–semiconductor interface or a heterointerface between two semiconductors with different band-gap energy.

Unilateral Power Gain (U): The maximum power gain that a transistor can deliver at a given frequency, when the input and output of the transistor are connected to conjugate-matched impedance and the internal feedback in the transistor is also nullified by an external feedback circuit for maximum power transfer.

INTRODUCTION

Power electronics is an essential part of a large variety of consumer and industrial systems. At lower power levels, it is used in power supplies (for computers and telecommunications), in lighting, in displays, and in automotive electronics. At medium power levels, it is used in motor control (for heating, ventilating, and air conditioning), in factory automation (or robotics), and in electric vehicle drives. At high power levels, it is used in traction (electric streetcars/trams and locomotives) and in electricity distribution (high-voltage dc transmission). In order to regulate the power flow, all the power electronic circuits must utilize a power switch. Power switches based upon semiconductor technology are recognized as the enabling technology with advances in their performance dictating improvements in the efficiency, size, and weight of all power-electronics–based systems. Power transistors are the predominant switch technology used in low- and medium-power applications. Their current- and voltage-handling capability (called ratings) is as yet insufficient for satisfying the requirements of the high-power applications, which rely on thyristors at present.

1. IDEAL POWER-TRANSISTOR CHARACTERISTICS

An *ideal* power transistor must be able to control the flow of power from a source to a load without internal power dissipation. The load may be inductive (such as motors, solenoids, etc.), resistive (such as heaters and lamp filaments), or capacitive (such as transducers and display elements). Most often, the power to the load is controlled by switching the device on a periodic basis to generate pulses of current flowing through the device. In this case, there must be no voltage drop across the device when it is conducting current in the on state, and there must be no current flowing through the device when it is supporting voltage in its off state. An *ideal* device must also be able to switch between these states with no power dissipation. This requires an instantaneous change in the voltage and current during the

digital Encyclopedia of Applied Physics

switching transients. In the ideal case with 100% efficiency, the output power must be controlled with zero input power. In addition, the device should be able to control an arbitrarily high power level, which implies high voltage- and current-handling capability.

The output characteristics of an ideal three-terminal power switch are shown in Fig. 1. For general applicability, the ideal switch must be able to block and conduct current for both directions of current flow under the control of a signal applied to its gate electrode. This requires operation of the device in both the first quadrant and third quadrant of the *I–V* characteristics. In either quadrant, the device must be capable of supporting a very high voltage with zero current flow. These states are referred to as *forward blocking mode* and the *reverse blocking mode.* When switched to the conducting state, the device must be capable of carrying a very high current with zero voltage drop. This is referred to as the *on state.* In addition, it is desirable for the device to regulate the output current under the guidance of the gate signal. This requires a gate-controlled current saturation characteristic as shown in the figure. In order to maintain zero power losses in the input circuit, the gate control signal can be a current applied with zero voltage drop in the control circuit or a voltage signal with zero current flow in the control circuit. It has been found that it is easier to approach the ideal control case with the latter option.

Power transistors are usually designed to operate only in the first quadrant. They are not expected either to support or to carry substantial current in the fourth quadrant. They are used in power circuits with a dc power bus to supply the power to loads. The output characteristics of power transistors that are commercially available vary greatly from those outlined for an ideal device. The characteristics of specific devices are discussed in this article. In general, all the devices can support only a limited voltage and with a finite *leakage current* when blocking current flow. This result is power dissipation during the blocking mode, which increases rapidly with increasing temperature. This can lead to a thermal runaway problem unless the heat sink is designed to maintain the temperature below defined limits. Further, all the transistors exhibit a finite voltage drop during on-state current flow, leading to power loss. Because of the nonzero switching times for the devices, substantial power losses can also occur during the turn-on and turnoff transients, leading to large power losses at higher operating frequencies. Further, there can be substantial power dissipation in the input control circuits for some devices, which must be accounted for when optimizing the overall power system performance.

2. BIPOLAR POWER TRANSISTORS

The basic structure for a bipolar power transistor (see TRANSISTORS, BIPOLAR) is shown in Fig. 2. The bipolar power transis-

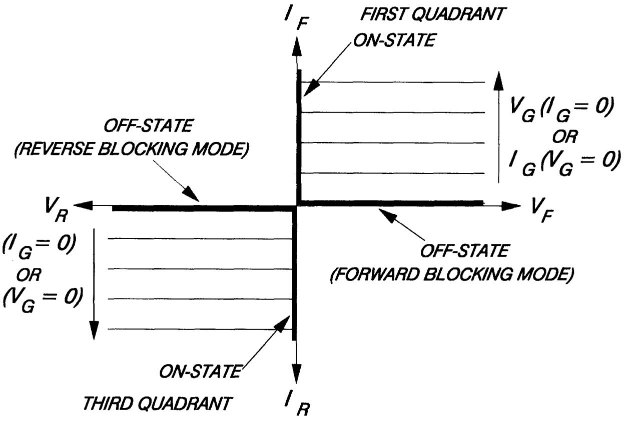

FIG. 1. Characteristics of an ideal power transistor. V_G, gate voltage; I_G, gate current; V_F (V_R), forward (reverse) voltage; I_F (I_R), forward (reverse) current.

tor is fundamentally a current-controlled three-terminal switch. It is usually operated in the common-emitter configuration with the collector current controlled by the magnitude and polarity of the input base current. For ease of control, it is desirable to operate the device with small base currents to control large collector currents. This allows operation of the device with a high power gain, which is of course also dependent upon the ratio of the collector and gate operating voltages. In some power circuits, it becomes necessary to operate the bipolar transistor in the common-base configuration as well. This operation results in a current gain of less than unity.

2.1 Current Gain

In both the common-base and common-emitter configurations, the collector current flow is controlled by the application of a voltage between the base and emitter terminals so as to forward bias the emitter–base junction. For the case of the *n-p-n* transistor, the forward bias results in the injection of electrons from the n^+ emitter into the *p* base region, and the injection of holes from the *p* base region into the emitter region. The emitter current is comprised of both of these components. However, the portion of the emitter current due to hole injection into the n^+ emitter region does not contribute to the collector current. The electrons injected into the *p* base region diffuse through it and are collected at the reverse-biased base–collector junction. Because of the finite minority-carrier lifetime in the *p* base region, some of the injected electrons are lost by recombination.

The current transport between the emitter and collector for an *n-p-n* transistor in the common-base configuration is shown in Fig. 2 with depletion boundaries indicated by the dotted lines and the internal electron current components indicated by the arrows. The emitter–base junction is assumed to be under forward bias while the collector–base junction is assumed to be under reverse bias. The current I_{nE} is the emitter-current component due to electron injection at the emitter–base junction. The current I_{nC} is the electron current at the collector–base junction. Using these current components, the common-base current gain can be written as

$$\alpha = \frac{\delta I_{\mathrm{C}}}{\delta I_{\mathrm{E}}} = \frac{\delta I_{\mathrm{nE}}}{\delta I_{\mathrm{E}}}\frac{\delta I_{\mathrm{nC}}}{\delta I_{\mathrm{nE}}}\frac{\delta I_{\mathrm{C}}}{\delta I_{\mathrm{nC}}}. \tag{1}$$

From this expression, it can be seen that the change in electron current flow between the emitter and collector can be partitioned into three portions. The first term, referred to as the *emitter injection efficiency* or *gamma*, is the fraction of the total emitter current that comprises the electron current. As the name implies, it is a measure of the ability of the emitter to inject electrons into the base region in an efficient manner. Since the emitter current due to hole injection into the emitter region does not contribute to the collector current, the injection efficiency term is always less than unity. In general, a higher injection efficiency can be obtained by increasing doping concentration of the n^+ emitter region relative to the *p* base region. However, it has been found that an optimum emitter doping is required to maximize the injection efficiency because of phenomena associated with high doping in semiconductors.

The second term in Eq. (1), referred to as the *base transport factor*, is a measure of the ability for electrons that are injected into the base from the emitter to reach the collector–base junction. In the presence of a finite recombination in the base region, some electrons will be lost during transport through the base region. Consequently, the base transport factor is always less than unity. A large base transport factor can be obtained by reducing the width of the p base region with high minority-carrier lifetime.

The third term in Eq. (1), referred to as the *collector efficiency,* is a measure of the ability to transport electrons through the collector region. In the case of a reverse-biased collector–base junction, a strong electric field is established within a depletion region at this junction. The electrons transported through the base region are swept out by this electric field into the collector region. At collector biases well below the avalanche breakdown voltage of the collector–base junction, this process occurs without loss of electrons. Consequently, the collector efficiency can be assumed to be equal to unity.

In the case of a power bipolar transistor, it is necessary to consider both the emitter injection efficiency and the base transport factor in analyzing the current gain. This is because, unlike signal transistors, power transistors must be designed with relatively large base thickness to prevent reach-through breakdown. Further, as a result of the high operating current densities in power transistors, high-level injection effects occur in the p base region that lead to a reduction in the current gain with increasing current density. This is referred to as the *Rittner effect.* Further, the effective base width becomes greater than the metallurgical base width at high current densities on account of an alteration in the electric-field distribution across the base–collector junction. This is called the *Kirk effect.* A detailed treatment of these effects is beyond the scope of this article. Their combined effect on the current gain, illustrated in Fig. 3, leads to a current gain of less than 10 at typical operating current densities.

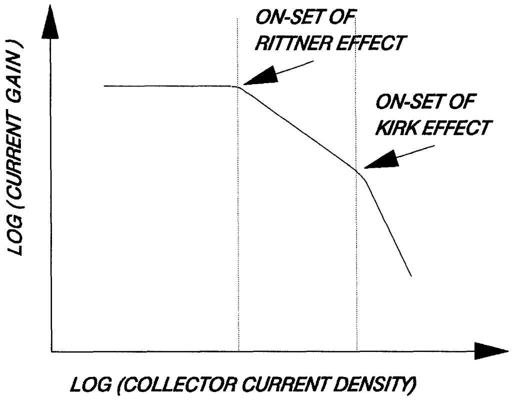

FIG. 3. Decrease in the current gain of a bipolar power transistor at higher current densities.

2.2 Voltage Saturation Region

The on-state portion of the current–voltage characteristic of the bipolar transistor is also referred to as the voltage saturation region. In this region of operation, the collector bias becomes less than the base drive voltage, which is about 1 V. Since both the emitter–base junction and the collector–base junction are then forward biased, the on-state voltage drop across the bipolar transistor in the voltage saturation region is less than the junction potential (typically 0.7 V). This is an advantage from the point of view of reducing the power dissipation in the on state. When the collector bias is sufficiently small, the base–collector junction operates with a sufficient forward bias to produce high-level injection (defined as a condition where the injected minority-carrier density exceeds the doping concentration) of carriers throughout the drift region. This regime of operation is called the *voltage saturation region.* As the collector bias is increased at any fixed base drive current, the forward bias across the base–collector junction is reduced. This results in a decrease in the injection of carriers into the drift region. Under these conditions, only a portion of the drift region near the base–collector junction operates under high-level injection while the rest of the drift region is not modulated. This regime of operation is called the *voltage quasisaturation region.* The different operating regions are illustrated in Fig. 4 at relatively small collector voltages close to the on-state voltage drop.

2.3 Emitter-Current Crowding

In the previous sections, the current flow through the bipolar power transistor was assumed to occur uniformly through its entire

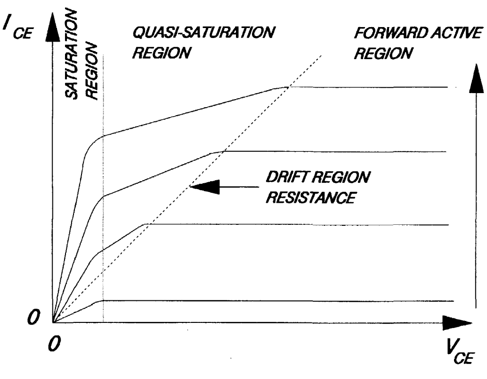

FIG. 4. Output characteristics of a bipolar power transistor. I_{CE}, collector–emitter current; V_{CE}, collector–emitter voltage.

emitter area. In an actual power transistor, the emitter and base contacts must be interdigitated as illustrated in Fig. 5. When the transistor is biased into its on state, a base drive current is applied at the base terminal. This current flows across the forward-biased emitter–base junction resulting in the injection of electrons from the emitter. Because of the interdigitation of the contacts, in order to forward bias the emitter–base junction at point A, the base current must flow through the base resistance R_{B}. This produces a voltage drop between points A and B, resulting in the forward bias across the emitter–base junction at point A being lower than that at point B. Consequently, the emitter injection at point A is smaller than that at point B, and the emitter current distribution is not uniform across the width of the emitter n^+ diffusion. Thus, it can be concluded that the current-carrying capability of the power bipolar transistor does not scale with increase in the emitter area. Instead, as a result of current crowding at the edges of the emitter, the current scales with increasing emitter periphery. Consequently, it is common practice to interdigitate the emitter and base contacts into a finger geometry. In spite of the need for interdigitation, the photolithography design rules for the fabrication of power bipolar transistors is not particularly demanding with state-of-the-art process technology because the emitter width (W_{E}) is relatively large (hundreds of microns in size).

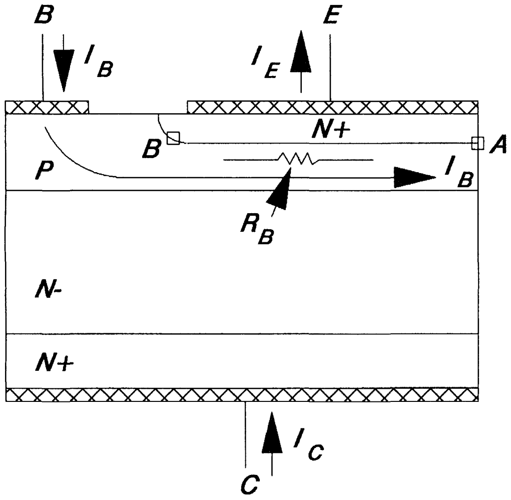

FIG. 5. Interdigitation of emitter and base contacts in a bipolar power transistor. R_{B}, base-region resistance to lateral current flow.

2.4 Turnoff

A high concentration of electrons and holes is present within the base and collector regions of the bipolar power transistor during the on state. This stored charge must be removed during the turnoff process to restore the device to its blocking state. One method for achieving this goal is to simply open circuit the base terminal, i.e., to stop providing the base drive current needed to keep the bipolar transistor in its on state. The stored charge will then decay by recombination at a rate dictated by the lifetime in the base and collector regions. Since this process is relatively slow and produces turnoff times that are too long for applications, it is preferable to apply a reverse bias to the base–emitter junction to enhance the turnoff process. The reverse base current flow extracts a significant fraction of the stored charge, which enables faster turnoff. However, this makes the control circuit for the bipolar power transistor complex and expensive because the reverse base current is typically one-fifth of the collector current.

2.5 Trends

The bipolar power transistor has been extensively used in power electronic systems since its initial commercialization in the

1950s. For these applications, devices have been developed with breakdown voltages up to 1500 V and with current-handling capability of several hundred amperes. However, the power bipolar transistor is a current-controlled device with a relatively low current gain (<10). Its application has required development of complex and expensive gate-drive circuits. For these reasons, the bipolar power transistor has been replaced by the power metal-oxide-semiconductor field-effect transistor (MOSFET) in applications where the operating voltages are below 200 V and by the insulated gate bipolar transistor (IGBT) in applications where the operating voltages range from 200 to 1500 V. The improvement in system performance achieved by the use of the MOS-gated devices in the 1980s has led to a lack of demand for further developments in bipolar power-transistor technology.

3. POWER METAL-OXIDE-SEMICONDUCTOR FIELD-EFFECT TRANSISTORS

In order to address the performance limitations experienced with power bipolar transistors, the power MOSFET was developed in the 1970s. These devices evolved from MOS integrated-circuit technology. In the power MOSFET (see TRANSISTORS, FIELD-EFFECT), the control signal is applied to a metal gate electrode that is separated from the semiconductor surface by an intervening insulator (typically silicon dioxide). The control signal required is essentially a bias voltage with no significant steady-state gate-current flow in either the on state or the off state. Even during the switching of the devices between these states, the gate current is small at typical operating frequencies (less than 100 kHz) because it serves only to charge and discharge the input gate capacitance. The high input impedance is a primary feature of the power MOSFET that greatly simplifies its gate-drive circuitry.

In contrast to the power bipolar transistor, the power MOSFET is a unipolar device. Current conduction occurs via transport of majority carriers in the drift region without the presence of minority-carrier injection required for bipolar transistor operation. No delays are observed due to storage or recombination of minority carriers in power MOSFETs during turnoff. Their inherent switching speed is orders of magnitude faster than for bipolar transistors. This feature is particularly attractive in circuits operating at high frequencies where switching power losses are dominant. Power MOSFETs have also been found to display an excellent safe operating area (i.e., they can withstand the simultaneous application of high current and voltage, for a short duration, without undergoing destructive failure). Further, these devices can be easily paralleled because the forward voltage drop of power MOSFETs increases with increasing temperature. This feature promotes an even current distribution between paralleled devices. These characteristics of power MOSFETs make them important candidates for many applications. They are being used in audio/rf circuits and in high-frequency inverters such as for switch-mode power supplies. Other applications for these devices are for lamp ballasts and motor control circuits.

3.1 Basic Structure and Operation

A cross section of the double-diffused MOSFET (DMOSFET) structure is shown in Fig. 6. This DMOS structure is fabricated by means of planar diffusion technology with a refractory gate, such as polysilicon, as a mask. In these devices, the *p* base region and

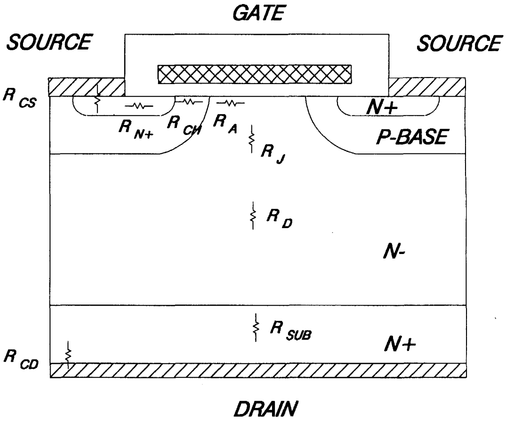

FIG. 6. Cross section of the DMOSFET structure with its internal resistances. R_{CH}, resistance of channel region; R_J, resistance of JFET region; R_{SUB}, resistance of substrate.

the n^+ source regions are diffused through a common window defined by the edge of the polysilicon gate. The name for this device is derived from this *double-diffusion process*. The p base region is driven in deeper than the n^+ source. The difference in the lateral diffusion between the p base and n^+ source regions defines the surface channel region.

In the power MOSFET structure, the p-n junction between the p base region and the n drift region provides the forward blocking capability. Note that the p base region is connected to the source metal by a break in the n^+ source diffusion. This is important to establishing a fixed potential to the p base region during device operation. If the gate electrode is externally shorted to the source, the surface of the p base region under the gate (i.e., the channel region) remains unmodulated at a carrier concentration determined by the doping level. When a positive drain voltage is now applied, it reverse biases the p-base/n-drift-region junction. This junction supports the drain voltage by the extension of a depletion layer on both sides. On account of the higher doping level of the p base region, the depletion layer extends primarily into the n drift region. A higher drain-blocking voltage capability requires a lower drift-region doping and a larger width, which results in a higher resistance within the device.

In order to carry current from drain to source in the power MOSFET, it is essential to form a conductive path extending between the n^+ source regions and the n drift region. This can be accomplished by applying a positive bias to the gate electrode. The gate bias modulates the conductivity of the channel region by the strong electric field created normal to the semiconductor surface through the oxide layer. The gate-induced electric field attracts electrons to the surface of the p base region under the gate. This field strength is sufficient to create a surface electron concentration that overcomes the p base doping. The resulting surface electron layer in the channel provides a conductive path between the n^+ source regions and the drift region. The application of a positive drain voltage now results in current flow between drain and source via the n drift region and the channel. This current flow is controlled by the resistance of these regions. Note that the current flow occurs solely by transport of majority carriers (electrons for n-channel devices) along a resistive path comprising the channel and drift regions. No minority-carrier transport is involved for the power MOSFET during current conduction in the on state.

In order to switch the power MOSFET into the off state, the gate bias voltage must be reduced to zero by externally shorting the gate electrode to the source electrode. When the gate voltage is removed, the electrons are no longer attracted to the channel and the conductive path from drain to source is broken. The power MOSFET then switches rapidly from the on state to the off state without any delays arising from minority-carrier storage and recombination as experienced in bipolar devices. The turnoff time is controlled by the rate of removal of the charge on the gate electrode because this charge determines the conductivity of the channel. Turnoff times of under 100 ns can be achieved with a moderate gate-drive current flow arising from the discharge of the input gate capacitance of the device.

3.2 Output Characteristics

The power MOSFET is capable of blocking voltage only in one quadrant. For n-channel structures, the devices are operated with a positive voltage applied to the drain. When the gate electrode is shorted to the source, the device can support a large drain voltage across the p-base/n-drift-region junction. The forward blocking capability is shown in Fig. 7 by the lowest trace. Although a finite leakage current is illustrated in the figure, it is very small except at high operating temperatures. The maximum forward blocking voltage is determined by the avalanche breakdown voltage of the p-base/n-drift-layer junction.

When a positive gate bias is applied, the channel becomes conductive. At low drain voltages, the current flow is essentially resistive with the "on" resistance determined by a combination of the channel and drift-region resistances. The channel resistance decreases with increasing gate bias while the drift-region resistance remains constant. The total "on" resistance decreases with increasing gate bias until it approaches a constant value. At large gate-bias voltages, the channel resistance becomes small compared with the

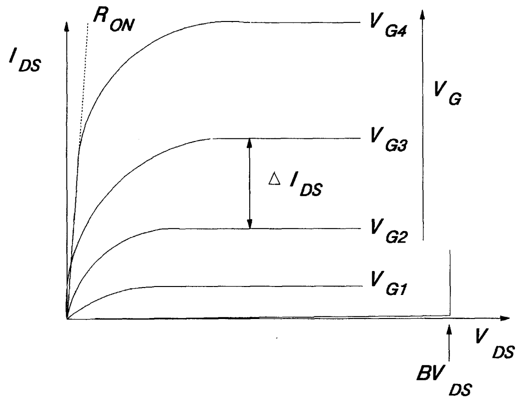

FIG. 7. Output characteristics of the power MOSFET. I_{DS}, drain-to-source current; V_{DS}, drain-to-source voltage.

drift-region resistance and the device "on" resistance becomes independent of gate bias. The "on" resistance is an important power MOSFET parameter. It is a measure of the current-handling capability of the device because it determines the power dissipation during current conduction. The "on" resistance is defined as the slope of the output characteristic in the linear region at low drain voltages. At high drain voltages, the resistance of the power MOSFET increases. Ultimately, the current saturates at high drain voltages as shown in Fig. 7. The current saturation in power MOSFETs can be used to provide a current-limiting function in power circuits as long as the power dissipation in the devices is kept within reasonable limits.

An important device parameter for power MOSFETs is the transconductance. It is defined by $g_m = \Delta I_{DS}/\Delta V_{GS}$ where $\Delta V_{GS} = V_{G3} - V_{G2}$ as illustrated in Fig. 7. A large transconductance is desirable to obtain a high current-handling capability with low gate-drive voltage, and for achieving high-frequency response. In the saturated-current region of operation, the output characteristics are controlled by the gate-induced channel characteristics. The transconductance is, therefore, determined by the design of the channel and gate structure.

3.3 Threshold Voltage

The voltage on the gate electrode at which strong inversion begins to occur in the MOS structure is an important design parameter for power MOSFETs because it determines the minimum gate bias required to induce an n-type conductance in the channel. This voltage is called the *threshold voltage.* For proper device operation, its value cannot be too large or too small. If the threshold voltage is large, a high gate-bias voltage will be needed to turn on the power MOSFET. This imposes problems with the design of the gate-drive circuitry. It is also important that the threshold voltage not be too low. On account of the existence of charge in the gate oxide, it is possible for the threshold voltage to be negative for *n*-channel power MOSFETs. This is an unacceptable condition because a conductive channel will now exist at zero gate-bias voltage; i.e., the devices will exhibit normally "on" characteristics. Even if the threshold voltage is above zero for an *n*-channel power MOSFET, its value should not be too low because the device can then be inadvertently triggered into conduction either by noise signals at the gate terminal or by the gate voltage being pulled up during high-speed switching. Typical power MOSFET threshold voltages are designed to range between 2 and 3 V.

3.4 On-State Resistance

Current flow in a power MOSFET during forward conduction is achieved by the application of a positive gate-bias voltage for *n*-channel devices in order to create a conductive path across the *p* base region underneath the gate. The current flow is then limited by the total resistance between the source and drain. This resistance consists of many components, as illustrated in the DMOS cross section in Fig. 6, which combine to determine the on-state voltage drop when the device is carrying current. The resistances of the n^+ emitter (R_{n+}) and substrate (R_{SUB}) regions are generally negligible for high-voltage power MOSFETs that have high drift-region resistance. They become quite important when the drift and channel resistances become small as in the case of low–breakdown-voltage (<100 V) devices. The channel (R_{CH}) and accumulation-layer (R_{A}) resistances are determined by the conductivity of the thin surface layer induced by the gate bias. These resistances are a function of the charge in the surface layer and the electron mobility near the surface. In addition to these resistances, the drift layer contributes two more components to the total "on" resistance. The portion of the drift region that comes to the upper surface between the cells contributes a resistance R_J that is enhanced at higher drain voltages by the pinch-off action of depletion layers extending from adjacent *p* base regions. This phenomenon has been termed the *JFET action*. Finally, the main body of the drift region contributes a large series resistance (R_D) especially for high-voltage devices. Only the channel and drift-region resistances will be treated in more detail in this article.

3.4.1 Channel Resistance The channel resistance can be derived as a function of the gate and drain voltages by using the *gradual channel approximation:*

$$I_D = \frac{\mu_{ns} C_{ox} Z}{2L} [2(V_G - V_T)V_D - V_D^2], \qquad (2)$$

where I_D is drain current, μ_{ns} is mobility of electrons in the inversion layer, C_{ox} is specific capacitance of the oxide layer, L is the channel length, V_G is the gate bias, V_T is the threshold voltage, V_D is the drain voltage, and Z is the channel width. According to this equation, when the drain voltage is small, the drain current increases linearly with drain voltage. In this linear region, the channel resistance R_{CH} is given by

$$R_{CH} = L/Z\mu_{ns}C_{ox}(V_G - V_T). \qquad (3)$$

As the drain voltage and current increase, the second term in Eq. (2) becomes increasingly important and causes the drain current to saturate. Physically, this corresponds to a reduction in the channel inversion-layer charge near the drain with increasing drain voltage. Ultimately, the inversion layer charge at the drain end of the channel becomes zero and the drain current saturates. The saturated drain current is given by

$$I_{DS} = \frac{\mu_{ns} C_{ox} Z}{2L} (V_G - V_T)^2. \qquad (4)$$

The saturated drain current is an important parameter because it determines the maximum current that the channel will support. The transconductance of the device in the saturated current region of operation can be obtained by differentiating Eq. (4) with respect to the gate voltage:

$$g_{ms} = \frac{dI_D}{dV_G} = \mu_{ns} C_{ox} \frac{Z}{L} (V_G - V_T). \qquad (5)$$

3.4.2 Ideal Specific "On" Resistance Consider the ideal case where the resistances of the n^+ emitter, n^+ substrate, *n*-channel region, accumulation region, and JFET region are negligible. The specific "on" resistance of the power MOSFET will then be determined by the drift region alone. In addition, if it is assumed that the current flows uniformly through the drift region without current-spreading effects, the resistance of the drift region is referred to as the *ideal specific "on" resistance* for the power MOSFET. This is the resistance of a drift region with the doping concentration and thickness required to support the desired breakdown voltage. For *n*-channel devices,

$$R_{on,sp} = \frac{W_D}{q\mu_n N_D} = 5.93 \times 10^{-9}(BV_{PP})^{2.5}, \qquad (6)$$

where W_D is the width of the drift region, μ_n is the mobility of electrons in the bulk, N_D is the dopant concentration in the drift region, and BV_{PP} is the breakdown voltage of a parallel-plane junction; while for *p*-channel devices,

$$R_{on,sp} = \frac{W_D}{q\mu_p N_A} = 1.63 \times 10^{-8}(BV_{PP})^{2.5}, \qquad (7)$$

where μ_p is the mobility of holes in the bulk. The ideal specific "on" resistance of the *p*-channel MOSFET is about 2.5 times larger than that for the *n*-channel MOSFET as a result of the lower mobility for holes in silicon when compared with electrons. For this reason, most commercial power MOSFETs are *n*-channel devices.

It is possible to approach the ideal specific "on" resistance for DMOSFETs with higher breakdown voltages when compared to those with lower breakdown voltages. This is illustrated in Fig. 8, where the specific "on" resistance is plotted as a function of the breakdown voltage. The ideal specific "on" resistance is also shown in the figure for comparison. The state-of-the-art line for devices of 1981 vintage is representative of a

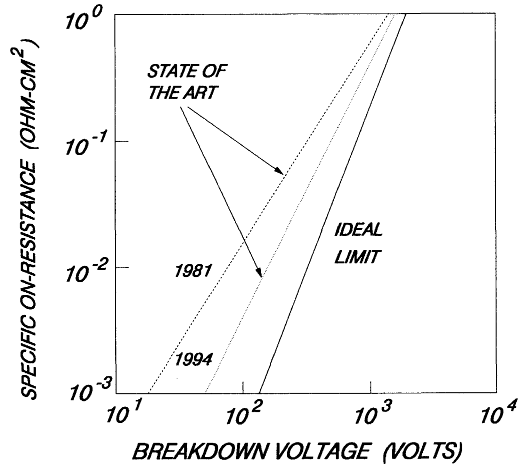

FIG. 8. Increase in the "on" resistance of a power MOSFET with increasing breakdown voltage.

process design rule that requires a 16-μm polysilicon window. With advancements in lithographic tools used to fabricate these devices, it has been possible to shrink the polysilicon window size. From the plots in Fig. 8, it can be seen that silicon power MOSFETs with high breakdown voltages approach the ideal performance limit, while improvements in the MOSFET structure are required for approaching ideal performance for the devices with lower breakdown voltages.

3.5 Input Capacitance

The power MOSFET is inherently capable of operation at high frequencies because of the absence of minority-carrier transport. Two limits to operation at high frequencies are set by the transit time across the drift region and the rate of charging of the input gate capacitance. In a power MOSFET, the input capacitance is relatively large on account of the large active area required to carry substantial drain currents. Consequently, the frequency response is usually limited by the charging and discharging of the input capacitance. To analyze the frequency response, it is necessary to evaluate each of the components of the input capacitance arising in the power MOSFET structure. Consider the conventional DMOS structure shown in Fig. 9 with the gate electrode extending between adjacent DMOS cells. The input gate-to-source capacitance for this structure contains several components:

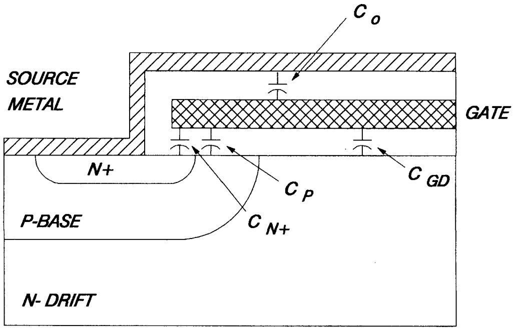

FIG. 9. Capacitances in the power DMOSFET structure.

1. the capacitance C_{n+} arising from the overlap of the gate electrode over the N^+ source region,
2. the capacitance C_p arising from the MOS structure created by the gate electrode over the p base region, and
3. the capacitance C_0 arising from running the source metal over the gate electrode.

The total gate-to-source capacitance is given by

$$C_{\mathrm{GS}} = C_{n+} + C_p + C_0. \tag{8}$$

The gate-to-drain capacitance varies with gate and drain voltage. It has a high value during the "on" state because the surface of the drift region is under accumulation. As the drain voltage increases and the device supports high voltages, the gate-to-drain capacitance decreases. Because of the amplification of the gate-to-drain capacitance by the Miller effect, this capacitance can severely reduce the frequency response. It is therefore important to reduce its magnitude. The gate-to-drain overlap capacitance can be drastically reduced by altering the gate structure by eliminating the gate overlap over the drift region. However, it is important to note that eliminating the gate-to-drain overlap creates a high electric field at the edge of the gate. This can reduce the cell breakdown voltage. In addition, it adversely affects the "on" resistance through an increase in the resistance between the channel and the drift region because an accumulation layer is no longer formed over a portion of the surface between the base regions.

3.6 Cell Topology

In previous discussions of power MOSFETs, cross sections of devices were shown without consideration of the cell layout on the surface. The cell windows that are commonly used for the design of power MOSFETs have linear, square, circular, hexagonal, or the atomic-lattice-layout (A-L-L) shapes. These windows can be located in either a square cell or a hexagonal cell pattern. The impact of the layout of these cells upon the resistance has been analyzed under the assumption that they all have the same drift-region doping concentration. It has been found that the "on" resistances of all cellular designs are equal if the size of the cell window and the ratio of the area of the cell window to the total cell area are kept the same. However, it has been found that the drift-region doping concentration must be adjusted on the basis of the electric field crowding within the cell. When this is taken into account, the A-L-L design has been found to be superior to the other designs. The A-L-L design also has a lower drain overlap capacitance, which is favorable for operation at high frequencies.

3.7 Trends

Power MOSFETs have the following attributes:

1. a voltage-controlled characteristic with low input gate power,
2. a stable negative temperature coefficient for the "on" resistance,
3. a wide safe operating area, and
4. a high switching speed.

Because of these features, when first introduced, the devices were expected to replace power bipolar transistors in many applications. This has occurred for systems with low operating voltages. Examples are switch-mode power supplies, computer peripherals, and automotive electronics. This displacement has not occurred for systems operating at high voltages on account of the high "on" resistance of power MOSFETs designed to support voltages above 200 V. With rapid progress along the learning curve, the manufacturing cost of power MOSFETs now rivals that for the bipolar transistors. Since the "on" resistance of the silicon power MOSFETs is already close to the ideal value, progress in increasing their power-handling capability can be achieved only by increasing the area of the device. This is expected to occur at a pace dictated by improvements in process technology that lead to a reduction in defect density. Recently, it has been theoretically shown that replacement of silicon with silicon carbide would lead to a 200-fold reduction in the specific "on" resistance. This offers a tremendous opportunity for improvement of device characteristics if the technological problems with manufacturing silicon carbide devices can be overcome.

4. INSULATED-GATE BIPOLAR TRANSISTORS

The development of the insulated-gate bipolar transistor (IGBT) was based upon a innovative approach that combines the physics of bipolar current conduction with the physics of MOS gated current control within the same semiconductor region. These devices have replaced bipolar power transistors in medium-power applications, where the blocking voltages lie between 300 and 1500 V.

4.1 Device Structure and Operation

A cross section of the IGBT is shown in Fig. 10 based upon the DMOS process. In this structure, current flow cannot occur

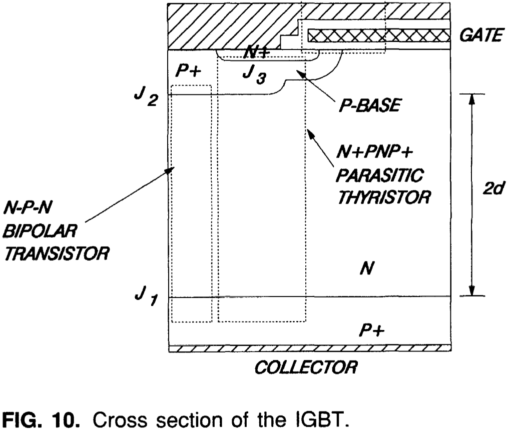

FIG. 10. Cross section of the IGBT.

when a negative voltage is applied to the collector with respect to the emitter because the lower junction (J_1) will become reverse biased. This provides the device with its reverse blocking capability. In this mode of operation, the depletion region extends in the *n* drift region. When a positive voltage is applied to the collector with the gate shorted to the emitter, the upper junction (J_2) becomes reverse biased, and the device operates in its forward blocking mode. In this mode of operation, the voltage is supported by a depletion region formed in the *n* drift region. The forward and reverse blocking capabilities of the IGBT cell structure shown in Fig. 10 are approximately equal because they are determined by the thickness and resistivity of the same *n* drift layer.

If a positive gate bias is applied of sufficient magnitude to invert the surface of the *p* base region under the gate when the device is in its forward blocking mode, it can be switched into its on state. In the forward conducting state, electrons flow from the n^+ emitter to the *n* drift region. This provides the base drive current for the vertical *p-n-p* transistor in the IGBT structure. Since the emitter junction (J_1) for this bipolar transistor is forward biased, the p^+ region injects holes into the *n* base region. (It is worth pointing out here that the IGBT terminals have been named from the point of view of replacing a power bipolar transistor with the IGBT in circuits. Unfortunately, this nomenclature is in conflict with the internal physics of operation of the device. Thus, the junction J_1 acts as an emitter of the internal *p-n-p* transistor even though the p^+ region is connected to the collector terminal.) When the positive bias on the collector terminal of the IGBT is increased, the injected hole concentration increases until it exceeds the background doping level of the *n* drift region.

If the inversion-layer conductivity is reduced by application of a gate bias close to the threshold voltage, a significant voltage drop occurs across this region due to the electron current flow in a manner similar to that observed in conventional MOSFETs. When this voltage drop becomes comparable to the difference between the gate bias and the threshold voltage, the channel becomes pinched off. At this point, the electron current saturates. Since this limits the base drive current for the *p-n-p* transistor, the hole current flowing through this path is also limited. Consequently, the device operates with current saturation in its active region with a gate-controlled output current. These characteristics of the IGBT are shown in Fig. 11.

In order to switch the IGBT from its on state to the off state, it is necessary to discharge the gate by shorting it to the emitter. In the absence of a gate voltage, the inversion region at the surface of the *p* base under the gate cannot be sustained. Removal of the gate bias cuts off the supply of electrons to the *n* drift region and initiates the turnoff process. Because of the presence of the high concentration of minority carriers injected into the *n* drift region during forward conduction, the turnoff does not occur abruptly. At first, an abrupt reduction in the anode current is observed because the electron current via the channel is terminated. The collector current then decays gradually with a characteristic time constant determined by the minority-carrier lifetime.

The IGBT structure contains a parasitic *p-n-p-n* thyristor structure between the collector and the emitter terminals as indicated in Fig. 10. If this thyristor latches up, the current can no longer be controlled by the MOS gate. It is important to design the device in such a manner that this thyristor action will be suppressed. This can be achieved by preventing the injection of electrons from the n^+ emitter region into the *p* base during

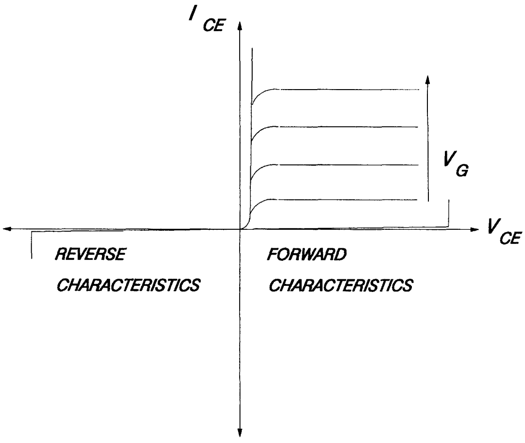

FIG. 11. Output characteristics of the symmetrical IGBT structure.

device operation. If the resistance to hole current flow within the p base region is sufficiently small, the thyristor will not be turned on because of the low gain of the upper n-p-n transistor. The equivalent circuit for the IGBT then consists of a MOSFET driving the base of the p-n-p transistor in a Darlington configuration.

4.2 Blocking Characteristics

The forward and reverse blocking voltage capability of the IGBT defines one of its important limits in performance for applications. When a negative collector voltage is applied, a large voltage can be supported by the IGBT structure shown in Fig. 11 because junction J_1 becomes reverse biased. When junction J_1 becomes reverse biased, its depletion layer extends primarily into the lightly doped n drift region. It is important to note that the breakdown voltage during reverse blocking is determined by an open-base transistor formed between the p^+ collector, the n drift region, and the p base region. This structure is prone to reach-through breakdown if the n drift region is too lightly doped. As a general guideline, the width of the n drift region is chosen so that its thickness is equal to the depletion width at the maximum operating voltage plus one diffusion length. In dc circuit applications, the IGBT is not required to support reverse voltage. This offers the opportunity to reconfigure the device structure to optimize the forward conduction characteristics for a given forward blocking capability without consideration for the reverse blocking capability. The doping profile and electric-field distribution for such an asymmetrical IGBT are shown in Fig. 12. In the asymmetrical IGBT structure, the uniformly doped n drift region of the symmetrical IGBT is replaced by a two-layer n drift region. This alters the electric-field distribution as illustrated on the right-hand side of the figure. If the critical electric field for breakdown is assumed to be independent of the n drift-region doping level and the n drift-region doping in layer 1 is very low, the electric-field distribution changes from the triangular case in the symmetrical IGBT to a rectangular case in the asymmetrical structure. Under these circumstances, if the n buffer-layer thickness (d_2) is assumed to be approximately equal to one diffusion length (L_p), the forward blocking capability of the asymmetrical device will be twice as high as for the symmetrical device.

4.3 On-State Characteristics

The analysis of the forward conduction characteristics can be performed by treating the device as a p-i-n rectifier connected in series with a MOSFET. The voltage drop across the p-i-n rectifier ($V_{\mathrm{F},pin}$) is related to its forward conduction current density ($J_{\mathrm{F},pin}$) by

$$V_{\mathrm{F},pin} = \frac{2kT}{q} \ln\left[\frac{J_{\mathrm{C}}d}{2qD_{\mathrm{a}}n_{\mathrm{i}}F(d/L_{\mathrm{a}})}\right], \tag{9}$$

where J_{C} is the collector current density, d is the half thickness of the drift region, D_{a} is the ambipolar diffusion coefficient, n_{i} is the intrinsic carrier current, L_{a} is the ambipolar diffusion length, and $F(d/L_{\mathrm{a}})$ is a complex function. The MOSFET current is given by

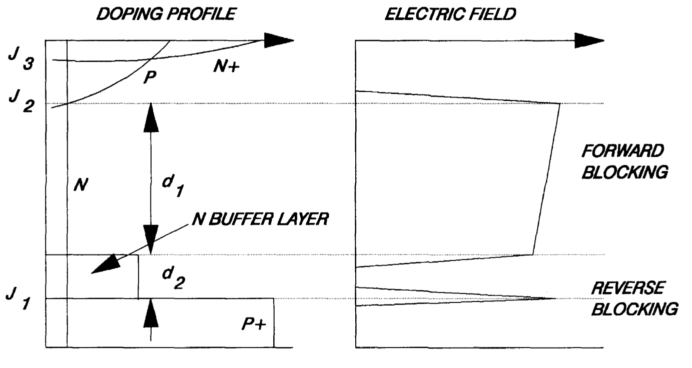

FIG. 12. Doping profile and electric-field distribution within the asymmetrical IGBT structure.

$$I_C = \frac{\mu_{ns} C_{ox} Z}{2L_{ch}} [2(V_G - V_T)V_{F,MOS} - V_{F,MOS}^2], \tag{10}$$

where $V_{F,MOS}$ is the voltage drop across the MOSFET portion of the IGBT and L_{CH} is the MOSFET channel length. In the forward conduction mode, sufficient gate voltage is applied that the forward voltage drop across the device is low. Under these conditions, $V_{F,MOS} \ll V_G - V_T$, and the MOSFET section of the devices is operating in its linear region. The voltage drop across the MOSFET section is, then, given by

$$V_{F,MOS} = \frac{I_C L_{CH}}{\mu_{ns} C_{ox} Z (V_G - V_T)}. \tag{11}$$

On the basis of this model for the IGBT, the forward voltage drop across the IGBT is the sum of the voltage drops across the MOSFET and the *p-i-n* rectifier:

$$V_F = \frac{2kT}{q} \ln\left[\frac{I_C d}{2qWZD_a n_i F(d/L_a)}\right] + \frac{I_C L_{CH}}{\mu_{ns} C_{ox} Z (V_G - V_T)}. \tag{12}$$

Several important conclusions about IGBT performance can be derived from the *p-i-n* rectifier/MOSFET model. First, it becomes apparent that there will be a knee in the output conduction characteristic (as shown in Fig. 11) below which very little current flow will occur, but the current density will rise very rapidly (exponentially) thereafter. This behavior has been experimentally verified in devices resulting in operating on-state current density for the IGBT being substantially greater than for the devices. This indicates that a smaller chip size can be used, resulting in reduced cost for the IGBT.

Using the *p-i-n* rectifier/MOSFET model, it is also possible to derive the IGBT characteristics under current saturation. When the gate bias is reduced to a value close to the threshold voltage such that the voltage drop across the MOSFET channel becomes significant, the current becomes limited by the MOSFET. As in the case of a MOSFET, the IGBT collector current will saturate as shown in Fig. 11 at a value given by

$$I_{C,sat} = \frac{\mu_{ns} C_{ox} Z}{2L_{CH}} (V_G - V_T)^2. \tag{13}$$

The transconductance of the IGBT will then be identical to that for the MOSFET with the same cell size and channel length. In actual devices, the transconductance for the IGBT has been found to be larger than that for the MOSFET with the same cell size and channel length. The reason for this is an additional component of current flowing through the *p-n-p* transistor, which was not accounted for in the *p-i-n*/MOSFET model.

4.4 Parasitic Thyristor Latchup

The maximum operating current for the IGBT is limited by the presence of the parasitic thyristor within the structure. As shown in Fig. 10, this thyristor is formed between the n^+ source region of the MOSFET acting as the cathode of the thyristor, the *p* base region, the *n* drift region, and the p^+ collector region. During operation of the IGBT in the on state, electrons are supplied via the MOSFET channel and holes injected from junction J_1 are collected at junction J_2. The hole current flows to the emitter terminal via the resistance of the *p* base region. This current flow produces a voltage drop that forward biases the junction J_3. At normal operating current levels for the IGBT, this voltage drop can be made much smaller than that for a forward-biased diode (V_{bi}) by making the shunting resistance small. Under these conditions, the current gain of the *n-p-n* transistor is very small, and the thyristor cannot latch up. However, when the on-state current density is increased, the forward bias on junction J_3 can become sufficiently large to increase the current gain of the *n-p-n* transistor. If the sum of the current gains of the *n-p-n* and *p-n-p* transistors exceeds unity, the thyristor can latch up. The collector current can now flow directly to the emitter terminal, bypassing the MOSFET channel. This implies that the IGBT current is no longer controlled by the gate bias.

From the above discussion, it can be concluded that it is essential to suppress the turnon of the parasitic thyristor in order to maintain gate control over the collector current. This can be achieved by reducing the gain of either the *n-p-n* transistor, the *p-n-p* transistor, or both transistors. Since the on-state current flows partially via the *p-n-p* transistor, a reduction in its gain produces an increase in the on-state voltage drop. It is therefore preferable to reduce the gain of the *n-p-n* transistor. However, methods employed to improve the turnoff time for the IGBT tend to reduce the gain of the *p-n-p* transistor, which then leads to an increase in the current density at which the parasitic thyristor will latch up. In consequence of successful suppression of the latchup of the parasitic thyristor, IGBTs have become commercially available with performance suitable for many applications.

4.5 Switching Characteristics

An important characteristic of the IGBT is its MOS-gate–controlled turnoff capability. Since the current flowing through the MOS channel controls the output characteristics, the collector current flow can be interrupted by removing the gate-drive voltage. To perform the transition from the "on" state to the forward blocking state, the gate is connected to the emitter terminal via an external circuit that allows discharging the gate capacitance. When the gate voltage falls below the threshold voltage of the MOS gate structure, the channel inversion layer can no longer exist. At this point, the electron current supplied by the channel ceases. If the gate turnoff is performed using a low external resistance in the gate-drive circuit so as to reduce the gate voltage abruptly to zero, the collector current will drop abruptly because the channel current is suddenly discontinued. Even after this occurs, the collector current continues to flow because the hole current (I_h) does not cease abruptly. The high concentration of minority carriers stored in the *n* drift region during the on state supports the hole-current flow. As the minority-carrier density decays through recombination, it leads to a gradual reduction in the collector current. This current flow is sometimes referred to as a *current tail.*

Typical examples of the IGBT voltage and current wave forms during device turnoff are provided in Fig. 13 for gate-controlled turnoff. In the case of a resistive load, the collector voltage rises during turnoff at the same rate at which the collector current decays. In contrast, in the case of an inductive load, the collector voltage abruptly rises to the supply voltage when the gate-drive voltage is reduced to zero. In either case, it is important to note that a large power dissipation occurs during the time that the collector current decays to zero because of the relatively high voltage across the IGBT during this time. It is therefore important to minimize the duration of the current tail by reducing the minority-carrier lifetime. The minority-carrier lifetime can be reduced by performing electron irradiation, directed perpendicular to the wafer surface, after device fabrication to introduce recombination centers. A reduction in the turnoff time from over 20 μs to less than 200 ns can be achieved by electron irradiation, making the IGBT suitable for applications operating over a wide frequency range.

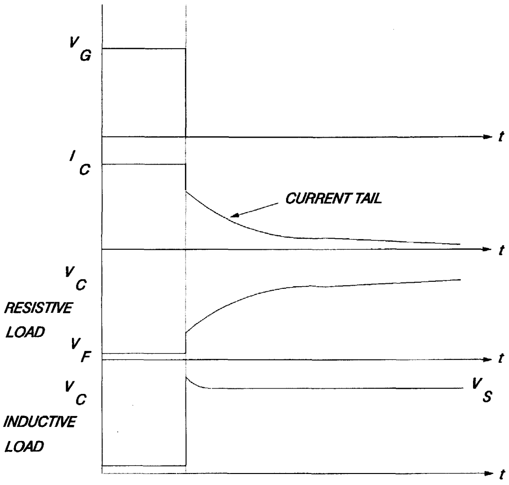

FIG. 13. Switching wave forms for the IGBT.

4.6 Trade-Off Curve

The results described above demonstrate that electron irradiation can be utilized to control the switching speed of IGBTs. However, this increase in the switching speed is accompanied by an increase in the forward voltage drop. Since a short gate turnoff time is desirable in order to reduce switching losses and a low forward voltage drop is desirable in order to reduce the conduction losses, it becomes necessary to perform a trade-off between these device characteristics. This can be most conveniently performed by using a plot of the forward voltage drop versus the gate-controlled turnoff time as shown in Fig. 14 for the symmetrical and asymmetrical IGBT structures.

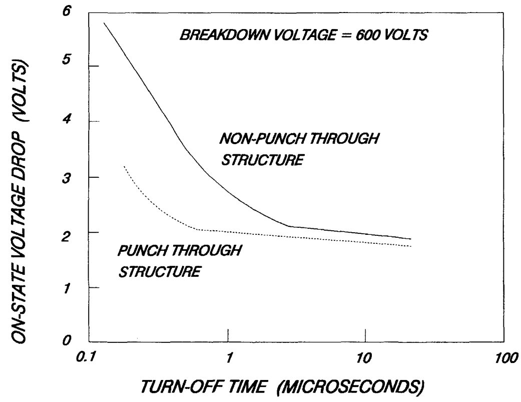

FIG. 14. Power loss trade-off curves for the IGBT.

Depending upon the application, the appropriate device characteristics can be selected by choosing the irradiation dose. In the case of circuits operating at low frequencies with large duty cycles, where the conduction losses dominate the switching losses, IGBTs with turnoff times in the range of 5–20 μs would be the best. An example of this is line-operated phase-control circuits. For higher-frequency circuits with shorter duty cycles, where the switching losses are comparable to the conduction losses, IGBTs with turnoff times in the range of 0.5–2.0 μs would be appropriate. An example of this type of application is in ac motor drives operating at frequencies ranging from 1 to 10 kHz. For high-frequency circuits, the switching losses would become dominant and IGBTs with gate turnoff times ranging from 100 to 500 ns would be necessary. An example of such circuits is in uninterruptible power supplies (UPS) operating at between 20 and 100 kHz. Thus, the IGBTs can be tailored to match the power switching requirements of a broad range of applications.

It is worth pointing out that the trade-off curve for the asymmetric IGBT structure has been found to be superior to that for the symmetric IGBT structure as shown in the figure. This is because of the smaller thickness of the drift region in the asymmetrical structure for obtaining the same forward blocking voltage as discussed earlier. The smaller drift-region thickness results in a lower on-state voltage drop for the same lifetime in the drift region. It has also been found that the trade-off curve can be improved upon by increasing the doping concentration in the buffer layer. This results in a reduction in the injection efficiency of the lower junction (J_1), which reduces the current gain of the *p-n-p* transistor.

4.7 Trends

The IGBT was the first commercially successful device based upon combining the physics of MOS-gate control with bipolar current conduction. The MOS gate provides an easy interface that can be addressed using low-cost integrated circuits. The bipolar current conduction makes high-current, high-voltage devices available to circuit designers at a relatively low cost. Further, the IGBT structure is very similar to that for the power MOSFET from a fabrication standpoint. This has made its manufacturing relatively easy immediately after conception and the suppression of the parasitic thyristor. After commercial introduction of IGBTs in the mid 1980s, the ratings of devices have grown at a very rapid pace because of the ability to scale up both the current and blocking voltage ratings. In addition, the differences in cost for production of these MOS-technology–based devices and the bipolar power transistor have diminished. This has made the IGBT very attractive from an applications point of view, resulting in rapid displacement of power bipolar transistors. Some of the applications for which the IGBT is used are adjustable-speed motor control for air conditioning, numerical controls for factory automation and robotics, and appliance controls. The device has also been chosen for the development of the electric car. As the ratings of the devices are scaled up, it is anticipated that the devices may find application in traction (electric street cars) as well.

6. CONCLUSIONS

An ideal power transistor must be able to operate with no internal power dissipation while controlling large amounts of power, and it should operate with infinite power gain. Historically, the first transistors developed for power electronics applications were the bipolar power transistors commercially introduced in the 1960s. Although refined and used for many applications, they had the drawback of requiring large input current to control the output current flow. This poor power gain resulted in complex and expensive control circuits. In the 1970s, the first power MOSFETs were introduced. Because of their very high input impedance, they have replaced the bipolar power transistors in applications operating at low (<100 V) voltages. In the 1980s, the IGBT was introduced for medium-voltage (up to 1500 V) applications. In addition to its high input impedance, the IGBT has the feature that it can control much greater power for the same chip size than the power MOSFET. As a consequence, the IGBT has replaced the bipolar transistor in medium-power applications. In order to replace the gate-turnoff thyristors used at present for high-power applications, manufacturers are now developing IGBTs with blocking voltages above 2000 V.

INTRODUCTION

Transparent optical materials encompass a broad class of materials—organic and inorganic, crystalline and amorphous, solids and liquids. The optical range of the electromagnetic spectrum is also broad—from the infrared to the ultraviolet. In this article, we consider the optical wavelength range extending from ~100 nm on the short-wavelength side, limited by the fundamental band gap of solids, to ~25 μm in the infrared, beyond which strong absorption by molecular vibrations limits the useful transmission of the material. The materials described are bulk transmitting optical materials of the types mentioned above; metals that reflect light, photodetector materials, and thin-film optical coatings are therefore not included.

We begin with a brief review of fundamental optical phenomena relevant to understanding the properties and applications of optical materials. Included are both passive properties (absorption, reflection, refraction, and polarization) and special properties such as electro-optic, magneto-optic, and elasto-optic effects, luminescence and stimulated emission, and other photosensitive processes

in materials. A more extensive discussion of optical properties of solids is presented in OPTICAL PROPERTIES OF SOLIDS.

Optical glasses are considered first because they are by far the most widely used optical materials. They are well-developed and well-characterized materials that are commercially available in a variety of chemical compositions, in high quality and large sizes, and with reproducible optical properties. Glasses are the quintessential optical material and epitomize an engineered material. Organic polymers constitute another class of noncrystalline optical materials, having a somewhat different and narrower range of properties than for glasses. Optical liquids are included in a separate section. Optical glasses, plastics, and liquids are optically isotropic materials. This simplifies the discussion of their optical properties and contributes to their general usefulness.

Optical crystals encompass a wide range of chemical compositions and atomic and molecular structures. Many cubic crystals exist that have isotropic optical properties and other desirable physical properties that render them attractive for many applications. Crystals of lower symmetry can, in addition, exhibit a variety of direction-dependent, anisotropic optical effects including polarization, double refraction, optical activity, and linear and nonlinear electro-optic phenomena. These features have made possible a large number of special and novel applications.

Both crystalline and amorphous optical materials can have multiple uses both as passive transmitting and absorbing materials and as active materials. In the latter case they may contain ions or molecular groups, either as a basic constituent or by doping, that are used to produce laser action, scintillation for detecting high-energy radiation, paramagnetic and ferromagnetic Faraday rotation, and photochromic and other photosensitive properties.

Prompted by the development of lasers and nonlinear optics, the fields of optics and electro-optics have expanded greatly. Concurrent research and development of optical materials has led to the availability of many different transmitting materials too numerous to tabulate within the scope of this article. Instead, for each class of optical material, fundamental optical properties, principal applications, and representative examples of the more useful materials are given. Other important physical and chemical properties and their variation with temperature and other ambient conditions are also covered. References to books and handbooks where more extensive discussion and tabulation of optical materials and their properties can be found are given in the list of Further Reading at the end of the article.

1. FUNDAMENTAL OPTICAL PHENOMENA

The interaction of light with a solid can be specified by various optical response functions. To describe the amplitude and phase of the response, these functions are generally frequency-dependent complex quantities. The complex dielectric constant ϵ, for example, relates the amplitude of an optical electric field E of frequency ω to the polarization wave $\mathbf{P}(\omega)$ induced in the material and is given in terms of the complex index of refraction $\mathbf{n}(\omega)$ by $\epsilon(\omega) = \mathbf{n}^2(\omega)$. The index of refraction, in turn, can be related to the amplitude and phase of the reflectivity. For each of these complex quantities the real and imaginary components are related by Kramers–Kronig integral equations (Zallen, 1983). Thus if one of the components is known over a sufficiently large frequency range, the other component can be obtained from an integral transform.

1.1 Absorption

The strong absorption of optical materials in the infrared (IR) is associated with the interaction of light with molecular vibrations giving rise to multiphonon absorption processes; in the visible and ultraviolet (UV), absorption is associated with electronic transitions between the valence band and the conduction band or exciton levels. The positions of both the long- and short-wavelength absorption edges depend on the chemical composition and the interatomic and intermolecular bonding of the material. Oxide materials typically have a broad transmission window in the visible and near infrared; halide materials, especially fluorides, can have a more extended range of transparency. The region of transparency is shifted into the mid-infrared for more covalently bonded halides and chalcogenide materials and into the ultraviolet for more ionic fluoride materials.

The intensity I of light transmitted through a material of path length l is given by the Lambert–Beer law as

$$I = I_0 \exp(-\alpha l), \tag{1}$$

where I_0 is the incident intensity and α is the absorption coefficient. The fundamental absorption edge at short wavelengths can be described by an absorption coefficient exponentially dependent on the frequency ω (Urbach's rule). The long-wavelength absorption edge arises from multiphonon excitation of overtone and combination bands of fundamental vibrational modes of the solid and can also be fitted by an exponential dependence on energy with an average optical phonon frequency and a material constant characterizing the vibrational anharmonicity.

The range of absorption coefficients for crystals and glasses over the entire optical spectrum covers many orders of magnitude, from 10^6 cm^{-1} in the UV to less than 10^{-4} cm^{-1} in the near IR. This is illustrated for a soda-lime-silicate glass in Fig. 1. The extremely low absorption in the region between the UV and IR absorption edges is obtained only in ultrapure materials. Absorption in this region is frequently dominated by the presence of trace quantities (parts per billion) of iron and other transition- or post–transition-group impurities in the raw materials, by color centers due to vacancies or electron traps, and by higher-order harmonics of the lattice or glass network vibrations. Impurities may also mask the true UV absorption edge. Water is frequently present in materials in the form of OH^- groups. This gives rise to a strong fundamental absorption near 3 μm and weaker overtone and combination absorption bands throughout the near infrared. For most optical materials, an absorption coefficient of $<10^{-2}$ cm^{-1} in the wavelength region of interest is sufficient. For laser materials, absorption due to impurities is usually kept to less than 10^{-3} cm^{-1} at the lasing wavelength.

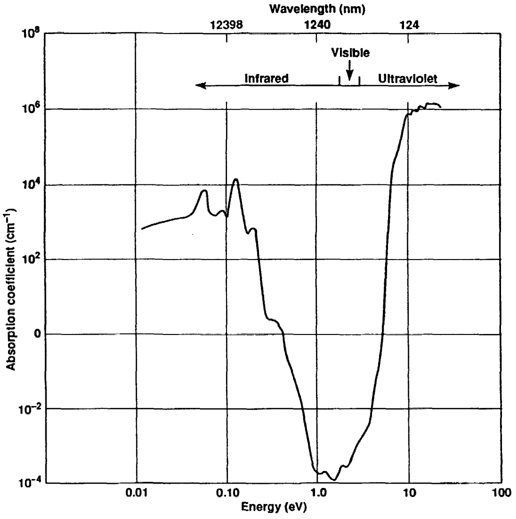

FIG. 1. Absorption spectrum of a soda-lime-silicate glass (Bagley *et al.*, 1976)

In many materials the absorption is polarization dependent. Dichroic materials (e.g., tourmaline) are materials in which light polarized in one direction is more strongly absorbed than light polarized at right angles to that direction.

1.2 Refraction

The index of refraction n for monochromatic radiation is the ratio of the velocity of light in vacuum to the velocity of light in the medium, that is, $n = c/v$. For an absorbing dielectric medium, the index of refraction at wavelength λ is complex and given by

$$\mathbf{n} = n - ik, \tag{2}$$

where the extinction coefficient k is related to the absorption coefficient by $k = \alpha\lambda/4\pi$. In vacuum the propagation velocity is the same for all wavelengths, but in a transmitting medium the velocity and refractive index vary with wavelength and direction of propagation. In regions far removed from absorption, where $k \approx 0$, the wavelength dependence of the refractive index is frequently expressed by the Sellmeier relationship

$$n^2(\lambda) - 1 = \sum_{i=1}^{m} \frac{A_i \lambda^2}{\lambda^2 - \lambda_i^2}, \tag{3}$$

where A_i and λ_i are the effective strength and mean wavelength of the ith absorption band and the summation is over all infrared (vibrational) and ultraviolet (electronic) bands.

The refractive index n and the dispersion $(dn/d\lambda)_\lambda$ are prime optical properties of materials.

For glasses and for crystals with cubic symmetry, the propagation of light is isotropic with a single index of refraction. Other symmetry classes of crystals are optically anisotropic. The propagation of light in these materials depends on the direction of wave propagation relative to the crystal axes and is treated using tensor calculus. The refractive index has a directional dependence, and Eq. (3) is extended to yield three indices of refraction n_1, n_2, n_3. These can be described by an index ellipsoid (optical indicatrix). A light wave propagating in an arbitrary direction can be decomposed into two waves having orthogonal polarizations and different velocities and thereby exhibiting double refraction. These waves have the same propagation velocity only in specific directions called optic axes. A uniaxial crystal has one such axis; a biaxial crystal has two. In birefringent materials, one polarization has an isotropic propagation velocity and obeys Snell's law (the ordinary wave); the orthogonal polarization has an anisotropic propagation velocity and does not obey Snell's law (extraordinary wave) (Guenther, 1990).

Materials that exhibit optical activity rotate the plane of polarization naturally, in contrast to rotation by electro-optic or magneto-optic effects that require an applied electric or magnetic field. Light traversing such a material of length l has its plane of polarization rotated through an angle

$$\theta = (\pi l/\lambda)(n_- - n_+), \tag{4}$$

where n_- and n_+ are the refractive indices for left- and right-circularly polarized light. For dextrorotatory materials $n_- > n_+$, and the right-circularly polarized light travels faster than the left; the opposite condition holds for levorotatory materials. Solids and liquids having molecules with no center of symmetry and no plane of symmetry exhibit optical activity.

1.3 Reflection

When a flux of light Φ traversing a medium of refractive index n' is incident on a material of index n, it is partially reflected and partially refracted as shown in Fig 2. By Snell's laws, $\theta_1' = \theta_1$ on reflection and $n \sin\theta_2 = n' \sin\theta_1$ on refraction. At Brewster's angle θ_p, given by $n'/n = \tan\theta_p$, only the component of light polarized perpendicular to the plane of incidence is reflected, and the intensity is plane polarized; at other angles of incidence the reflected light has mixed polarization. In general, the dependence of the reflectivity on wavelength and angle of incidence (Fresnel laws) is complex, especially near an absorption band and for anisotropic materials (Born and Wolf, 1980). The index of refraction and the absorption coefficient of a material can be derived from reflectivity data integrated over a broad range of wavelengths beyond the IR and UV absorption edges using a Kramers–Kronig analysis.

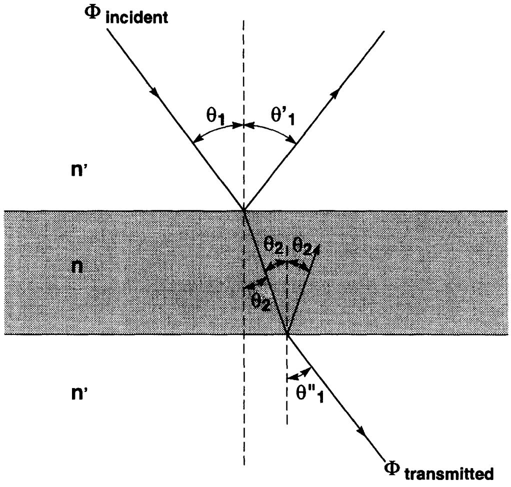

FIG. 2. Reflection, refraction, and transmission of light at material boundaries ($n' < n$).

The fraction of light of a given wavelength reflected by a material in air ($n' \approx 1$) for normal incidence is given by the Fresnel reflectivity

$$r = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}. \tag{5}$$

In the nonabsorbing transparent region where $k \approx 0$, this reduces to $r = 4\%$ for a material of refractive index $n = 1.5$. The reflection of normal-incidence, monochromatic radiation when multiple reflections at both entrance and exit surfaces are considered is given by the reflection factor

$$R = \frac{2n}{n^2 + 1}. \qquad (6)$$

Fresnel reflective losses become large for materials and at wavelengths where n is large. Above the fundamental absorption edge, materials are highly reflective.

More generally, the reflectance depends on the angle of incidence and whether light is incident from the more dense or less dense medium. In addition to spectral reflection, the transmitted flux may also be reduced by diffuse reflection from irregular entrance and exit surfaces and imperfections in the interior of the material.

1.4 Scattering

The flux transmitted through an optical material is reduced from the incident flux by a combination of losses due to absorption, reflection, and scattering. Light scattering may be due to extrinsic causes or it may be intrinsic in nature. The former include discrete scattering centers such as bubbles, inclusions, impurities, or flaws introduced during production. The latter includes Rayleigh scattering caused by stationary density, temperature, and compositional fluctuations and Brillouin scattering caused by propagating fluctuations in the dielectric constant. Colloidal particles that diffract light—the Tyndall effect—also contribute to light scattering.

Scattering processes may be distinguished by the size and absorptivity of the active centers (Van de Hulst, 1957). Rayleigh scattering is caused by scattering centers that are small compared to the wavelength of light and exhibits a characteristic λ^{-4} dependence on wavelength. As the particle size increases, scattering occurs increasingly in the forward direction and exhibits a λ^{-2} dependence (Rayleigh–Gan scattering). Mie scattering occurs when the scattering centers have a size comparable to the wavelength of light. Scattering in optical materials begins to be visible for centers $\gtrsim 10$ nm in size. For large numbers of centers of dimensions ~100 nm, the material appears cloudy. For high densities of centers having dimensions $\gtrsim 1000$ nm, the material is usually opaque.

For most bulk optical materials, losses due to extrinsic imperfections and impurity absorptions are usually larger than intrinsic scattering losses. Light-scattering losses in single-component glasses such as SiO_2 are small and limited by microscopic density fluctuations associated with the random molecular structure. Light-scattering losses in multicomponent glasses and mixtures are generally larger because of additional concentration fluctuations (Schroeder, 1977). For optical fibers, scattering is the major loss mechanism when absorption is successfully reduced.

1.5 Elasto-optic Properties

Materials normally considered to be isotropic (cubic crystals, glasses, and plastics) become anisotropic when subject to mechanical stress or strain. Photoelastic properties describe the effects of elastic deformation on the refractive index and result in distortions of the optical wave front; acousto-optics are dynamic strain effects. The piezo-optic and elasto-optic coefficients determine the effects of stress and strain, respectively, and their number depends on the symmetry of the material. In general, a material may possess 36 independent piezo-optic or elasto-optic constants (tensor components) (Nye, 1976). Because of the high sensitivity of optical properties to material strain, the presence of strain can lower the apparent point-group symmetry of a crystal.

Because glass is isotropic, only two independent coefficients are needed to characterize the piezo-optic or elasto-optic properties. The change in refraction index Δn caused by a change in stress σ for light polarized parallel or perpendicular to the line of stress is given by

$$\Delta n = \Delta n_{\parallel} - \Delta n_{\perp} = \frac{n^3}{2}(q_{11} - q_{12})\sigma, \qquad (7)$$

where the q's are the piezo-optic constants. Corresponding relations involving elasto-optic constants p (Pockels coefficients) describe changes in refractive index and the state of strain in the glass. Mechanical stress in an optical material, either developed internally during production, applied externally, or as a consequence of fluctuating temperature, changes the refractive index. The resulting change in optical path length S for a material of length l caused by stress birefringence is $\Delta S = \Delta nl = Kl\sigma$, where from Eq. (7) the stress-optical coefficient K is defined by

$$K = \frac{n^3}{2}(q_{12} - q_{11}). \tag{8}$$

Stress birefringence varies with both temperature and wavelength.

1.6 Thermo-optic Properties

Absorption of intense light in a material can lead to the formation of temperature gradients and stress in the material. The optical path length of light passing through a material varies with temperature as a result of thermal expansion and of changes in the refractive index and is given by

$$dS/dT = (n - 1)\alpha + dn/dT, \tag{9}$$

where α is the linear coefficient of thermal expansion. For most crystals and glasses $|dn/dT| \leq 10^{-5}$/K and increases at shorter wavelengths. By adjusting the composition of a glass so that the change in path length due to thermal expansion is compensated by a negative value of dn/dT, the thermo-optic coefficient can be made positive, negative, or zero (Izumitani, 1986). In principle, with the proper combination of glass properties, no optical distortions would appear in the presence of a nonuniform temperature distribution. Even if this ideal athermal glass is not achieved, thermo-optic distortions in optical glass can be reduced by compositional tailoring. Glass ceramics have also been tailored to be athermal over a wide temperature range, but with poorer transmission.

1.7 Magneto-optic Properties

Optical rotation occurs in a medium when the refractive indices n_+ and n_- for right- and left-circularly polarized light are unequal. The microscopic origin of magnetic-optical rotation is the inequality that is created by the splitting of the ground- or excited-state energy levels due to an applied magnetic field or magnetization (Zeiger and Pratt, 1973). When the magnetic vector is parallel to the light propagation vector (Faraday effect), the angle of magnetic-optical rotation is given by Eq. (4). The sense of rotation is positive if the rotation is in the direction of the positive current in the coil that produces the magnetic field. In contrast to natural rotation, which depends on the direction of wave propagation, Faraday rotation depends on the direction of the magnetic field. When the magnetization vector is perpendicular to the light propagation vector (Cotton–Mouton effect), the magnetic linear birefringence is much smaller and of less technological importance. For the Faraday effect, the rotation of the plane of polarization of light is given by

$$\theta_F = Vl\mathbf{H}\cdot\boldsymbol{\epsilon}, \tag{10}$$

where $\mathbf{H}$ is the strength of the applied field, $\boldsymbol{\epsilon}$ is a unit vector in the direction of light propagation, and the constant of proportionality V is the Verdet constant. In the small-field limit, the Verdet constant is a function of ω, T, and n and may be of diamagnetic, paramagnetic, or ferromagnetic origin. The classical formula for the Verdet constant of diamagnetic materials, due to Becquerel, is

$$V_{\text{dia}} = -\frac{e\lambda}{2mc^2}\frac{dn}{d\lambda}. \tag{11}$$

This expression holds for most materials if a multiplicative factor γ, the magneto-optic anomaly, is introduced. This factor varies with the nature of the bonding in the material and ranges from near unity for predominantly ionic bonding to 0.28 for strongly covalently bonded diamond. The Verdet constant of diamagnetic materials exhibits only a small temperature dependence and in the long-wavelength limit (far from the absorption edge) varies as $1/\lambda^2$.

When paramagnetic ions are present in a material, Faraday rotation is dependent on the number of paramagnetic ions and the frequency of electronic transitions of the ions. Magnetic-optical rotation occurs for ions from various transition-metal groups (Buckingham and Stephens, 1966). In the long-wavelength limit, V_{para} is negative, again varies as $1/\lambda^2$, and, except for extremely low temperatures, is inversely proportional to temperature. All transparent materials exhibit diamagnetic Faraday rotation; however, when paramagnetic ions are present in sufficient quantities, paramagnetic Faraday rotation can dominate. Because the diamagnetic and paramagnetic effects produce opposite rotations, the sign of the net Verdet constant of a material can change with paramagnetic ion content.

The magneto-optic Kerr effect observed when light is reflected from the surface of a solid has the same physical origin as the Faraday effect.

1.8 Nonlinear Optical Properties

The polarization **P** induced in a medium by an external optical electric field E of frequency ω can be expressed by the power series

$$\begin{aligned}\mathbf{P}(\omega) = \mathbf{P}^{(1)} + \mathbf{P}^{(2)} + \mathbf{P}^{(3)} + \ldots = \chi^{(1)}(\omega)E(\omega) \\ + \chi^{(2)}(\omega = \omega_1 + \omega_2)E(\omega_1)E(\omega_2) \\ + \chi^{(3)}(\omega = \omega_1 + \omega_2 + \omega_3)E(\omega_1) \\ \times E(\omega_2)E(\omega_3) + \ldots, \qquad (12)\end{aligned}$$

where the complex dielectric susceptibilities $\chi^{(n)}$ are tensors of rank $(n + 1)$ and are related to the microscopic (electronic and nuclear) structure of the material (Bloembergen, 1965; Shen, 1984). Classical or linear optics is concerned with the first-order term $\chi^{(1)}$. The linear refractive index n_0 and the linear absorption coefficient k are proportional to the real and imaginary parts of $\chi^{(1)}$. In regions of no absorption, $n^2 - 1 = 4\pi\chi^{(1)}$.

Second-harmonic generation, the linear electro-optic (Pockels) effect, and sum- and difference-frequency mixing are described by the second-order nonlinear susceptibility $\chi^{(2)}$ in Eq. (12). In the first process an optical signal is generated at twice the frequency of the incident optical field, that is, $\omega_1 = \omega_2$ and $\omega = 2\omega_1$. In the second process, the refractive indices for the ordinary and extraordinary waves become different on account of the birefringence induced by the application of the strong dc field. The second-order nonlinearity term $\chi^{(2)}$ is important for those materials having point-group symmetry with no center of inversion. Materials that exhibit a linear electro-optic effect are also piezoelectric. The strain produced by the piezoelectric effect modifies the index of refraction, giving rise to the photoelastic or strain-optic effect.

When a material has inversion symmetry (glasses, plastics, liquids, and gases), the Pockels effect is absent and the observable effect of an applied electric field E on the refractive index is the dc Kerr effect, given by

$$\Delta n = BE^2\lambda, \qquad (13)$$

where the Kerr constant B is proportional to the real component of $\chi^{(3)}$. Thus in an applied field an isotropic material can exhibit birefringence due to this quadratic effect. The crystal symmetry determines the nonzero terms in the nonlinear coefficient tensor.

Other third-order nonlinear processes involving $\chi^{(3)}$ are third-harmonic generation, two-photon absorption, Raman and Brillouin scattering, self-focusing, self-phase modulation, optical-phase conjugation, and a large number of four-wave mixing processes (Hellwarth, 1977). The optical (ac) Kerr effect is a four-wave mixing process involving optical-frequency fields. Through the optical Kerr effect, the refractive index becomes intensity-dependent and is given by

$$n = n_0 + n_2 I, \qquad (14)$$

where n_0 is the linear index of refraction, I is the time-averaged intensity of the incident optical beam, and n_2 is the nonlinear refractive-index coefficient, derived from the real part of $\chi^{(3)}$. If a high-intensity beam propagating through a material has a nonuniform spatial profile, the spatial variation of the induced refractive index will lead to self-focusing (or -defocusing depending on the sign of n_2) (Bliss *et al.,* 1974). The intensity-dependent refractive index also causes the phase at the peak of an optical pulse to be retarded with respect to its leading or trailing edges. In addition, certain solutions of the nonlinear wave equation, called solitons, propagate without any change in shape (Mollenauer *et al.,* 1980).

The imaginary part of $\chi^{(3)}$ contributes to two-photon absorption. Raman and Brillouin scattering also arise from the imaginary part of $\chi^{(3)}$ and involve interactions with optical and acoustic vibrations of the material.

1.9 Luminescence and Stimulated Emission

Many forms of luminescence occur in optical materials: photoluminescence (excited by optical radiation), electroluminescence (*q.v.*) (excited by electrons in an applied electric field), radioluminescence (excited by ionizing radiation), thermally induced luminescence (from trapping centers), and cathodoluminescence (*q.v.*) (electron-beam excitation) (Blasse and Grabmeier, 1994). Luminescence may be due to a variety of ionic and molecular species (activator ions or molecules) listed in Table 1. Photoluminescence (*q.v.*) can arise from the presence of various transition-metal ions (principally iron-group and lanthanide-series elements having partially filled electron shells), filled-shell and post–transition-group elements, semiconductor clusters, molecular complexes, organic dyes, radiative electron–hole recombination, excitons, and defect or color centers. Fluorescence lifetimes range from nanoseconds or less to milliseconds or more depending on the degree of forbiddenness of the radiative transition probability. While many of the general features of the luminescence from a given species are similar whether the host is an amorphous or crystalline material, site-to-site variations in the local environments in the former result in a distribution of energy levels (inhomogeneous broadening) and of radiative and nonradiative transition probabilities (non-single-exponential excited-state decays).

Stimulated emission (laser action) requires an inverted ion population of the excited species (Siegman, 1994) and has been achieved for a large number of ions and transitions at wavelengths ranging from the far infrared to soft x rays (Weber, 1991a). Solid-state lasers incorporate many different transition-metal ions, organic dyes, and color centers in inorganic and organic crystalline and amorphous hosts. Lasing is produced principally by optical pumping. In semiconductor-junction laser materials, a large electron current creates excited electron and hole states and induces laser action (Yariv, 1989).

1.10 Optical Damage

The extremely large optical electric fields associated with the high peak powers and fluences of lasers can lead to dielectric breakdown and damage of reflecting and transmitting optical components (Wood, 1986). Because of the intensity-dependent index of refraction, a light beam having a nonuniform spatial profile will self-focus as it traverses a glass (Bliss *et al.*, 1974). If uncontrolled, self-focusing can lead to catastrophic damage in the form of bubbles or tracking along the light path. Self-focusing is minimized by using optical materials with small nonlinear refractive-index coefficients n_2 and by controlling spatial nonuniformities in the beam profile. Interaction of intense light with structural or chemical imperfections at the surface leads to damage in the form of pitting. Laser-induced damage usually arises from both extrinsic and intrinsic material properties. The damage threshold is usually dependent on the optical wavelength and pulse duration.

2. OPTICAL GLASSES

Glasses constitute a broad class of optical materials including oxides, halides, and chalcogenides (Kreidl, 1983). Their chemical

Table 1. Luminescent species in solids.

Species	Transition	Examples
Transition-metal ions	*nd*–*nd*	Mn^{2+}, Ni^{2+}, . . ; Ti^{3+}, Cr^{3+}, . . ,
Lanthanide/actinide ions	*nf*–*nf*	Pr^{3+}, Nd^{3+}, . . , Yb^{3+}
	nf–$(n+1)d$	Ce^{3+}, Eu^{2+}, Yb^{2+}
Filled-shell ions	nd^{10}–$nd^{9}(n+1)s$	Cu^{+}, Ag^{+}, Zn^{2+}, Ga^{3+}, Sb^{5+}
Post–transition-group ions	ns^2–$nsnp$	Sn^{2+}, Sb^{3+}, Tl^{+}, Pb^{2+}, Bi^{3+}
Molecular complexes (d^0 ions)	Charge transfer	VO_4^{3-}, WO_4^{2-}, TaO_4^{3-}
Color centers	$2p$–$1s$	LiF (F_2^{+}), KCl [F_A(II)]
Band-to-band	Electron-hole recombination	GaAs, (Ga,In)N
Donor-acceptor pair	Electron-hole recombination	GaP:S,Si; ZnS:Ag,Cl
Excitons	Electron-hole recombination	Alkali halides, ZnS, CdS, GaP
Core (hole)–valence (electron)	*np*(cation)–*n′p*(anion)	BaF_2, CsF, CsCl, RbF, $KMgF_3$
Organic molecules	Singlet–singlet; triplet–singlet	Anthracene, stilbene, rhodamine

composition consists of a glass network former such as silicate, phosphate, borate, etc. and numerous network-modifier cations added to improve durability, ease of glass forming, or other physical and chemical properties. With this compositional versatility, it is possible to tailor the chemical composition to optimize various desired properties. In addition to homogeneous glass, two-phase glasses, such as borosilicates (Pyrex), and glass ceramics (e.g., Zerodur), which contain fine crystals dispersed in a glass matrix, are used as optical materials. Glass ceramics can exhibit good optical transparency if there is a good match of the refractive index of the crystalline and glassy phases or if the dimensions of the crystals are small compared to the wavelength of light.

2.1 Classification

Commercially available glasses for optical components and ophthalmic use are principally colorless oxide glasses. They provide a wide range of refraction, dispersion, specific gravity, and other optical, thermal, and mechanical properties. Optical glasses are characterized and designated by their refractive index and dispersion. The most common measure is the refractive index at the wavelength of the He *d* line (587.6 nm) or the Na *D* line (589.3 nm). The difference in the refractive indices at the hydrogen *F* (486.1 nm) and *C* (656.3 nm) lines, $n_F - n_C$, is called the average or principal dispersion. The ratio $(n_F - n_C)/(n_d - 1)$ is called the relative dispersion; the reciprocal of this quality is the Abbe number ν_d. A six-digit number is used to specific optical glasses, where the first three digits designate the refractive index n_d with the preceding "1" omitted and the last three digits designate the Abbe number ν_d with the decimal point omitted. Thus a borosilicate glass BK 7 having an $n_d = 1.51680$ and $\nu_d = 64.17$ has a designation 517 642. This six-digit refraction index–Abbe number code is the most universally useful way of designating optical glasses used in standard applications in which precise n and ν values are not required.

Glasses having $n_d < 1.60$, $\nu_d > 55$ are called "crown" (K) glass; other glasses having $n_d > 1.60$, $\nu_d < 50$ are called "flint" (F). These letters, plus others, are usually contained in the manufacturer's designation of optical glasses. Designations vary with the country of origin. "Light" or "dense" indicate the relative amounts of heavy-metal oxides such as PbO or La_2O_3. Designations for various glass types are given in Table 2; the first designation is that used for Schott glasses (Schott, 1982), and designations used by other manufacturers are given in parentheses (Weber, 1991b). Only a few nonoxide optical glasses such as heavy-metal fluorides and chalcogenides are available commercially. These are specified by the manufacturer's name or by the composition if it is simple. Heavy-metal fluoride glasses are usually designated by their chemical composition, e.g., ZBLAN for a ZrF_4-BaF_2-LaF_3-AlF_3-NaF fluoride glass.

Table 2. Designations and types of commercial optical glasses. Schott designations are given; other designations are in parentheses.

Designation	Type	Designation	Type
BaF (BF, FB)	Barium flint	LaSK	Dense lanthanum crown
BaK (BaC, LBC)	Barium crown	LF (FL)	Light flint
BaLF (LBC, BCL)	Light barium flint	LLF (BLF, FEL)	Extra light flint
BaSF (DBF, FBD)	Dense barium flint	PK (PC)	Phosphate crown
BK (BSC)	Borosilicate crown	PSK (DPC, PCD)	Dense phosphate crown
F (DF, FD)	Flint	SF (EDF, FDS)	Dense flint
FK (FC)	Fluorocrown	SFS	Special dense flint
FP (FK)	Fluorophosphate	SK (DBC, BCD)	Dense barium crown
FZ	Fluorozirconate	SSK (EDBC, BCDD)	Extra dense barium crown
K (C)	Crown	TaF	Tantalum flint
KF (CF, CHD)	Crown flint	TaK	Tantalum crown
KzFS (ADF)	Dense short flint	TaSF	Dense tantalum flint
LaF (LaFL)	Lanthanum flint	TiF	Titanium flint
LaK (LaC, LaCL)	Lanthanum crown	TiK	Titanium crown
LaSF	Dense lanthanum flint	TiSF (FF)	Dense titanium flint

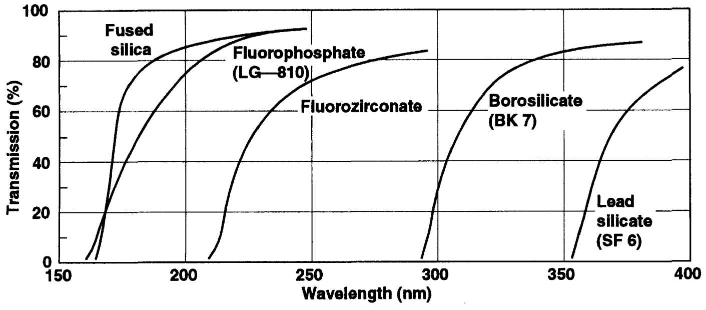

FIG. 3. Ultraviolet absorption edge of representative optical glasses. Sample thicknesses: 5 mm except for SiO_2 and LG 810, which are 2 mm. (From Cook and Mader, 1980; Schott, 1982).

Amorphous silica glass, SiO_2, is called fused quartz if made by melting crystalline quartz and fused silica if prepared synthetically by chemical vapor deposition starting with $SiCl_4$. The latter process can yield material of high purity with respect to metal impurities and OH^-. Various grades of silica are available that differ with respect to their UV and IR transmission properties and susceptibility to radiation damage.

2.2 Properties

2.2.1 Optical Properties Glasses exist that are optically transparent in the vacuum ultraviolet (VUV) and others in the mid-infrared. Figures 3 and 4 illustrate the variation of the ultraviolet (see also Sigel, 1977) and infrared absorption edges of representative optical glasses. The optical transmission in these figures depends on the wavelength dependence of the absorption, reflection, and scattering of the glass. The transmission of optical glasses is frequently given in terms of the internal transmission T_i after correction for reflective losses; that is, $T_i = T/R$, where R is the reflection factor given by Eq. (6). The deviation of T_i from 100% is a measure of absorption due to impurities and scattering due to defects. The internal transmittance is usually reported at a number of standard wavelengths from the ultraviolet to the infrared.

Optical glasses cover a general range of refractive indices $n_d = 1.4$ to 2.0 and reciprocal dispersions $\nu_d = 20$ to 90. These are almost exclusively oxide glasses and are shown in an n_d-ν_d plot in Fig. 5 where the lines divide the main compositional types in Table 2. Optical-glass companies supply such a figure with markers scattered throughout this parameter space indicating available glasses. The range of n_d and ν_d values shown in Fig. 5 is larger than that given in the usual glass catalog so as to include low-index, low-dispersion fluoride glasses (Baldwin *et al.*, 1981). Amorphous SiO_2 and BeF_2 are the extrema for oxide and halide glasses (many fluoroberyllate glasses transmit well into the vacuum ultraviolet). Many higher-index chalcogenide glasses cannot be located in an n_d-ν_d plot because the absorption edge extends into the visible and it is not always possible

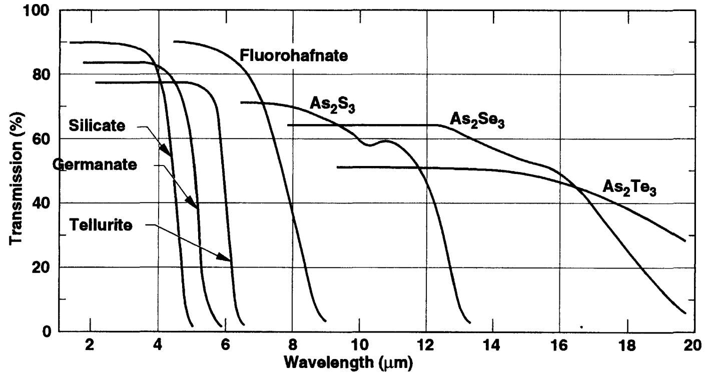

FIG. 4. Infrared absorption edge of representative optical glasses. Sample thicknesses: 2 mm. (From Dumbaugh, 1985.)

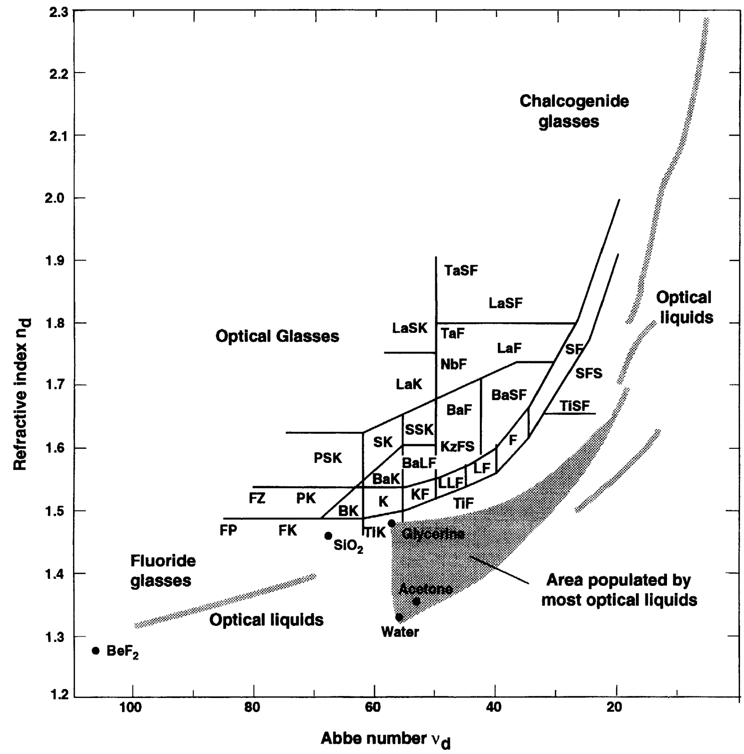

FIG. 5. Location of the optical glasses in Table 1 and optical liquids in a refractive index–Abbe number diagram.

to measure ν_d. For these infrared materials, plots are made using a reciprocal dispersion based on measurements of refractive index at longer wavelengths.

To interpolate values of the refractive index at the other wavelengths, glass manufacturers use an approximate dispersion formula derived from a power-series expansion of Eq. (3) of the form

$$n^2 = A_0 + A_1\lambda^2 + A_2\lambda^{-2} + A_3\lambda^{-4} + A_4\lambda^{-6} + A_5\lambda^{-8}, \qquad (15)$$

where the constants A_i are determined from a least-squares fit of the measured values (Schott, 1982). Using this equation, refractive indices in the wavelength range 370–1000 nm can be calculated to an accuracy of $\pm 5 \times 10^{-6}$ or better.

Various relative partial dispersions $P_{xy} = (n_x - n_y)/(n_F - n_C)$ are defined for other wavelengths x and y. The relative partial dispersion of most glasses obeys a linear relationship on ν_d of the form

$$P_{x,y} \approx a_{xy} + b_{xy}\nu_d, \qquad (16)$$

where a and b are constants. Because it is not possible to correct for second-order chromatic aberrations using so-called "normal" glasses that satisfy Eq. (16), optical-glass catalogs also list deviations of the relative partial dispersions from the normal for glasses covering a wide range of ν_d values.

2.2.2 Thermal Properties The temperature range in which a glass transforms from its solid state into a "plastic" state is called the transformation region. The viscosity of the melt at the transformation temperature T_g is approximately 10^{13} poise. A low T_g is important for molded optical elements as are the tendency of the glass to stick to the mold and the flatness of the viscosity-temperature dependence.

The coefficient of thermal expansion α of glass ranges from near zero for special low expansion glasses such as titania-doped SiO_2 and tailored glass ceramics to values greater than 20×10^{-6}/K. For optical glasses α ranges from about $(4 \text{ to } 16) \times 10^{-6}$/K. The thermal expansion coefficient increases with increasing temperature, exhibiting a nonlinear increase up to about room temperature, followed by an approximately linear range until the glass begins to exhibit plastic behavior, and then a rapid increase with increasing structural mobility in the glass.

The thermal coefficient of refractive index depends on the wavelength, temperature, and pressure. Both positive and negative values of dn/dT occur. The thermal conductivity κ of optical glasses ranges from about 0.5 to 1.5 W/m K, being high for silica and low for fluoride glasses and oxide glasses containing large quantities of heavy elements such as Pb, Ta, Ba, and La. The thermal conductivity of glass increases with temperature but only slightly above 300 K and is generally much smaller than that for crystals. Values of T_g, α, κ, specific heat c_p, and the hardness H (discussed below) are included in Table 3.

2.2.3 Mechanical Properties The mechanical response of a glass to an applied force is described by various moduli. Optical-glass catalogs usually list moduli such as Young's modulus E (extension in tension) and the modulus of rigidity or shear G, which are important for thermal and mechanical stress determinations. The stress-optical coefficient K varies with glass type and wavelength. It is usually positive, although it can become negative for silicate glasses having a high lead content (so-called Pockels glasses). Values of K generally range from $-2 < K < 4$ TPa^{-1} for oxide glasses to $-40 < K < 20$ TPa^{-1} for chalcogenide glasses.

The hardness H of a glass is an indicator of its vulnerability to surface damage and the ease with which it can be polished. It is usually measured from the indentation of Knoop or Vickers penetrators. Values (Knoop) for oxide glasses range from ~250 for high-lead-content glasses to >600 for lanthanum crown glasses. Representative values for a variety of glass types are included in Table 2. The Knoop hardness generally correlates with the Young's modulus.

2.2.4 Chemical Durability An important consideration for many optical glasses is their chemical reactivity with slurries during cutting and polishing of components such as lenses, windows, and prisms and with its environment where it may be subject to chemical attack by water, water vapor, other gases, acids, etc. in the atmosphere. No simple test and parameter is sufficient to characterize chemical reactivity and corrosion under all conditions. Thus many terms and tests are used by glass manufacturers to rank their glasses with respect to their resistance to acids, straining, climate, weathering, etc. This information is given in optical-glass catalogs.

2.3 Quality and Forms

Several hundred optical-glass types are available commercially. These are multicomponent glasses whose chemical compositions have been tailored to achieve the range of refractive indices and other physical properties discussed above. By careful batching, processing, and annealing, optical glasses can be made with very reproducible properties. The refractive index is controlled by the rate of annealing in the transformation range. Tolerances for n_d of ± 0.001–0.002 and for ν_d of $\pm 0.8\%$ are standard. The homogeneity of the refractive index is important for imaging systems; for selected melts or selected blanks, homogeneities of $\pm 10^{-5}$–10^{-7} are possible.

Table 3. Properties of common optical glasses (temperature range: 20–300 °C).

Glass type	ρ (g/cm^3)	H (Knoop)	α (10^{-6} K^{-1})	κ (W/m K)	c_p (J/g K)	T_g (°C)
Fused silica (SiO_2)	2.20	635	0.55	1.38	0.75	1175
Fluorophosphate (FK 54—487 865)	3.18	390	14.6	1.06	0.71	410
Fluorosilicate (FK 5—487 704)	2.45	520	9.2	0.92	0.81	464
Fluorozirconate (ZBLA)	4.61	240	18.7	~0.6	0.52	310
Borosilicate (BK 7—517 642)	2.51	610	7.1	1.11	0.85	557
Barium silicate (SK 14—603 606)	3.44	600	6.0	0.85	0.64	644
Alkali lead silicate (F 2—620 364)	3.61	420	8.2	0.78	0.56	438
Lanthanum borate (LaF 2—744 448)	4.34	560	8.1	0.67	0.48	658
Lead silicate (SF 6—805 254)	5.18	370	8.1	0.67	0.39	426
Arsenic trisulfide (As_2S_2)	3.20	180	26.1	0.17	0.47	163
Zerodur (Schott)	2.53	630	0.5	1.64	0.82	—
Pyrex (Corning 7740)	2.23	418	3.2	1.13	1.05	287

Residual stress birefringence varies with glass size and type. For some glasses values of ≤20 nm/cm are achievable for large (~1 m) diameter blanks. For smaller pieces (~100 mm), values of ≤4 nm/cm are possible by special annealing. Most glasses can be produced virtually striae and inclusion (bubble) free.

Optical glass is available in many forms including

1. slabs and blocks with two or more machined and polished faces used for test purposes,
2. strips, rods, and rolled glass with unfinished surfaces,
3. semi-finished and pressings of some required form, and
4. simple gobs.

Glass fibers are produced by controlled drawing from a melt or preform with diameters of <10 to >100 μm. Doped silica fibers are the most commonly used for optical applications (see FIBER OPTICS; OPTICAL COMMUNICATIONS), but fibers can be prepared from many different single- or multiple-component oxide and fluoride glasses. To reduce losses, a core glass is clad with another glass or plastic of lower refractive index so that light being transmitted is totally reflected internally. For ultralow-loss glass fibers for optical communications, losses of less than 1 dB/km have been achieved in the near infrared corresponding to an absorption coefficient of $\sim 10^{-6}$ cm^{-1}.

2.4 Special Glasses and Applications

2.4.1 Abnormal-Dispersion Glass The partial dispersions of optical glass are important in the design of compound lenses. By combining a positive lens of a crown glass with a negative lens of a flint glass, chromatic aberration can be avoided at two wavelengths. Correction for second-order chromatic aberration (secondary spectrum) is accomplished using glasses with equal partial dispersions for different Abbe values. Abnormal-dispersion glasses depart from the "normal line" and the linear relationship in Eq. (16). These glasses are produced by tailoring the chemical composition of the glass so as to alter the relative strength and positions of the ultraviolet and infrared absorption bands of the constituents and thereby change the dispersion.

2.4.2 Gradient-Index Glass A conventional glass lens consists of a homogenous material with a single index of refraction. Glass elements can also be manufactured in which the index of refraction varies continuously within the material. These are called gradient-index or GRIN materials. The refractive-index gradient may be axial (varying along the optical axis), radial (varying outwardly from the optical axis), or spherical (varying symmetrically from a point) (Moore, 1980). For imaging systems, gradient-index glass provides an alternative to the generation of complex aspheric lens surfaces to control aberrations. Gradient-index rods and fibers are used in micro-optics, imaging optics, and optical-fiber communication systems. Techniques for creating refractive-index variations include neutron irradiation, chemical vapor deposition of layers of glass of slightly different refractive indices, ion exchange by immersing the glass in an appropriate solution, ion stuffing in porous glass, and sol-gel methods.

2.4.3 Mirror-Substrate Glass For front surface mirrors where retention of the optical figure is important, the thermal stability of the environment is a major consideration. In a temperature-controlled environment, low-cost borosilicate glasses can be used for mirror substrates. If, however, the substrate is subject to temperature variations, materials with the lowest possible coefficient of thermal expansion are needed. Silica containing small quantities of titanium dioxide or other heavy-metal oxides and glass ceramics can be produced that are hard materials with extremely small, near-zero coefficients of thermal expansion ($\alpha \leq 0.1 \times 10^{-6}$/K). Glass ceramics (such as Zerodur) are solid solutions in which the very small or even negative thermal expansion coefficient of the crystalline phase compensates for the positive expansion coefficient of the remaining glass matrix. Glass-ceramic mirror blanks with diameters of more than 8 m have been produced for telescope mirrors.

2.4.4 Optical-Filter Glass Transmitting filter glasses change the spectral properties of optical radiation and provide selective filtering for scientific and technological applications, for color enhancement in ophthalmic lenses, and for contrast enhancement in displays (see OPTICAL FILTERS). Filters are categorized as band-passing and band-blocking filters, short-wavelength and long-wavelength cutoff filters, and neutral-density and color-conversion filters. The transmission characteristics are determined by a combination of the base glass and ion doping or colloidal coloration. The UV and IR cutoff wavelengths vary greatly depending on the glass composition; thus the composition can be tailored to achieve selected transmission characteristics. Other cutoff and bandpass filters are produced by doping with transition metals, rare earths, and uranium (Cook and Stokowski, 1986). The fundamental absorption edge of semiconductor-doped glasses depends on the size and absorption characteristics of the colloidal particles. By careful heat treatment and processing of Cd(S,Se)- and CdTe-doped silicate and borosilicate glasses, a series of long-pass filters can be manufactured with sharp cutoff wavelengths varying over a wide spectral range in the visible and near infrared.

Optical-filter glass, like other optical glasses, is manufactured in high optical quality, free of striae and inclusions, and in a variety of forms. Transmission is carefully controlled. Filter-glass catalogs present extensive data on transmittance; data on refractive index and other thermal and mechanical properties and chemical durability are also listed. Under prolonged exposure to high-intensity ultraviolet radiation, some filter glass may solarize and exhibit reduced transmission, particularly at shorter wavelengths. Some ionically or colloidally colored filter glasses also exhibit *photoluminescence* (Turner, 1973).

2.4.5 Nonlinear Optical Glass Optical nonlinearities in glass arising from the ac Kerr effect are of interest in two extremes: in high-power lasers where glass with a small nonlinear refractive index n_2 is desired to reduce self-focusing and optical damage, and in all optical switching devices where glass with a large n_2 is desired to minimize the optical power requirements (Vogel *et al.*, 1991). The magnitude of the optical Kerr effect is known for a wide range of undoped and doped glasses (Borrelli and Hall, 1991). Glasses with small values of linear refractive index and dispersion generally have small n_2 values (Adair *et al.*, 1987). The smallest linear and nonlinear refractive indices for glass occur for fluoride-containing glasses (Weber *et al.*, 1978).

For all-optical switching devices, materials are sought having a large n_2 and a small absorption loss coefficient at the operating wavelength. Very large resonant optical nonlinearities are observed in semiconductor-doped glasses (glasses doped with I–VII, II–VI, and III–V compounds). The nonlinear behavior appears as intensity-dependent changes in absorption and refractive index with response times of $<10^{-11}$ s originating from the generation of a short-lived free-electron plasma and band-filling effects. Organic dye molecules have intense singlet–singlet transitions and have been added to low–melting-point glasses such as boric-acid glass and lead-tin fluorophosphate glass (Tompkin *et al.*, 1987) without decomposition. Saturation of the ground-state absorption of the dye produces optical nonlinearities with a very large effective $\chi^{(3)}$. Because the response time is governed by the relaxation time of the triplet state of the dye, recovery of the saturated nonlinearity is very slow compared to that of nonresonant electronic nonlinearities. Glasses containing very small metallic particles also exhibit an efficient, fast optical Kerr effect (Vogel *et al.*, 1991).

The dc Kerr constants for glasses are in the order of or less than 2×10^{-14} m/V^2 (Borrelli and Hall, 1991). The largest values are found for glasses containing large quantities of heavy, polarizable ions such as Nb, Ta, Tl, Pb, and Bi. Although glass is macroscopically isotropic and therefore it is not expected to exhibit second-harmonic generation due to the second-order nonlinear susceptibility $\chi^{(2)}$, several photoinduced nonlinear optical effects are observed after a glass has been exposed to light for periods of time varying from minutes to hours (see Vogel *et al.*, 1991, and references cited therein). These include refractive-index gratings and second-harmonic generation in fibers. These effects have been reported primarily for Ge-P- or Ge-doped silica fibers.

2.4.6 Laser Glass A large number of different lasing ions (principally trivalent lanthanides) and host glasses (oxides and fluorides) have been used for glass lasers (Hall and Weber, 1991). The forms used for laser glasses include bulk, fiber, and planar waveguide. The spectral range of glass lasers extends from ~0.4 to 3.9 μm. The spectroscopic properties important for laser action vary with the chemical composition of the host. Although a large number of experimental laser glasses have been reported in the literature, commercial laser glasses are almost exclusively silicates and phosphates. Fluorophosphate glasses have been developed for applications requiring low n_2 values. Phosphate glasses generally have narrower linewidths and, for ultraphosphates, have less fluorescence concentration quenching than for silicate glasses; thus they are more appropriate for applications requiring high gain and efficient energy extraction (Marion and Weber, 1991).

Laser glass shares with optical glass the requirements of refractive-index homogeneity (variations $\leq 10^{-6}$), high purity (absorption coefficient at the lasing wavelength of $\leq 10^{-3}$ cm^{-1}), freedom from bubbles and striae, low birefringence ($\leq$5 nm/cm), good chemical durability, and capacity of being finished to high optical tolerances (λ/20). High-quality phosphate laser glasses satisfying these requirements have been produced with dimensions greater than 0.5 m. Athermal phosphate glasses have been developed in which the change of optical path length with temperature is near zero (Izumitani, 1986).

2.4.7 Faraday-Rotator Glass The Faraday effect has been utilized in the construction of fast optical switches, modulators, circulators, isolators, and sensors for magnetic fields and electric currents. Diamagnetic and paramagnetic glasses have been used in bulk and fiber forms for these applications. The largest diamagnetic Verdet constants are found for high-index, high-dispersion glasses located in the upper right-hand corner of Fig. 5. Chalcogenide glasses have very high dispersion and large Verdet constants and are appropriate for use in the infrared. The temperature dependence of V_{dia} is very small, which makes diamagnetic glasses attractive for high-stability Faraday-effect sensors.

The magnitude and the wavelength and temperature dependences of paramagnetic glasses vary depending upon the choice of the paramagnetic ion. For lanthanide-series ions Ce^{3+}, Tb^{3+}, and Eu^{2+} have large regions of transparency in the visible-near infrared region and large paramagnetic Verdet constants. Because V_{dia} and V_{para} have opposite signs, the best host glasses are those having low dispersion (therefore small V_{dia}) and capable of incorporating large quantities of the paramagnetic ion. Verdet constants for several diamagnetic and paramagnetic glasses are given in Table 4.

2.4.8 Acousto-optic Glass Acoustic waves create a time-varying refractive-index grating in a material via the photoelastic effect. The grating spacing is equal to the acoustic wavelength; the grating depth is determined by the drive power of the transducer. A light beam traversing the medium is deflected by the grating. This phenomenon provides fast deflection or modulation of light and is used in display technology. An acousto-optic material, in addition to having low losses at the acoustic and optical wavelengths, should also have a large index of refraction and small sound velocity. These include materials containing heavy cations such as lead silicate or tellurite glasses and chalcogenide glasses. If a large bandwidth is desired, materials should have a large sound velocity. In Table 5 the properties of glasses are compared to those of other acousto-optic materials. Glasses are attractive for many applications because they are isotropic and can be prepared in large sizes of excellent optical quality.

Table 4. Verdet constants of diamagnetic and paramagnetic materials at 633 nm and 300 K.

Crystals	V (rad/T m)	Glasses	V (rad/T m)	Liquids	V (rad/T m)
NaCl	8.5	Fused silica (SiO_2)	3.7	Water (H_2O)	3.35

[a] L, longitudinal wave; S, shear wave.

2.4.9 Radiation-Detection Glass Glass is used in two forms for detection of high-energy radiation and particles: as a pure glass for the generation of Cherenkov radiation by energetic particles and as a doped glass for scintillation caused by x rays, gamma rays, charged particles, and neutrons. Since *Cherenkov radiation* is intense in the blue-violet, for the radiation to be detected the glass must maintain good transparency in this spectral region. Large blocks of lead-silicate optical glass having a high refractive index, $n \geq 1.7$, are used in Cherenkov counters capable of detecting particles traveling at 0.6 of the speed of light in vacuum.

High-energy charged particles and ionizing radiation are detected by scintillation from glass activated by a fluorescing species such as Ce^{3+}. Absorption of ionizing radiation leads to the creation of large numbers of electron–hole pairs, subsequent excitation of the activator, and fluorescence, which is detected. Glasses containing ^6Li, which has a large neutron-capture cross section, are used for detecting neutrons. Scintillation glasses are available in bulk form for energy calorimetry and in fiber form for particle tracking. The light yield of glass scintillators is usually much less than that of the best crystalline scintillators because of low transfer efficiency from the host to the activator.

2.4.10 Radiation-Shielding Glass Glass is used for remote viewing of radiation environments such as x-ray facilities, hot cells in nuclear research, irradiation facilities for food preservation, and medical sterilization and therapeutic installations. In these applications the optical glass must both provide adequate shielding and not discolor during exposure to the radiation. High–lead-content glasses are used for radiation-shielding glass. These glasses have about one-half the absorption of lead of comparable thickness.

2.4.11 Photosensitive Glass Photosensitive glasses are a special class of glasses whose optical properties are changed by optical/thermal treatment. Among these are photochromic glasses that change color under ultraviolet or short-wavelength light, then revert back to the original state when the light is reduced. In ophthalmic and architectural applications, the transmission of such glasses in the 400–700-nm region can be reduced by more than 50% when exposed to bright light. Photochromism is observed in strongly reduced alkali silicate and other multicomponent silicate and borosilicate glasses, in glasses containing suspensions of crystallites, and in glasses colored by silver halides. Many different base glasses can be used; the choice of composition, especially the halide, and thermal treatment influence the photochromic properties. The mechanisms involved in photochromism are complex and include treatment of precipitation kinetics and charge-carrier diffusion (Araujo, 1977). Most glasses are photosensitive in the negative sense that they become colored (so-

Table 6. Properties of common optical plastics.

Polymer (trade names)	n_D	ν_D	Density (g/cm^3)	Relative haze	Hue (coloration)
Polyurethane (Isoplast)	1.65	—	1.2	Light	Colorless
Polysulfone (Udel)	1.63	22.5	1.24	Light	Yellow
Polystyrene (styrene, Dylene, Styron, Lustrex)	1.589	31	1.06	Low	Colorless
Polycarbonate (Lexan, Merlon, Calibre)	1.585	30	1.2	Slight	Light straw

larize) after exposure to ultraviolet or ionizing radiation. To prevent solarization in optically pumped laser glass and in glass used for UV lamps, small quantities ($\lesssim 1\%$) of polyvalent ions such as cerium, antimony, and molybdenum are added to the glass.

3. OPTICAL PLASTICS

Many clear and colored plastics are of interest for optical applications. Optical plastics differ from optical glasses in several ways that make them uniquely suited for certain components. Their advantages are that they are less costly, lightweight, and not fragile, and they can be formed into complex shapes using simple fabrication techniques; their disadvantages are that they have a low tolerance for heat and abrasion, are subject to haze (internal scattering) and solarization (radiation-induced coloration), and have a narrower range of optical properties than other solid materials. Because plastics are normally formed in molds, nonspherical (aspheric) surfaces and nonrotationally symmetric surfaces are nearly as easy to produce as spherical surfaces. Although not every polymer exhibits the high clarity and absorption-free visible transmission associated with acrylic plastics, some may have other properties such as solvent resistance, thermal stability, or moldability that make them useful in particular optical applications.

3.1 Optical and Physical Properties

A number of the optical properties of some common plastics are summarized in Table 6. The refractive indices of plastics are in the general range from 1.3 to 1.7. The location of several optical plastics are shown in a refractive index–Abbe number diagram in Fig. 6 and compared to the larger, more extensive range of optical glasses. The maximum useful operating temperature for most plastics is ≤100 °C. The temperature dependence of the refractive index is large, in the

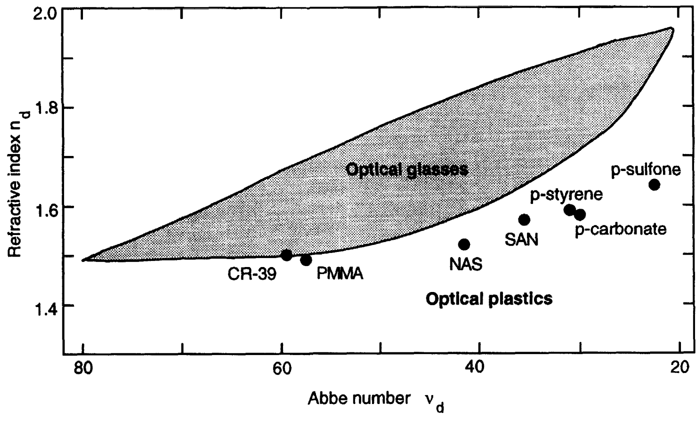

FIG. 6. Location of optical glasses and optical plastics in a refractive index–Abbe number diagram.

order of (1–2) × 10^{-4}/K for glassy polymers compared to ~3 × 10^{-6}/K for a typical optical glass. The coefficient of linear expansion with temperature is also large: (6–7) × 10^{-5}/K for a typical polymer compared to (5–10) × 10^{-6}/K for a typical glass. With such large temperature dependences, thermal changes must be considered in any optical design involving plastics. A laser beam traversing a plastic may also exhibit "blooming" as a result of thermally induced refractive-index changes. Because the temperature dependence of the refractive index is negative for polymers, it is possible to design thermally compensated glass/polymer optical doublets.

Transmission spectra of common optical plastics are given in Fig. 7. The useful transmittance range for most polymers is from about 380 to 1000 nm. The short-wavelength limit for 50% transmission through a 3-mm path length is approximately 380 nm for polystyrene, 340 nm for polycarbonate, 280 nm for ultraviolet acrylic, and below 250 nm for fluoropolymers (where some or all of the hydrogen atoms are replaced by fluorine atoms). Most of the near-infrared region above 1000 nm is absorbed by C–H vibrational overtone and combination bands, except for transmission windows around 1300 and 1500 nm. Optical properties can also change with water content and the humidity of the environment.

Transmission losses are process and thickness dependent; therefore, haze and coloration are described by relative values. Most high–refractive-index plastics may have some intrinsic yellowness, but other plastics are clear with good transmission throughout the visible and into the near-ultraviolet. Haze levels well below 0.5% for 5-mm thicknesses of plastics are readily possible. For some materials the haze can be reduced at the sacrifice of some other properties. Lower haze is often achievable in casting materials (e.g., cast polymethylmethacrylate, PMMA) since these can be filtered more easily than molding compounds. Plastics are marketed either with or without chemical additives to prevent or reduce yellowing or the development of haze. Some clear resins are supplied with a blue "toner" as an optical brightener; the color additive imparts a "water clear" appearance by compensating for the slight yellow coloration of some plastics. Plastic fibers for optical transmission may have typical losses of about 400–500 dB/km, but fibers have been produced with losses of ~13 dB/km.

3.2 Applications

Stryene, polycarbonates, and acrylics are thermoplastics. Styrenes are low-cost, high-clarity, high-index materials; polycarbonates have high heat and impact strength but poor scratch resistance; acrylics have high scratch resistance and good optical transmission and hence are used for ophthalmic lenses. Thermoplastics (which can be reheated to a viscous state and reformed) are generally processed by injection or compression molding. Very high-volume or large flat pieces may be extruded onto rollers. Thermosetting plastics and epoxy are usually cast and are able to be formed only once. The resins are usually received from the vendor in monomer form or in a partially polymerized state. The material

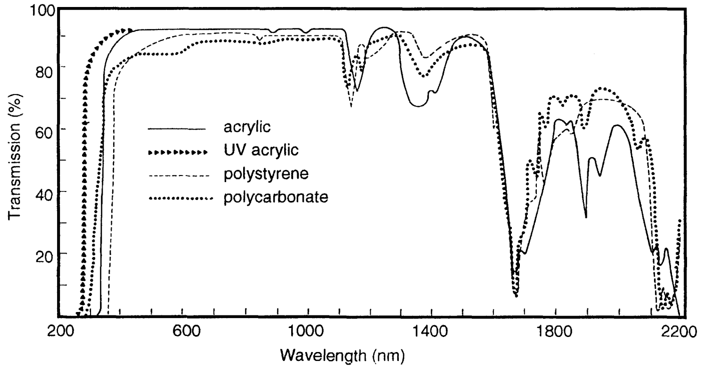

FIG. 7. Transmission spectra of optical plastics. Sample thickness: 3.2 mm. (From Welham, 1979.)

is then cast or heated by compression or transfer molding to finish the polymerization. The classical injection-molding process typically leaves some inhomogeneities in the material due to shear and cooling stresses. Cast thermosets exhibit fewer of these defects. Acrylic (PMMA), (poly)stryene, and the (poly)urethanes can be obtained in monomer form for casting.

Small-volume or prototype optical parts are often machined from cast or molded and annealed blanks. With diamond-turning technology, a number of polymers can be machined into optics such that polishing is no longer necessary. Reflective, antireflective, and dichroic coatings have been successfully applied to many optical plastics.

Dichroic polarizers are produced by stretching sheets of plastic or rubbing the surface of a plastic in one direction, thereby aligning long-chain polymeric molecules that make up polyvinyl alcohol. The layer is then treated with polymeric iodine or other appropriate dye. These are useful polarizers in the visible and have maximum-to-minimum transmission ratios of 10^{-3}–10^{-5}.

Pigments and dyes are used to provide transparent colored optics. Dye molecules can also be incorporated into plastics and used for optically pumped, tunable dye lasers. The useful lifetime of such materials depends on the resistance of the dye to photodegradation and varies with the dye and the host.

Plastics used for scintillator materials are produced by adding various chromophors such as *p*-terphenyl to polystyrene or polyvinyltoluene host materials (Knoll, 1989). Absorption of radiation by the host material results in fluorescence that is transferred radiatively or nonradiatively to the chromophore, which then emits radiation at a longer wavelength. Plastics are susceptible to radiation-induced coloration in the near-ultraviolet and visible. Since this absorption reduces scintillation light output, one or more wavelength-shifting dyes are frequently added, which absorb radiation from the first dye and re-emit it at a longer wavelength that is less subject to absorption. Plastic scintillators have relatively large light outputs, but because their density and effective atomic number are low, they are not efficient for detecting gamma rays but are used in large volumes for charged-particle detectors.

4. OPTICAL CRYSTALS

Crystals exist with isotropic properties comparable to amorphous materials; other crystals have anisotropic optical properties that make additional optical phenomena possible such as polarization and phase matching in wave mixing (Yariv and Yeh, 1984). Although crystals have a fixed chemical composition and therefore their composition cannot be tailored to achieve properties as in the case of glasses, an extremely wide range of synthetically produced crystalline materials are available with physical properties that in most cases exceed those available with glasses. Hundreds of optical crystals have been synthesized using a variety of techniques including flux growth, flame fusion (Verneuil), Bridgman, pulling (Czochralski), floating zone, heat exchanger method, chemical vapor deposition (CVD), and hydrothermal (Musikant, 1985). The obtainable sizes may be limited in some cases, but many crystals of dimensions of several centimeters or more (approaching 1 m) can be prepared. Single-crystal fibers are prepared using a laser-heated–pedestal growth technique (Yen, 1995). Several cubic materials are prepared in large sizes as polycrystalline materials by hot pressing (e.g., MgO, NaCl, MgF_2, CaF_2, ZnS, ZnSe, CdTe). The cost of crystalline materials depends on the availability and purity of the starting material, the cost of growing or processing the crystal to the size required, and final fabrication and surface finish of the material required for the application of interest. The plethora of crystalline materials is available not only for transmitting optics but as hosts for solid-state laser and nonlinear-optics applications.

4.1 Optical Properties

The fundamental band gaps of crystals range from >10 eV for some insulating fluoride materials to ~0.1 eV for some semiconductors. The dependence of transmission on chemical composition and bonding is similar to that of the glasses as shown in Figs. 3 and 4; however, several crystals transmit further into the UV than do the glasses in Fig. 3. The refractive indices of crystals also extend over the same general range of the n vs ν_d space in Fig. 5 and have varying dependences on both wavelength and temperature.

Table 7. Properties of crystals having cubic symmetry. Refractive index measured at 0.6 μm unless noted otherwise.

Material	Transmission range (μm)	Refractive index	Density (g/cm^3)	Hardness (kg/mm^2)	Melting point (K)	Thermal expansion (10^{-6}/K)	Therm. cond. (W/m K)
Oxides

ZnSe	0.5–20	2.59	5.42	137	1790	7.1	19
CdTe	0.9–30	2.81 (10.6 μm)	6.20	56	1320	5.0	6.3
Other crystals							
C (diamond)	0.22–2.5, 6–100	2.42	3.51	5,700–10,400	3770	1.2	660
Si	1.2–7.0	3.48 (1.5 μm)	2.33	1150	1690	2.6	160
Ge	1.8–23	4.05 (2.8 μm)	5.35	800	1210	5.7	59
BN	0.2–6	2.12	3.48	4600	3500	3.5	~1300
InP	0.9–14	3.43	4.8	430	1320	4.5	70
GaAs	0.9–15	3.35 (1.9 μm)	5.32	720	1240	5.0	52

The temperature variations of n are in the general range of 10^{-5}/K but may be an order of magnitude larger or smaller. The range of transmission and refractive index of representative cubic crystals are given in Table 7. As noted earlier, whereas cubic crystals have a single index of refraction, uniaxial crystals have two (n_0,n_e), and biaxial crystals have three (n_1,n_2,n_3). Examples of the magnitude of the birefringence of crystals are tabulated in Table 8. The dependence of the refractive index on the direction of vibration of plane-polarized light traveling through a crystal can be described by an ellipsoidal surface, the optical indicatrix. The orientation of the indicatrix is related to the symmetry directions of the crystal.

Crystalline materials exhibit a metallic-like reflection at approximately twice the infrared cutoff wavelength. This reststrahten reflection is associated with fundamental resonant vibrations of the lattice.

For a discussion of nonlinear optical properties, see OPTICS, NONLINEAR.

4.2 Physical Properties

Optical crystals are generally superior to glasses and plastics with respect to their thermal and mechanical properties. Thermal conductivities of crystals may be one or more orders of magnitude greater than for glasses. The thermal conductivity of crystals is usually smaller the more atoms there are in the unit cell. Crystals exhibit a large range of hardnesses and fracture strengths; again

Table 8. Birefringence of common optical crystals at 0.60 μm and 300 K.

Crystal	Transmission (μm)	n_e–n_0	Crystal	Transmission (μm)	n_e–n_0
Al_2O_3 (corundum)	0.19–5.1	−0.008	MgF_2	0.13–7.7	0.012
$CaCO_3$ (calcite)	0.21–3.3	−0.172	SiO_2 (quartz)	0.16–4.0	0.009
CdS	0.51–14.8	−0.018	TiO_2 (rutile)	0.42–4.0	0.287
$LiNbO_3$	0.35–4.2	−0.092	YVO_4	0.35–4.8	0.023
KH_2PO_4 (KDP)	0.20–1.5	−0.041	$ZrSiO_4$ (zircon)	0.4–4.0	0.055

optical crystals exist that are greatly superior to glasses in these respects. Some crystals, however, have a tendency to cleave. As in the case of the refractive index, many physical properties of crystals are anisotropic (thermal conductivity, thermal expansion, and hardness). Melting points, hardnesses, thermal conductivities, and thermal expansion coefficients of several cubic crystals are included in Table 7.

4.3 Applications

4.3.1 Optical Components The availability of large, uniform crystals of high purity make them attractive for use as transmitting optical components such as windows, lenses, polarizers, transmission gratings, and selective reflectors. Cubic crystals, such as those listed in Table 7, or uniaxial crystals, with light propagating along the optic axis, are used for window materials and lenses covering a wide range of wavelengths—from the VUV through the IR. Crystals are especially useful in high-power optical applications where their toughness and thermal shock resistance are superior to those of glass. Alumina (Al_2O_3, corundum, and sapphire) is available in many sizes and forms and is attractive for many applications because of its hardness (1370 kg/mm^2), high melting temperature (2300 K), transmission (0.19–5.1 μm), and good thermal properties ($\alpha = 5.6 \times 10^{-6}$/K and $\kappa = 33$–35 W/m K).

The birefringence properties of crystals are utilized for various types of polarizers. A number of commonly used birefringent materials are listed in Table 8. Birefringent crystals are available for use throughout the visible and infrared regions.

4.3.2 Electro-optic Crystals Electro-optic crystals are noncubic and lack a center of symmetry. Of the 32 point-group symmetries, 11 are centrosymmetric and exhibit only third-order electro-optic effects (dc Kerr effect). The properties of a large number of crystals have been investigated; some of the more commonly used electro-optic crystals are listed in Table 9. Their ranges of transparency extend from the VUV to the mid-IR. Materials such as BBO, LBO, KTP, and KDP are useful in the UV–visible region; proustite, ZnSe, $ZnGeP_2$, and CuCl are useful in the infrared region.

In addition to inorganic crystals, many organic molecular crystals exhibiting large nonlinear coefficients have been investigated (see, for example, Chemla and Zyss, 1987). In many instances, obtaining molecular crystals of sufficient size, optical quality, and photochemical stability has been a limitation to their usefulness. Urea [$CO(NH_2)_2$], however, has been used successfully in nonlinear applications.

The Pockels effect can be used to control the intensity and phase of propagating radiation and therefore has many applications for light modulators and switches. The effect is characterized by tensor coefficients r_{ij}, where $i = 1, 2, 3$ and $j = 1$–6. The number of nonzero Pockels coefficients depends on the crystal symmetry class and is tabulated in various books (Nye, 1976). The number of wavelengths of retardation is given by $n_0^3 r_{63} V/\lambda$, where V is the applied voltage. Optical properties and the half-wave voltage required to produce a phase shift of π for an electric field applied parallel or transverse to the direction of light propagation are tabulated for several representative crystals in Table 10. Lithium niobate is widely used as an electro-optic light modulator.

A key to utilization of the second-order nonlinearity for optical harmonic generation is phase matching to compensate for material dispersion (Yariv and Yeh, 1984). For efficient energy transfer from the fundamental

Table 9. Electro-optic crystals and regions of optical transparency.

Crystal	Transmission (nm)	Crystal	Transmission (nm)

to the second-harmonic wave, the phase velocities of the two waves must match. Because the refractive indices of birefringent crystals depend on the direction and polarization of the light, crystal orientations are selected to achieve phase matching for the two frequencies. The general condition for phase matching for second-order nonlinear processes, in which two photons of different frequencies and momenta **k** either add or subtract to create a third photon, is

$$\mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}_3. \tag{17}$$

So-called type I phase matching, where $2\mathbf{k}_1^{(o)} = \mathbf{k}_2^{(e)}$, is illustrated in Fig. 8.

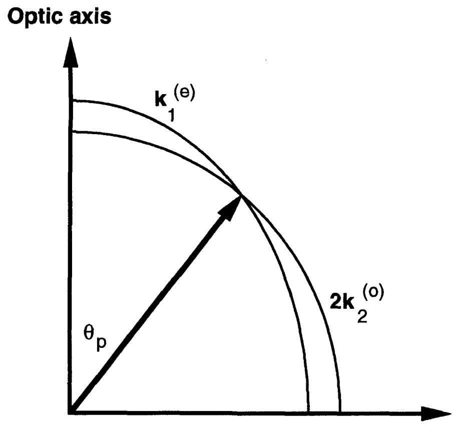

FIG. 8. Principle of phase matching in birefringent materials for second-harmonic generation.

4.4 Magneto-optic Crystals

All transmitting crystals exhibit diamagnetic Faraday rotation and, as noted for glasses, this rotation is largest for high-index, high-dispersion materials. Paramagnetic Faraday rotation depends on the presence of paramagnetic ions. Since these may be present as a constituent of the crystal rather than as a dopant, their concentration can be greater than is possible in most glasses, thus providing large Verdet constants. Only cubic or uniaxial crystals are usable for Faraday rotation. The diamagnetic and paramagnetic Verdet constants of several crystals are listed in Table 4.

The magneto-optic effect in ferromagnetic, ferrimagnetic, and antiferromagnetic materials can be much larger than in diamagnetic and paramagnetic crystals because of spin ordering (Deeter *et al.*, 1995). Rare-earth transition-metal alloys (e.g., $Y_3Fe_5O_{12}$ with trivalent rare earths or bismuth substituted for Y) are available commercially for applications at wavelengths ≥ 1 μm. Dilute magnetic semiconductors, such as $Cd_{1-x}Mn_xTe$, also exhibit large Faraday effects in the near-IR. The effect is strongly dependent on composition and wavelength.

4.5 Acousto-optic Crystals

The acousto-optic effect in a crystal can affect the direction, polarization, phase, frequency, and amplitude of an optical beam. Beam deflectors and intensity modulators are produced by generating an acoustic wave in the material with a piezoelectric driver in the frequency range 10^5–10^9 Hz. The sound wave may be oriented parallel (longitudinal wave) or normal (shear wave) to the light beam. By varying the applied radiofrequency, acousto-optic diffraction can also be utilized for tunable optical filters. Examples of acousto-optic crystals and their properties are given in Table 5.

4.6 Laser Crystals

Laser action has been demonstrated in hundreds of insulating crystals of many different symmetries and chemical compositions and at wavelengths extending from 0.17 to 7 μm (Kaminskii, 1990; Weber, 1991a). The lasing ions have been predominantly lanthanide and transition-metal ions (see LASERS, SOLID STATE). All trivalent rare earths and several divalent rare earths (Eu, Dy, and Tm) have been reported to lase in crystals. Among the most prominent host crystals for trivalent rare earths are $Y_3Al_5O_{12}$, $YAlO_3$, YVO_4, and $LiYF_4$; for divalent rare earths and transition metals, MgF_2 and CaF_2; and for iron-group elements (Ti^{3+}, V^{2+}, Cr^{3+}, Cr^{4+}, Co^{2+}, Ni^{2+}), Al_2O_3, $MgSiO_4$, and $LiCaAlF_6$ or $LiSrAlF_6$. Because the emission lines in crystals are narrower than in glasses, lower thresholds for lasing and higher optical gains are possible for crystalline lasers.

Many color-center lasers use alkali halide crystals as host materials because they are optically isotropic and transparent in the visible to near-IR. The most commonly used crystals are LiF, NaCl, KCl, and RbCl. Color-center laser action has also been reported in diamond, sapphire, and alkaline earth crystals (Mollenauer, 1991).

Semiconductor and heterojunction lasers have used binary and ternary III–V and II–VI compounds and lead salts as the active medium (Kressel and Butler, 1987).

4.7 Scintillator Crystals

Scintillator crystals are widely used for the detection of ionizing radiation in a variety of applications including high energy and nuclear physics, astrophysics, geophysical exploration, medical imaging, security inspection, and industry (Knoll, 1989). The emission may arise from the introduction of activator ions [NaI(Tl), CsI(Tl), Lu_2SiO_5(Ce)] or from intrinsic ions in the materials ($Bi_4Ge_3O_{12}$ and CeF_3), charge transfer transitions of molecular groups ($CdWO_4$ and $PbWO_4$), excitons (CsI), or core-valence transitions (BaF_2,CsF). No single scintillator crystal is optimum for all applications. Major considerations for the selection of scintillator materials include light yield and associated energy resolution, high density and stopping power to minimize the amount of material required, decay time and afterglow, emission wavelength to match photodetectors, stability with respect to environmental conditions, and radiation damage. For applications utilizing large volumes of scintillator materials, such as in detectors for high-energy physics or medical imaging tomography (where several thousand crystals and volumes of materials measured in cubic meters may be required), production and cost become major considerations. Dense crystals with good UV transmission such as PbF_2 are used for Cherenkov detectors.

5. OPTICAL LIQUIDS

Although many pure fluids may have useful optical properties, they may also have other undesirable properties. For a specific application a liquid tailored for one or more special properties is usually required. Commercial optical liquids consist of standard or custom formulations of one or more organic oils, solids, or polymers to give consistent specified properties (Sacher and Sacher, 1995). The selection of an optical liquid frequently entails more considerations than in selecting an optical solid. For example, in addition to transmittance, refractive index, and dispersion, there may be a need for stability, low toxicity, and system compatibility. Liquids that are homogeneous solutions can be considered to be an isotropic medium and their properties treated with the same concepts and formulas used to describe the properties of glasses.

5.1 Optical Properties

The most important properties for optical applications are usually the transparency of the liquid and its refractive index and dispersion. Liquids with high transparency are available from below 250 nm in the ultraviolet to greater than 2.5 μm in the infrared. The useful transmission in the infrared is dependent upon the absence of strong molecular absorption bands. The refractive indices of many liquids are in the range 1.4–1.6, but liquids exist covering the range from 1.3 to 2.1. Fluorocarbon formulations are used to achieve values in the range 1.3–1.4. The higher-index optical liquids ($n > 1.7$) may contain methylene iodide, arsenic tribromide, arsenic disulfide, sulfur, and selenium. Low–melting-point solids that must be warmed to become liquid extend the range to 2.3. The general ranges of index and dispersion of commercially available optical liquids are included in Fig. 5. A number of optical liquids, including aqueous solutions with strong hydrogen bonds, have abnormal dispersions much greater than those obtainable for optical glasses (Sigler, 1990).

Optical liquids have a high degree of internal transmission but are also subject to scattering losses, especially those having high molecular weights. Fluorescence is sometimes present, which may be detrimental for some optical applications. The high-index liquids ($n > 1.6$) exhibit a yellow to brown coloration that becomes more pronounced in the higher-index liquids. The refractive index of standard commercial optical liquids may vary with temperature on the order of several hundreds of parts per million per °C. The change is negative; therefore if significant absorption of light occurs in a liquid, it will be heated, and the refractive index will be lowered. Because of this large change, the index can be tuned by controlling the temperature. If heating is present, liquids may have to be stirred to achieve a homogeneous medium and avoid temperature gradients.

5.2 Physical Properties

The viscosity of optical liquids (measured in centistokes) covers a wide range from 1 for water, tens and hundreds for various oils, to >500 for glycerin, molasses, and honey. High viscosity is advantageous for holding two optical components together or to bridge a gap and reduces proneness to spillage; low-viscosity liquids, on the other hand, take less time to reach a uniform temperature, are easier to mix and pump, are less likely to entrain air bubbles, and are usually easier to clean off of substances. Density can be important if the suspension of particles or the formation of layers of optical liquids is required. Surface tension (cohesion) and adhesion are other considerations for some applications.

Boiling and flash points of optical liquids are usually chosen to be well above the intended working temperature, whereas the freezing point should be below the working temperature. Mixtures of liquids will not have a distinct freezing temperature, instead the liquid increases in viscosity with decreasing temperature until a transparent glasslike liquid is formed. The pour point is a measure of its useful liquid range, although it may still have satisfactory clarity and optical properties.

Whereas evaporation does not affect the index of pure materials, when the liquid is formed from mixtures of liquids with different refractive indices, the effective index may change with time as a consequence of evaporation. This effect can be minimized by using liquids with very low and/or matching vapor pressures. The specific heat may be a consideration if the liquid also serves as a circulating coolant. Thermal expansion, thermal conductivity, sound velocity, compressibility, etc. are generally of less importance. Optical liquids composed of organic oils are good insulators.

5.3 Chemical Properties

The mutual solubility of optical liquids allows one to blend them for desired optical and physical properties, such as refractive index, dispersion, and viscosity. Aqueous-based optical liquids can be removed by water and, sometimes, by ethanol or acetone. Organic-based optical liquids require specific solvents, ethyl ether, acetone, xylene, and naphtha being the most commonly used.

As noted in Sec. 5.1, many of the higher-index optical liquids ($n > 1.7$) contain substances that are toxic and corrosive; therefore suitable protective clothing and handling devices may be mandatory when using them. Odoriferous optical liquids may require ventilation. Polychlorinated biphenyl materials and chlorofluorocarbons have generally been eliminated from the formulation of optical liquids. Optical liquids may be affected by what they come in contact with, e.g., plastics, rubbers, and metals. Information about the compatibility of specific optical liquids with common materials, their toxicity, and other hazards associated with their use are usually available from the supplier.

Some optical liquids deteriorate with time because of their inherent chemical instability; inhibitors can be used to reduce these effects. Absorption of light may also cause discoloration. Extremes of temperature are to be avoided: high temperature can lead to evaporation, boiling, or decomposition; low temperatures can lead to high viscosity, crystallization, or clouding,

5.4 Applications

Optical liquids have a broad range of applications in diverse fields. One of the main uses of optical liquids is the determination of the refractive index of transparent or translucent solids by immersing them in optical liquids of different known refractive indices until the solid is observed to disappear in the liquid that matches its refractive index. This is usually done on a microscopic scale under a microscope. Using immersion liquids, surface features may be made to disappear so that interior features such as bubbles, flaws, and striae can be inspected. Stress and strain effects are examined using polariscopic immersion techniques.

Another major use for optical liquids is to reduce interface reflective losses between two optical components. This is achieved by replacing the air between the components with an optical liquid formulated with a refractive index matching one of the two components or having a value between the two. Optical lenses can be formed by filling hollow lenses with a suitable index-of-refraction liquid. Because of their abnormal dispersion properties, liquids have been used in combination with glasses for color correcting optical elements.

Optical liquids or gels (aliphatic hydrocarbons and gelling agents) are used for coupling optical fibers to reduce or eliminate internal reflections and for mode stripping, i.e., as a coating to remove signal propagating within the fiber cladding. They are also used in liquid-core fibers.

Solutions of hundreds of aromatic compounds and organic dyes in various solvents have been used for tunable lasers in the range 0.3–1.0 μm. Aprotic liquids have also been used as hosts for rare-earth laser ions, but the general corrosiveness and toxicity of these materials have limited their usefulness.

Other uses of optical liquids include microscopic studies of solids by dispersion straining, calibration of refractometers and other optical instruments, and as a mounting medium. As noted earlier, liquids can exhibit optical activity with specific rotations of >10 deg/mm. Faraday rotation is also observed in liquids; representative values of Verdet constants are included in Table 4. Many liquids have large Kerr constants.

5.5 Liquid Crystals

Liquid crystals are materials that flow like a liquid but exhibit anisotropic properties characteristic of a crystal (DeGennes, 1974). Most liquid crystals are organic substances whose general molecular structure is represented by elongated rod- or cigar-shaped groups of atoms tens of angstroms in length and a few angstroms wide. Compounds that exhibit liquid crystalline properties include aromatic esters, azoxy compounds, biphenyls, cyclohexylcyclohexanes, phenylcyclohexanes, and Schiff's bases. The ability to tailor their optical properties makes liquid crystals attractive for applications from the ultraviolet to the infrared and involving both small and large apertures.

Three types of liquid crystals are

1. smectic, where molecules are arranged in layers and the materials have high viscosity,
2. nematic, which are less highly ordered and where molecules are spontaneously aligned with their long axes parallel, and
3. cholesteric, which have long chains of carbon and hydrogen atoms with protruding side groups of atoms that destroy their rodlike appearance.

Cholesteric liquid crystals have a layered structure with molecules within the layer ordered as in a nematic. The alignment of molecules in adjacent layers traces out a helical path through the material. Cholesterics are often referred to as chiral nematics. The optical axis of a cholesteric is the helix axis. Their viscosity is low and the optical anisotropies are large. Schiff-base chiral smectic materials exhibit ferroelectric behavior.

The polarization-altering properties of liquid crystals are used extensively in nonemissive optical displays and medical thermography. Nematic liquids have an optical birefringence of 0.04–0.40 and when aligned in the homogeneous orientation can serve as a wave plate. Cholesterics have negative birefringence. The ability to adjust the cholesteric pitch by varying the temperature or composition provides selective reflectivity for polarizer, filter, mirror, and optical isolator applications. The electro-optic effect provides control of birefringence and dynamic scattering in laser applications. Nonlinear optical field-induced effects in nematic and cholesteric compounds can be large.

GLOSSARY

Acousto-optic Effect: The modification of the refractive index of a material resulting from periodic strain field (acoustic wave). It can be used to vary the direction, polarization, phase, frequency, and amplitude of an optical beam.

Activator Ion: A constituent or dopant in a material that has energy levels appropriate for luminescence, stimulated emission, scintillation, magnetic-optic, or other optical effects.

Anisotropic: Description of a material exhibiting different optical properties along different axes of propagation or for different polarizations of a light wave.

Birefringence: A characteristic of anisotropic crystals in which two light waves having the same propagation vector but different linear or circular polarizations experience different indices of refraction.

Damage Threshold: The lowest optical power or energy density at which physical damage to the surface or bulk of a material occurs.

Dichroism: For isotropic materials, the selective reflection or transmission of light as a function of wavelength independent of the direction of vibration; for anisotropic materials, the selective absorption of light vibrating in a particular plane relative to the crystalline axes.

Dispersion: The variation of the index of refraction of a material as a function of the wavelength of electromagnetic radiation.

Elasto-optic Effect: The modification of the optical properties of a solid when subject to mechanical strain.

Electro-optic Effect: The modification of the optical properties of a solid induced by an external electric field (see **Pockels Effect** and **Kerr Effect**).

Index of Refraction: A complex quantity: the real part defines the speed of light in a medium; the imaginary part is the extinction coefficient.

Isotropic: Description of a material exhibiting the same optical properties in any direction.

Kerr Effect: Quadratic electro-optic effect; it is observed in all solids.

Magneto-optic Effect: Rotation of the polarization direction of light waves due to an applied magnetic field (e.g., Faraday effect).

Optical Activity: An effect in materials in which right- and left-handed circularly polarized light experience different indices of refraction.

Photochromism: The reversible change in the absorption spectrum of a material when irradiated with a given wavelength of light.

Pockels Effect: Linear electro-optic effect; observed in noncentrosymmetric crystals.

Polarization: The restriction of the vibrations of light wave to a single plane. The polarization vector is always in a plane at right angles to the beam direction. The polarization direction can be random (unpolarized), constant (plane polarized), or due to two coherent polarization components at right angles (elliptically polarized).

Striae: Transparent imperfections in optical glass, often in the form of approximately straight, parallel streaks, having a slightly different refractive index than that of the remaining glass.

Thermoplastic: Polymeric material that can be remolded again and again, unlike thermoset plastics that cannot be remolded.

INTRODUCTION—MAGLEV AND ITS HISTORY

Maglev (magnetic levitation) is a new form of high-speed ground transport that offers major improvements in speed, mobility, and efficiency, along with substantial reductions in cost and effect on the environment. Unlike existing ground transport, where wheeled vehicles travel along roads or rails, in Maglev the vehicles are magnetically levitated and propelled at high speed along a dedicated guideway. Because the Maglev vehicles do not contact the guideway, the drag and wear that accompany mechanical friction are eliminated.

This article reviews the historical development of Maglev, starting with the concepts of the early 1900s and continuing through the present prototype development programs in Japan and Germany. The four basic concepts for Maglev suspensions are described—an attractive-force suspension, based on the attraction of electromagnets on a vehicle to an iron rail guideway, and three different repulsive-force suspensions, based on the magnetic repulsion between

1. permanent magnets on the vehicle and opposing magnets on the guideway,
2. ac current loops on the vehicle and the induced opposing currents in a normal aluminum sheet guideway, and
3. superconducting dc magnets on a moving vehicle and the induced opposing cur-

rents in a normal aluminum loop of sheet guideway.

Development programs have demonstrated technical feasibility of Maglev. However, engineering improvements, particularly with regard to capital cost, are required before Maglev can be implemented on a larger scale. New approaches for achieving these engineering improvements are discussed.

It has been known for more than a century that the very strong forces exerted by electromagnetism could be used for magnetic levitation. Goddard, the renowned rocket pioneer, and others discussed magnetic levitation of vehicles. Before the First World War, Bachelet (1912) proposed levitation of a vehicle utilizing eddy-current repulsion between ac coils and a conducting metal plate, and Graemiger (1911) proposed levitation by the attractive force between electromagnets on a vehicle and an overhead steel rail. These ideas were not practical at the time. The ac method was very lossy and power intensive. The electromagnet–iron-rail suspension was unstable, and feedback control systems were not then adequate for a practical transport system. Magnetically levitated transport, now popularly termed Maglev, lay dormant for half a century.

The first practical concepts for Maglev were proposed in the 1960s. In 1966, Powell and Danby (1967) proposed placing dc superconducting magnets on a vehicle to interact with passive short-circuited normal-metal loops in the guideway. The magnets on the moving vehicle automatically induced currents by transformer action in the guideway loops underneath the vehicle as it passed by. The resultant strong lifting and restoring forces—both vertical and horizontal—generated by the magnetic interaction between the magnets on the vehicle and the induced currents in the guideway loops enabled inherently stable suspensions with large clearances, typically in the range of 15–20 cm.

Subsequently, Powell and Danby (1970, 1971) proposed the "null-flux" suspension geometries. These can magnetically levitate very heavy loads while maintaining very low I^2R resistive losses in the guideway. They also invented the Linear Synchronous Motor (LSM), which uses an actively powered ac winding in the guideway to propel the vehicle with high motor efficiency (Powell and Danby, 1969). The velocity of the vehicle is precisely controlled by the frequency of the ac current wave that interacts with magnets on the vehicle. The combination of stable, phase-locked propulsion combined with inherent and passively stable levitation forces enables very reliable and safe high-speed transport.

Danby *et al.* (1974) also proposed and analyzed systems in which the superconducting vehicle magnets were attracted to iron located in the guideway. By combining the iron lift forces with null-flux stabilization loops, which provide overall inherent strong stability, extremely heavy vehicles can be levitated with very low power consumption.

Powell and Danby's work stimulated a broad-based field of Maglev studies and research projects. In 1967 and 1968, following discussions with Powell and Danby, Stanford Research Institute (SRI) and Rockwell International studied magnetic levitation of very high-speed rocket sleds in collaboration with Sandia Corporation (Williams, 1969; Guderjahn and Wipf, 1969). As an alternative to loop guideways SRI proposed a continuous, shaped aluminum steel guideway, which they felt would be lower in capital cost. The higher drag power necessitated by the sheet guideway was deemed acceptable.

In 1969, Coffey *et al.* (1969, 1973) described a sheet guideway for vehicle levitation, and in 1970 they built a 500-ft-long test guideway. Reitz and Davis (1970) also studied a continuous sheet guideway in 1969. In 1970, Kolm and Thornton (1972, 1973) designed and subsequently constructed a 1/25 scale model of a system called the Magneplane. This was based on a conducting-sheet trough-shaped guideway. It differed from other sheet concepts in that vehicles could roll in a coordinated bank in the trough guideway, with the capability of operating at different bank angles if vehicle speed were altered. The model was propelled by a Linear Synchronous Motor.

In 1975 the Department of Transportation decided not to pursue the development of high-speed ground transport systems for the United States. The elimination of federal funding also discouraged private investment. This policy continued until 1990. Maglev programs continued in other countries, particularly Japan and Germany. They constructed full-scale demonstration systems that are discussed later (Miyata *et al.*, 1993; Wiescholek *et al.*, 1993).

Interest in Maglev has recently revived in the United States where a huge potential market exists. Maglev could greatly improve mobility, increase energy efficiency, and reduce pollution and reliance on oil imports. This revival was sparked by the request in 1988 by U.S. Senator Daniel Patrick Moynihan for a Maglev Task Force study. The findings of the Task Force (Powell and Danby, 1989), which was organized and chaired by the authors, laid out the benefits to the United States of a large-scale Maglev transport system. Its recommendations for a U.S. Maglev development program were incorporated into the 1990 Intermodal Surface Transport Energy Efficiency Act (ISTEA).

1. BASIC CONCEPTS FOR MAGNETIC LEVITATION

1.1 Ferromagnetic Attraction

The strong force of attraction of ferromagnetic material to a source of magnetic induction is a familiar phenomenon. At its saturation induction of 2.1 T an area of only 48 cm^2 (7 in.^{2}) on an iron pole face exerts a force of 1 t (tonne). Even at 1.0 T, to avoid saturation due to edge effects, etc., only 190 cm^2 (30 in.^{2}) is needed to suspend 1 t. These large forces can readily support heavy vehicles.

The force of attraction is very unstable, however. If the source of induction is an electromagnet of constant ampere turns, the magnetic field in the air gap between two iron pole faces is inversely proportional to the thickness of the air gap, assuming that the iron is not saturated and that edge effects can be ignored. The magnetic force is then proportional to the square of the field strength. For example, with an air gap of 0.5 cm, the attractive force between the iron pole faces is four times as great as for an air gap of 1.0 cm.

This instability is familiar from the attraction of a small permanent magnet to a steel refrigerator door. The force strongly increases as the distance decreases. Even a weak permanent magnet generates a force stronger than gravity when it is close to the surface of the door; however, this force diminishes rapidly with distance from the surface.

In order for ferromagnetic attractive forces to be useful for Maglev, the force attracting the vehicle electromagnets to the iron rails above them must be servo-controlled to prevent a crash. With a sufficiently fast-acting and sensitive control system, the vehicle can be levitated with a quasiconstant air-gap thickness between the vehicle magnets and the iron rails. The vehicle can oscillate about its equilibrium position because of inevitable imperfections in guideway position, wind forces, etc., but it will not strike the guideway as long as the control system functions adequately.

Figure 1 illustrates how electronic feedback can be used to levitate objects stably, using the inherently unstable magnetic force of attraction. The magnitude and rate of change of the thickness of the air gap (in both vertical and horizontal directions, though only the vertical is shown in Fig. 1) are continuously sensed. A fast electronic control system (millisecond response time) rapidly and appropriately changes the magnet ampere turns, altering the attractive force between the electromagnets on the vehicle and the iron rails in the guideway above, so as to maintain the air gap at the design value.

This technique has long been used for magnetically suspended high-speed centrifuges (Polgren, 1966). The same approach is used in the German Transrapid Maglev System (Wiescholek *et al.*, 1993). Laminated iron rails are located on each side of the guideway, with sets of vehicle electromagnets positioned under the rails. The upward

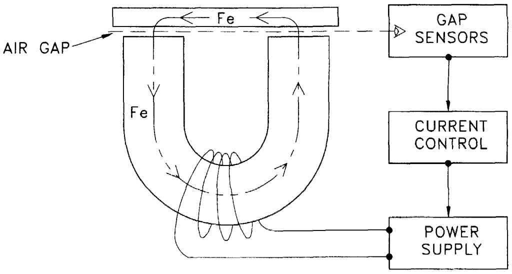

FIG. 1. Magnetic suspension based on servo control of the attractive force between an electromagnet and a ferromagnetic sheet.

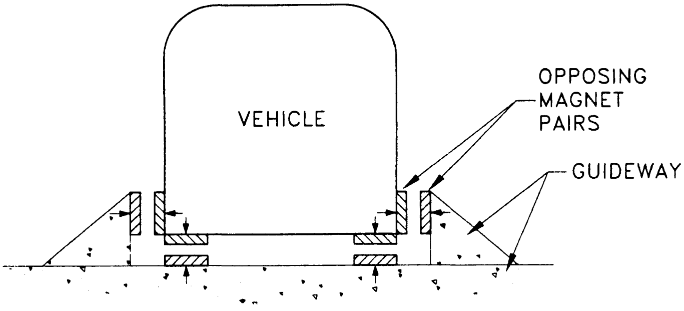

FIG. 2. Magnetic suspension based on the repulsive force between permanent magnets on a vehicle and guideway.

magnetic force then suspends the vehicle. Other suitably positioned horizontally oriented magnets are electronically controlled to provide lateral stability.

In order that electromagnetic Maglev vehicles operate safely, the sensing and electronic control systems must be extremely reliable and accurate. The iron magnets, servoed reactive power supplies, and backup power sources substantially increase vehicle weight. The maximum practical air gap is approximately 1 cm; larger gaps result in excessive I^2R power requirements for the vehicle magnets.

1.2 Permanent-Magnet Repulsion

Levitation by mutual repulsion between permanent magnets with opposed magnetic fields is a familiar phenomenon. Pairs of repelling magnets oriented for repulsion in both the vertical and horizontal directions can produce stable levitation, and lightweight toy vehicles using weak ferrite magnets have been marketed based on this approach. The suspension (Fig. 2) is inherently stable because the force of repulsion increases as the gap becomes smaller.

To date, Maglev systems based on this approach have not appeared practical because of the large cost of guideways constructed with permanent magnets. Forces 10 times greater than those obtained with ferrite magnets are possible with neodynium-iron-boron or samarium-cobalt magnets. Unfortunately, their cost is almost 100 times greater than for ferrite. The weight of the magnets required on the vehicle is also high.

In principle, electrodynamic repulsion levitation is possible using vehicle-mounted permanent magnets to interact with passive normal-metal guideway loops or a conducting-sheet guideway. However, the heavy weight, low field strength, and high cost of the necessary permanent magnets do not result in a practical transport system.

1.3 Inductive Repulsion Using ac Currents

Figure 3 illustrates the levitation of an ac current coil by a repulsive force generated by the magnetic interaction between it and eddy currents that are induced in a conducting sheet underneath. Assuming 60-Hz ac in the current loop, an aluminum sheet of 2.5 cm (1 in.) in thickness behaves diamagnetically. The resulting force on the ac current loop equals the force that would be produced between the real ac current loop and an image loop of opposite polarity located at the distance *d* below the sheet. The vehicle loop will be suspended at the height *d* where the repulsive force equals its weight. This suspension is inherently stable vertically, since the vertical force increases as *d* decreases. Horizontal stability can be provided by bending the edges of the sheet upward to make a

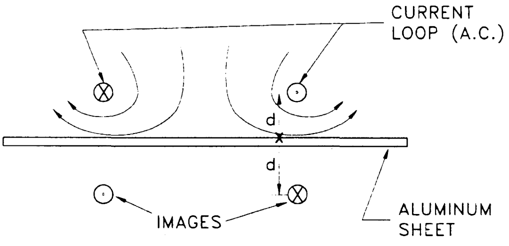

FIG. 3. Magnetic suspension based on the repulsive force between a coil carrying alternating current (ac) and a conducting sheet.

trough shape. The geometry in Fig. 3 could be inverted if desired; that is, the aluminum sheet could be located on the bottom of the vehicle, and the ac current loops, on the guideway.

The ac eddy-current repulsion concept was proposed by Bachelet (1912). Although feasible in principle, in practice to suspend useful loads the concept requires impractically large powers, both reactive and resistive. A Maglev vehicle weighing 40 metric tons, for example, would have resistive power requirements (counting both the losses in the ac coils on the vehicle and in the sheet guideway) on the order of 10 MW.

1.4 Superconducting Inductive Repulsion

Powell and Danby (1967) proposed that practical, large-clearance inductive repulsion suspensions could be provided by strong, light-weight superconducting dc magnets mounted on a moving Maglev vehicle. As the vehicle moves along a guideway, its superconducting magnets induce opposing currents in the normal-metal (e.g., aluminum) loops or sheets located beneath. The repulsive magnetic forces between the superconducting magnets and the induced currents in the guideway levitate the vehicle. The suspension is inherently stable in the vertical direction, since the repulsive forces monotonically increase as the distance between the vehicle magnets and the loops or sheets on the guideway decreases. The suspension can be designed to be inherently and strongly stable in the other directions—lateral, pitch, yaw, and roll—while continuing to move freely along the guideway.

Since the superconducting dc magnets alternate in magnetic polarity along the vehicle, the guideway beneath experiences the electromagnetic equivalent of the ac current loop described in the previous section. The equivalent ac frequency is given by dividing the vehicle speed by the magnet pole pitch (the pole pitch is twice the length of a magnet of a given polarity). For example, at 500 km/h (300 mph) and a pole pitch of 2.2 m, the effective ac frequency is 60 Hz. It is desirable that the effective ac frequency be relatively high, so as to minimize the L/R decay of induced currents in the guideway, and to allow the vehicle to "lift off" the guideway at low speed. This can be achieved by using short magnets and alternating their polarity.

Unlike the three previous suspension concepts, which can levitate vehicles at zero speed, vehicles with superconducting dc magnets must move along the guideway to levitate. Using magnet pole pitches on the order of 2 m, vehicles can lift off at only 30 km/h (20 mph). Auxiliary wheels or other devices would be used at lower speeds, primarily when entering or leaving a station.

The superconducting magnets can be positioned either along the full length of the Maglev vehicle, at the front and back ends only, or at intermediate locations along the vehicle, depending on design. In general, full-length placement results in a more efficient, structurally simpler vehicle. However, end or intermediate placement may be desirable to minimize the magnitude of the stray magnetic fields in the passenger compartment. In this connection, the use of short magnets of alternating magnetic polarity also helps to reduce stray magnetic fields.

2. MAGLEV SYSTEMS CONCEPTS AND PERFORMANCE

2.1 Superconducting Electrodynamic Suspensions

In superconducting electrodynamic Maglev, superconducting (SC) magnets on the moving vehicle induce currents in ambient-temperature metal loops (or sheets) in the guideway beneath. These induced currents levitate and stabilize the vehicle. Levitation and stabilization are automatic and inherent, requiring neither active control nor power from the vehicle or the guideway. The only requirement is that the vehicle be moving. Stability is sufficiently strong that occasional external forces—winds, curves, grades, etc.—cannot make the vehicle contact the guideway, so that safety is inherently assured under all conditions. External forces and guideway variations may cause a magnetically levitated vehicle to oscillate slightly about its equilibrium suspension point, however. Depending on amplitude, these oscillations could be objectionable from the standpoint of passenger ride comfort. If necessary, they can be countered and damped by active control systems (e.g., magnetic or aerodynamic), or by passive mechanical devices (e.g., shock absorbers), or by a combination of active and passive methods.

There are many ways to design for a superconducting Maglev system based on the fundamental idea of the inductive "magnetic spring." In this concept, as the gap between a SC magnet on the vehicle and the guideway loop or sheet beneath it *decreases*, the induced current in the guideway *increases*. The increased current, together with the smaller distance, results in stronger magnetic repulsive force. Conversely, as the gap *increases*, the magnetic repulsive force *decreases*. Consequently, there is a particular gap at which the upward magnetic repulsive force exactly counteracts the weight of the vehicle. This gap is termed the "equilibrium suspension height."

For displacements upward (gap increases) or downward (gap decreases) the magnetic suspension behaves as if there is a "magnetic spring" that pulls the vehicle back toward its equilibrium suspension point. The location of the equilibrium point is determined by the designer, according to the choice of geometry, SC magnet strength, etc. The "magnetic spring" can be stiff or soft, linear or nonlinear, damped or undamped, lossy or nonlossy, etc., depending on design.

Figure 4 illustrates in cross section three types of guideway configurations:

1. the simple loop (Powell and Danby, 1967),
2. the null-flux loop circuit (Powell and Danby, 1970), and
3. the conducting sheet (Coffey *et al.*, 1969).

The three guideway configuration options for superconducting Maglev—simple loops, null-flux loop circuits, and conducting sheets—are described in more detail below, and in the following sections their performance is analyzed. There are important and fundamental differences among the three options that affect performance. First, in the conducting-sheet guideway, the integrated induced current in the sheet must approximately equal the effective dc current in the loop above it, since the sheet diamagnetically excludes magnetic flux from the space below it. As a result of these large currents in the sheet and their consequent I^2R losses, there is a strong magnetic drag force on the vehicle. In the simple and null-flux loop guideways, on the other hand, the guideway current can be made a small fraction of that in the superconducting dc magnets. This greatly reduces the I^2R losses in the guideway and results in a much smaller magnetic drag force on the vehicle.

Second, for loop guideways the superconductive magnets on the vehicle have substantially higher ampere turns than those for sheet guideways; however, they are still far below any technical limit and, since dc superconducting magnets are lossless, do not require any additional electrical power.

FIG. 4. Guideway configurations that provide magnetic suspension by inductive interaction with superconducting (SC) magnets on a moving vehicle.

Third, in the conducting-sheet guideway, stability is relatively "soft"—that is, the restoring force per unit displacement from equilibrium is inherently low and can only be slightly adjusted in the design process. In loop guideways, by contrast, stability can be readily adjusted by design. Stability can be made "soft" or "stiff"—that is, the restoring force per unit displacement is either small or large—depending on the performance level desired. Finally, lateral stability in the conducting-sheet guideway is provided by having large induced currents flow all the time in the side wings of the sheet, even when the vehicle is centered on the guideway. These substantially increase the magnetic drag on the vehicle. In the null-flux guideway, in contrast, current does not flow in the lateral stability loops until the vehicle departs from its equilibrium position. The magnitude of this stabilizing current is proportional to the displacement from equilibrium—low for small displacement, greater for large displacement.

To simplify analysis of these guideway configurations, the SC loops on the vehicle are assumed to be long compared to the equilibrium suspension height, so that 3D effects caused by loop ends can be neglected. In addition, the velocity is assumed high enough that L/R decay of the induced currents is negligible. In practice, at high speed, the L/R decay effect is small. For a pole pitch of 3 m, for example, the transit time of a given polarity magnet past a point on the guideway is approximately 10 ms, for a vehicle speed of 500 km/h. For loop-type guideways, the L/R time constant for an optimized loop design is on the order of several hundred milliseconds. Under these conditions, the L/R decay has only a minor effect on the operating behavior of the suspension. The suspension clearance will decrease slightly—i.e., the change in clearance is only about 1% of the nominal clearance—and the I^2R losses will slightly increase, by a few percent above their value at infinite speed. The results based on the above simplifying assumptions may thus differ by a few percent from nonidealized analyses. However, the scaling relationships are valid and show the overall behavior of each configuration in relatively simple analytical form.

For each type of configuration, the moving SC loop on the vehicle induces oppositely directed currents in the ambient-temperature aluminum guideway loops or sheets. The magnitude of the induced guideway current, I_G, is some fraction f_G of the current in the SC loop, I_{SC}, such that

$$I_G = f_G I_{SC}. \tag{1}$$

The value of f_G depends on the suspension height, type of guideway, and specific design details, such as the geometric dimensions, loop inductance, etc. The magnetic repulsive force between the SC loop and the guideway for a suspension height y_0, per unit length of guideway, is then

$$F_m = \frac{k_G I_G I_{SC}}{y_0} = \frac{k_G f_G I_{SC}^2}{y_0} = \frac{K_G I_{SC}^2}{y_0}. \tag{2}$$

The values of the constants k_G and K_G depend on the type of suspension and design details. Note that K_G will in general increase as y_0 decreases because the magnitude of the guideway current will increase.

2.2 Conducting-Sheet Suspension

The solution for the sheet guideway is determined as follows. The magnetic force $(F_m)_{y_0}^S$ between the SC loop and the sheet guideway equals the force between the actual SC loop and an image loop at the distance y_0 below the sheet and is given by

$$\begin{aligned}(F_m)_{y_0}^S &= \left(\frac{\mu_0}{2\pi}\right)\frac{I_{SC}^2}{y_0}\left[1 - \frac{4y_0^2}{W_0^2 + 4y_0^2}\right]\\ &= (K_G)_{y_0}^S\left(\frac{I_{SC}^2}{y_0}\right) = mg,\end{aligned} \tag{3}$$

where W_0 is the width of the superconducting loop and mg is the suspended weight. For the case where $W_0 = 3y_0$, for example, the value of the constant $(K_G)_{y_0}^S$ is given by ($\mu_0 = 4\pi \times 10^{-7}$ H/m)

$$(K_G)_{y_0}^S \sim \frac{9}{13}\left(\frac{\mu_0}{2\pi}\right).$$

For a displacement Δy from y_0 (i.e., $y = y_0 + \Delta y$), there is a net restoring force that acts to restore the SC loop to its equilibrium suspension point. The magnitude of the restoring force, $(\Delta F_m)_y^S$, normalized to the suspended weight, is

$$\frac{(\Delta F_{\mathrm{m}})_{y}^{S}}{(F_{\mathrm{m}})_{y_0}^{S}} = \left(\frac{y_0}{y}\right)\left[\frac{(K_{\mathrm{G}})_{y}^{S}}{(K_{\mathrm{G}})_{y_0}^{S}}\right] - 1. \tag{4}$$

For an upward displacement ($\Delta y > 0$) the restoring force is downward; for a downward displacement ($\Delta y < 0$) the restoring force is upward. Figure 5 shows the variation of restoring force with displacement for the conducting-sheet suspension (chain curve). The restoring force is strongly nonlinear and relatively low for large upward displacement—that is, the "magnetic spring" is "soft" in this region.

An additional feature of the sheet suspension is that the design current in the superconducting loop is automatically determined by the choice of suspended weight and y_0, as evident from Eq. (3), and cannot be independently varied. (I_{SC} actually varies logarithmically with W_0, but the variation is small.)

2.3 Simple Loop Suspension

The magnetic lift force for the simple loop suspension (Fig. 4) is given by

$$\begin{aligned}(F_{\mathrm{m}})_{y_0}^{L} &= 2\left(\frac{\mu_0}{2\pi}\right)^2 \frac{I_{\mathrm{SC}}^2}{y_0(1+\lambda)L_{\mathrm{G}}^{\mathrm{L}}} \\ &\quad \times \left\{\left[1 - \frac{y_0^2}{W_0^2 + y_0^2}\right]\left[\ln\frac{(W_0^2 + y_0^2)}{y_0^2}\right]\right\} \\ &= (K_{\mathrm{G}})_{y_0}^{L} I_{\mathrm{SC}}^2 / y_0, \end{aligned} \tag{5}$$

where $L_{\mathrm{G}}^{\mathrm{L}}$ is the self-inductance of the guideway loop and λ is any additional (normalized) external inductance that is incorporated into the loop circuit. As with the sheet guideway, if the SC loop is displaced up or down from the equilibrium suspension height y_0, there is a magnetic restoring force acting to push it back to y_0, where the normalized restoring force, $(\Delta F_{\mathrm{m}})_{y}^{L}/(F_{\mathrm{m}})_{y_0}^{L}$, is given by

$$\frac{(\Delta F_{\mathrm{m}})_{y}^{L}}{(F_{\mathrm{m}})_{y_0}^{L}} = \left(\frac{y_0}{y}\right)\left(\frac{(K_{\mathrm{G}})_{y}^{L}}{(K_{\mathrm{G}})_{y_0}^{L}} - 1\right). \tag{6}$$

Figure 5 shows the variation of restoring force with displacement for the simple loop suspension (solid curve), for the case where $W_0 = 3y_0$. The restoring force for the loop suspension is more nearly linear with displacement, but the "magnetic spring" is somewhat softer, than that for the sheet suspension.

In contrast to the sheet suspension, in the simple loop suspension the current in the SC loop can be independently selected even when suspension height y_0 and weight mg are fixed, by adding external inductance to the guideway loop circuit. As the total inductance of the loop circuit is increased, the design value of I_{SC} has to be correspondingly increased in order to keep the lift force constant. As seen from Eq. (5), I_{SC} will scale as $(1 + \lambda)^{1/2}$. The restoring force curve is not affected by the addition of external inductance—that is, the "spring" stiffness remains

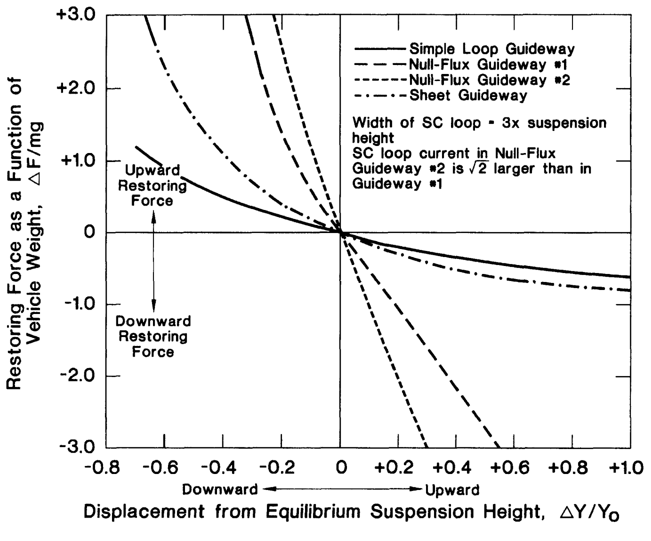

FIG. 5. Restoring forces for loop and sheet magnetic suspensions as a function of displacement from equilibrium.

constant—but the I^2R losses in the guideway loop decrease, since its current drops as the design value of I_{SC} increases. This results in an improved magnetic lift-to-drag ratio, as discussed later.

2.4 Null-Flux Suspension

The null-flux suspension behaves in a different manner than the sheet and simple loop suspensions. The restoring force is almost linear with displacement, and the magnitude of the "spring constant" is readily adjustable—that is, one can choose whether the suspension is stiff or soft.

There are many null-flux suspension geometries that can be designed. The configuration shown in Fig. 4 is illustrative of the principles involved and can be readily compared with the other two types of suspensions. The null-flux circuit shown here consists of two multiturn loops, one above the vehicle SC loop and the other below. The two loops are oppositely wound or cross connected, so that the *net* magnetic flux from the SC loop through the complete circuit is zero when the SC loop is centered between the upper and lower guideway loops. Since the net flux is zero, no current is then induced in the null-flux circuit as the SC loop moves past it.

When the SC loop is not at the center plane of symmetry between the upper and lower guideway loops, there is a net flux through the guideway loop circuit. An induced current then flows in the circuit, in such direction that the magnetic interaction between the guideway loops and the SC loop always acts so as to push the SC back toward the center plane of symmetry. If the SC loop were weightless, its equilibrium suspension location would be at the center plane of symmetry. However, since the SC loop has to support the vehicle, the SC loop only reaches equilibrium after it drops below the center to $y^* = y_0^*$, where y^* is the distance from the center plane of symmetry. The induced current in the guideway loop circuit then becomes large enough to support the vehicle. For $y^* < 0$, the magnetic force $(F_m)^{NF}_{y^*}$ on the SC loop is upward and results from the interaction of the two SC line currents with the four line currents in the guideway loop circuit:

$$(F_m)^{NF}_{y^*} = 2\left(\frac{\mu_0}{2\pi}\right) I_{SC}(i_G)_{y^*}\left[\frac{1}{y_0 + y^*} + \frac{1}{y_0 - y^*} - \frac{y_0 + y^*}{W_0^2 + (y_0 + y^*)^2} - \frac{y_0 - y^*}{W_0^2 + (y_0 - y^*)^2}\right] \tag{7}$$

with the induced current $(i_G)_y^*$ in the guideway loop circuit given by

$$(i_G)_{y^*} = \frac{(\phi_{net})_{y^*}}{L_G^{NF}} = \left(\frac{\mu_0}{2\pi}\right)\frac{I_{SC}}{L_G^{NF}}\left\{\ln\left[\frac{W_0^2 + (y_0 + y^*)^2}{(y_0 + y^*)^2}\right] - \ln\left[\frac{W_0^2 + (y_0 - y^*)^2}{(y_0 - y^*)^2}\right]\right\}, \tag{8}$$

where L_G^{NF} is the self-inductance of the guideway loop circuit, including mutual inductive coupling between the top and bottom loops, and $(\phi_{net})_y^*$ is the net flux through the guideway loop circuit.

The net force (magnetic plus gravity) is then

$$(F_{net})^{NF}_{y^*} = (F_m)^{NF}_{y^*} - mg, \tag{9}$$

where mg is the suspended weight. At $y^* = y_0^*$, $(F_m)^{NF}_{y^*} = mg$, and the net force equals zero. If the SC loop is above y_0^* ($y^* > y_0^*$), the net force acts downward; if the SC loop is below y_0^* ($y^* < y_0^*$), the net force acts upward.

The parameters y_0^* and I_{SC} are related to the suspended weight by Eqs. (7)–(9). Selecting a value for y_0^* determines I_{SC}, and vice versa. The stiffness of the null-flux suspension is thus independent of the equilibrium suspension height y_0, in contrast to the simple loop and sheet guideways, and can be selected to have whatever value is desired. Figure 5 illustrates how the restoring force varies with displacement $\Delta y/y_0$ for the null-flux suspension for two design variations. The first variation has a y_0^*/y_0 value of 0.2, while in the second, stiffer suspension, y_0^*/y_0 equals 0.1. The SC loop current in the second suspension is a factor of 2 larger than that in the first suspension.

Figure 6 shows examples of other null-flux geometries. The cross-coupled lateral loop geometry was used in the JR Maglev system at Miyazaki, and the vertical figure-

of-eight geometry will be used in the new JR Maglev system under construction in Yamanishi Prefecture. Many other geometries are possible. The choice of geometry depends on many factors—the shape of the guideway, whether high-speed switching is used, fringing-field constraints, etc.

2.5 Stability of Magnetic Suspensions

Besides providing stable levitation, the guideway must also be configured so that vehicles are stable against displacement in the lateral, pitch, yaw, and roll directions. For the conducting-sheet guideway, roll and pitch stability is provided by having two lines of SC magnets on the vehicle, one at each side, and magnets at the front and rear ends. Lateral and yaw stability is provided by shaping the guideway sheet into a trough. The trough can be a U-shaped channel or part of a circle, as in the Magneplane design (Kolm and Thornton, 1972). For loop guideways, stability is provided by two guideway loop arrangements (one for stable levitation and the second for stable lateral guidance) and two lines of SC magnets, one at each side of the vehicle. The discrete nature of the sequential loops along the guideway automatically provides pitch, yaw, and roll stability. If the vehicle rolls to the left, for example, due to an external force, the left line of guideway loops will have a stronger upward force, and the right side a weaker, countering the roll. A nose-down pitch is countered by the guideway loops at the front of the vehicle having a stronger upward force than those at the back, countering the pitch. Similarly, yaw displacements are countered by the individual guideway loops acting to return the vehicle to its equilibrium position.

The vehicle is thus held in a five-dimensional "magnetic well." Any displacement in the vertical, lateral, pitch, yaw, or roll directions is immediately and strongly countered by a magnetic restoring force or moment. In the sixth dimension, the suspension is neutrally stable, and the vehicle is free to move along the guideway, with only a slight retarding force caused by *L*/*R* decay of the induced currents in the sheet or loop guideway. The accompanying I^2R losses equal the thrust power that must be supplied to the propulsion system to overcome the magnetic drag.

The magnetic well can be designed to be very deep with null-flux suspensions, so that no conceivable external force can make the vehicle contact or leave the guideway. Typically, an external force of several times the vehicle weight is required for such an event to occur. These forces are far greater than those due to winds, curves, etc. The large margin also provides suspension redundancy, so that a large fraction of the SC magnets on the vehicle could fail without loss of levitation.

A slow application of external force (i.e., a quasisteady wind or curve) on the vehicle simply shifts its position slightly in the magnetic well. When the external force is removed, the vehicle then returns to its normal equilibrium point. However, a fast-pulsed external force, such as a sudden wind gust or an out-of-line guideway loop, may cause the vehicle to oscillate spatially about its equilibrium suspension point. Depending on the direction of this external force or forces, the oscillation can be in the vertical, lateral, pitch, yaw, or roll direction or any combination. Because the guideway loops have low electrical resistance and the vehicle oscillation frequency is much lower than the effective frequency at which the alternating SC magnets pass the guideway loops, vehicle oscillations are damped very weakly by loop resistance.

However, vehicle oscillations can be effectively countered and damped by active and/or passive control techniques, including variable pulsed magnets, secondary mechanical and/or hydraulic suspensions and shock absorbers/dampers, variable aerodynamic surfaces, etc. used separately or in combination. Good ride quality can then be maintained even when strong external impulse forces act on a vehicle.

2.6 Magnetic and Aerodynamic Drag

A high magnetic lift/drag ratio is very important for Maglev systems, in order to minimize energy consumption and propulsion power. The I^2R losses, P_{TOT}, in the guideway are affected by the magnitude of the guideway currents, guideway geometry, amount of conductor material, and its specific resistance. For a loop-type guideway, the I^2R losses are, summing over the N guideway loops that interact with the SC magnets in the vehicle,

$$P_{\mathrm{TOT}} = \sum_{j=1}^{j=N} (i_{\mathrm{GL}})_j^2 \frac{\rho_j l_j}{A_j}, \tag{10}$$

where $(i_{\mathrm{GL}})_j$ is the single-turn equivalent current in the jth guideway loop for levitation and/or stabilization, ρ_j the specific resistance of the conductor (2.8×10^{-6} Ω cm for aluminum), A_j the total conductor cross section of the multiturn loop, and l_j the single-turn equivalent winding length of the loop.

The equivalent magnetic drag force $(F_D)_{\mathrm{MAG}}$ on a vehicle moving at velocity V_0 is then

$$(F_D)_{\mathrm{MAG}} = P_{\mathrm{TOT}}/V_0, \tag{11}$$

and the corresponding magnetic lift/drag ratio, $(L/D)_{\mathrm{MAG}}$, for a vehicle of weight F_L is

$$\left(\frac{L}{D}\right)_{\mathrm{MAG}} = \frac{F_L}{(F_D)_{\mathrm{MAG}}} = \frac{F_L V_0}{P_{\mathrm{TOT}}}. \tag{12}$$

Since the I^2R losses are constant at speeds where the guideway loops behave inductively, rather than resistively, for constant conductor cross section the magnetic lift/drag ratio increases linearly with velocity.

This is in contrast to aerodynamic drag, where the equivalent aerodynamic lift/drag ratio, $(L/D)_{\mathrm{AERO}}$, for the vehicle decreases with increasing speed, as $(\text{velocity})^{-2}$:

$$\left(\frac{L}{D}\right)_{\mathrm{AERO}} = \frac{F_L}{(F_D)_{\mathrm{AERO}}} = \frac{2F_L}{\rho_{\mathrm{AIR}} C_D A_{\mathrm{F}} V_0^2}. \tag{13}$$

Here, ρ_{AIR} is the density of air, A_{F} the frontal area of the Maglev vehicle, and C_D the effective drag coefficient based on frontal area. The value of lift force F_L in Eq. (13) is not the true aerodynamic lift, but instead is the weight of the magnetically levitated vehicle. The value of $(L/D)_{\mathrm{AERO}}$ is thus a convenient way to compare aerodynamic drag to magnetic drag on a Maglev vehicle. By suitably shaping the Maglev vehicle, a modest aerodynamic lift could be generated to assist the magnetic lift at high speeds. However, the aerodynamic lift will be relatively small and could result in a greater drag force.

Figure 7 compares the magnetic lift/drag ratio for a vehicle with its aerodynamic lift/drag ratio. The magnetic lift/drag ratio is based on the NF-2 null-flux suspension illustrated in Fig. 4, with a conductor cross-sectional area of 10 cm^2. For the short sections of guideway near stations where vehicle speed is less than 150 km/h (95 mph), conductor cross section becomes greater to maintain the magnetic lift/drag ratio at 50/1. Maglev vehicles would reach 150 km/h after 20 s and a distance of 400 m, and achieve cruise speed (500 km/h) after 70 s and 5 km.

The aerodynamic lift/drag ratio shown in Fig. 7 is based on a 40-metric-ton vehicle with a frontal area of 10 m^2 and an effective drag coefficient of 0.2, representative values for Maglev systems.

The combined lift/drag ratio, $(L/D)_{\mathrm{COMB}}$, representing the sum of the two drag effects, is given by

$$\left(\frac{L}{D}\right)_{\mathrm{COMB}} = \frac{F_L}{(F_D)_{\mathrm{MAG}} + (F_D)_{\mathrm{AERO}}} = \frac{(L/D)_{\mathrm{AERO}}}{1 + (L/D)_{\mathrm{AERO}}/(L/D)_{\mathrm{MAG}}}. \tag{14}$$

Figure 7 shows that the combined lift/drag ratio is dominated by aerodynamic drag at cruise speed and by magnetic drag at low speed, i.e., near stations. At cruise speed the combined lift/drag ratio is approximately 15, corresponding to a drive power of 3.7 MW. With an 80% efficient linear synchronous propulsion, the actual drive power would be 4.6 MW. Electric energy consumption is less than 0.1 kW h per passenger kilometer of travel for a 100-passenger vehicle. At lower speeds, lift/drag ratio and energy efficiency increase. At 400 km/h, for example, energy consumption is only 0.05 kW h per passenger kilometer. Simple loop guideways also achieve high magnetic lift/drag ratios if external inductance is incorporated in the loop circuits to reduce guideway current.

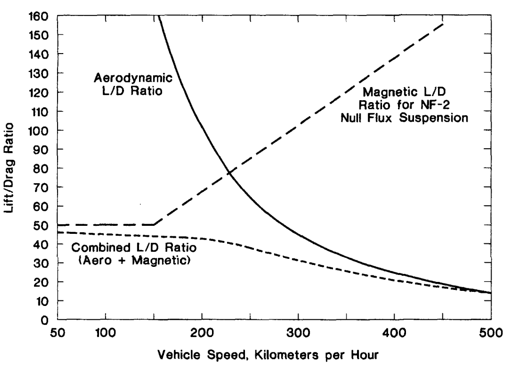

FIG. 7. Vehicle lift/drag ratios as a function of vehicle speed.

Conducting-sheet guideways have a low magnetic lift/drag ratio, since the guideway currents are large and inherently comparable to those in the superconducting magnets on the vehicle. At 500 km/h, the magnetic lift/drag ratio for conducting-sheet suspensions is in the range of 10–20, depending on design and the amount of lateral stability. Lift/drag ratio for conducting-sheet suspensions scales as (velocity)$^{-1/2}$, a result of the skin depth changing with speed. At cruising speeds of 500 km/h, the magnetic drag on a Maglev vehicle using a conducting-sheet suspension is comparable to the air drag. As a result, total drag is approximately double that of air drag, with a corresponding increase in propulsion power.

At speeds much above 500 km/h, the propulsion power to overcome air drag scales as (velocity)^3, and becomes impractically large. Moreover, the radius of curvature constraints on the horizontal and vertical straightness of the guideway also limit the maximum speed of Maglev vehicles. At 500 km/h, for example, the minimum horizontal radius of curvature for the guideway is 3 km. This assumes a bank angle of 24.5° and lateral acceleration of 1 m/s^2, which appears acceptable for passenger comfort (Powell and Danby, 1991). The radius of curvature scales as (velocity)^2, so that speeds much above 500 km/h require extremely straight and flat guideways. Accordingly, the practical limit for Maglev vehicles in the atmosphere is approximately 500 km/h. Airplanes travel faster, but at high altitudes where the air density is much less.

Approximately 70% of the proposed Tokyo–Osaka Maglev route is in deep tunnels through the mountains of central Japan. The tunnels will operate at atmospheric pressure; however, air drag is greater in enclosed tunnels (Maeda *et al.*, 1989) and may necessitate speeds less than 500 km/h. Studies of Maglev operating in low-pressure tunnels (Rather,

1992) indicate that at pressures of a few Torr, speeds of 2000 km/h are possible with very little propulsive power. Maglev technology for ultrahigh speed is similar to that for Maglev in the atmosphere; however, the low-pressure tunnels, and in particular, reducing their cost, requires long-term development. Ultrahigh-speed Maglev systems probably will not operate until well into the 21st century.

2.7 Magnetic Propulsion

The third important measure of Maglev performance, in addition to the "magnetic spring" behavior and lift/drag ratio, is propulsive effectiveness. The Linear Synchronous Motor (LSM) is used because it does not require mechanical contact. Figure 8 shows an idealized LSM system for superconducting Maglev.

The guideway incorporates an LSM drive winding that carries a small ac current. This ac current magnetically interacts with a SC loop on the vehicle, producing a thrust on it. The ends of the SC loop magnetically interact with the vertical field component of the LSM drive winding to create a forward thrust force on the vehicle. An equal and opposite magnetic reaction force on the ac LSM loop is simultaneously produced by the interaction of its current with the vertical field component from the SC loop.

The ac current in the LSM winding advances with a phase speed $V_{\mathrm{LSM}} = fz_p$, where z_p is the pole pitch of the alternating-polarity SC loops on the vehicle—i.e., z_p is twice the length of an individual SC loop—and f is the frequency of the ac current fed to the LSM drive winding. In Fig. 8(a), the SC loop on the vehicle is in a position where it magnetically interacts with the ac winding to propel the vehicle forward; in Fig. 8(b), the loop has advanced a distance 0.5 z_p in the time $(2f)^{-1}$ at the speed fz_p, and continues to receive a forward thrust.

In order to maintain phasing, the LSM drive windings and SC loops have the same pole pitch; however, the frequency of the ac current fed to the guideway can be changed to alter vehicle speed. Vehicles accelerate after leaving a station so that they can rejoin the main guideway. ac frequency monotonically increases until cruise speed is reached. When a vehicle decelerates, ac frequency de-

creases. When the ac wave runs in a braking mode, it feeds the kinetic energy of the vehicle back into the grid. Conversely, when the vehicle accelerates, it extracts energy from the grid.

Solid-state SCRs or other devices would control the frequency- and time-dependent LSM power flow to the guideway in the acceleration and deceleration sections. At cruise speed, the ac frequency is constant. Whether there should be variable ac drive-frequency capability in the cruise section of the guideway is an unresolved issue. There are arguments for this capability; it is easier to restart stalled vehicles on the guideway after grid power is restored following a large-scale blackout, and vehicles can operate at lower speeds if there is an emergency condition on the guideway. Providing this capability will increase guideway cost, however.

The loop and the conducting-sheet guideways differ with regard to LSM propulsion. In loop guideways, both simple loop and null-flux, the LSM system uses the same SC magnets that levitate and stabilize the vehicle. In contrast, conducting-sheet guideways cannot use the same SC magnets since the ac LSM currents would generate parasitic eddy-current losses in the sheet. Instead, there is an additional and separate line of SC magnets on the vehicle for LSM propulsion. In loop-type guideways, the loops are arranged so that they do not magnetically couple to the LSM drive windings.

Minimizing LSM winding current minimizes the I^2R losses and cost. LSM current is minimized by using strong SC magnets, efficiently coupling the SC magnets to the LSM windings, maximizing SC magnet coverage along the vehicle, and making the pitch of the SC magnet poles small.

The null-flux suspension enables very efficient LSM propulsion because of the high–field-strength magnets and excellent coupling. Figure 9 shows the thrust power on a 500-km/h Maglev vehicle with a NF-2 suspension, as a function of LSM current. Three cases are compared: case 1, 100% magnet fractional coverage along the vehicle and a pole pitch of 2 m; case 2, 50% coverage and pole pitch of 2 m; and case 3, 50% coverage and a pole pitch of 4 m.

The total magnetic thrust $(F_T)_{MAG}$ on the vehicle is the summation of the longitudinal magnetic forces acting on its SC magnets:

$$(F_T)_{MAG} = (N_{LI})(N_{LO})(f_C)\left(\frac{l_{vehicle}}{l_{pole}}\right) \times (2)\left(\frac{\mu_0}{2\pi}\right) I_{SC} \ln\left(\frac{W_0^2 + y_0^2}{y_0^2}\right), \quad (15)$$

where N_{LI} is the number of lines of SC magnets along the vehicle (generally, $N_{LI} = 2$); N_{LO} is the number of guideway loops per SC magnet ($N_{LO} = 2$ for the NF-2 suspension); f_C is the fraction of the vehicle length that has SC magnets; $l_{vehicle}$ is the total vehicle length; and l_{pole} is the length of a SC loop on the vehicle ($= \frac{1}{2}$ of pole pitch).

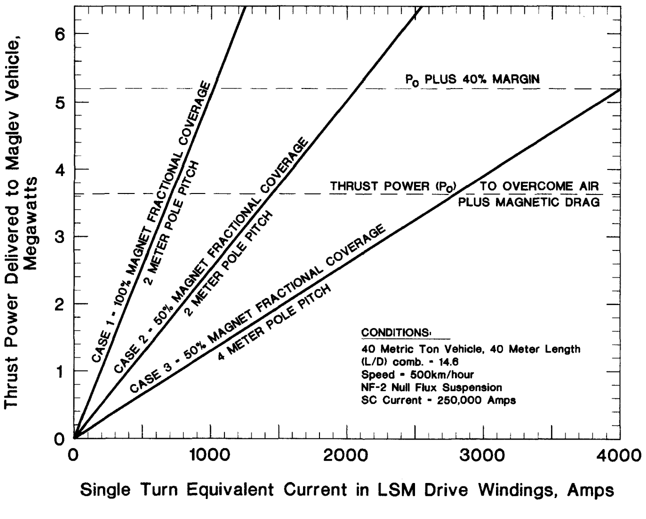

FIG. 9. Thrust power delivered by the linear synchronous motor (LSM) as a function of LSM current and SC magnet coverage and pole pitch.

With 100% coverage and a pole pitch of 2 m (case 1), the LSM drive requires only 1000 A to overcome air and magnetic drag on a Maglev vehicle at 500 km/h, with a margin of 40% for occasional head winds and upgrades. The phase angle of the SC magnets relative to the current wave in the LSM windings shifts if drag force changes, as does delivered thrust power, but vehicle speed remains constant. Clearly, it is advantageous to have strong SC magnets, as complete a coverage as possible, and short pole pitch.

Low-current LSM designs, i.e., ~1000 A, allow a 1–2-km-long block to be energized with high LSM motor efficiency (80% or more), because the I^2R losses are small. High-current LSM designs require much shorter block lengths; this increases the number and cost of controls, switches, and transformers along the guideway. Optimizing LSM design involves many trade-offs; in general, however, low-current designs appear preferable.

2.8 Electromagnetic Suspensions

Electromagnetic Maglev suspensions are very different from superconducting suspensions. They are inherently unstable and require active servo control of magnet current to prevent contact of the vehicle with the guideway. When the vehicle moves upward, the air gap between its electromagnets and the iron rails on the underside of the guideway decreases. If magnet excitation current remained constant and the iron in the magnetic circuit did not saturate, the magnetic field strength and the upward attractive force would increase. To first order, the attractive force F_Z scales with the air-gap dimension Z as

$$F_Z/mg = (Z_0/Z)^2, \tag{16}$$

where Z_0 is the gap dimension at which the attractive force equals vehicle weight. The net upward acceleration on the vehicle increases rapidly with decreasing Z; at $Z/Z_0 = 0.5$, for example, it is $3g$ if the magnet current is constant. At some point, saturation in the iron limits the net upward acceleration; the vehicle would still hit the guideway, however.

Using room-temperature electromagnets, such as those on the Transrapid and HSST Systems, Z_0 must be small, approximately 1 cm, to keep magnet power reasonable. As a consequence, small changes in gap along a guideway that result from normal construction variations or from differential settling after construction pose challenges for the magnet control system.

As the vehicle moves at high speed along the guideway, small changes in the position of the iron rail appears to the vehicle as a fluctuating thickness of the air gap. A change of 1 mm in gap thickness corresponds to a $0.2g$ net acceleration on the vehicle, with the acceleration upward if the gap thickness decreases, and downward if it increases. Because the vertical movements are very small, the magnet control system must respond very quickly. The necessary response time is on the order of 10^{-2} s.

Safe operation of electromagnetic suspensions has been demonstrated in full-scale tests of the Transrapid and HSST systems. Because of the small clearance, guideways for electromagnetic Maglev must be built and maintained to much tighter tolerances—approximately a factor of 10—than those for superconducting Maglev. Tests of the JR superconducting Maglev system, at Miyazaki, for example, have shown that high-speed operation is not affected when individual guideway loops are displaced by several centimeters to simulate the effects of an earthquake. Such displacements are not acceptable for electromagnetic Maglev. The much tighter tolerances for construction and maintenance of electromagnetic Maglev increase guideway cost substantially.

3. MAGLEV DEVELOPMENT AND PROTOTYPE DEMONSTRATION

Maglev development has proceeded in various countries during the last three decades. The Japanese and German programs have been by far the largest, both in their total funding and in the demonstration of operating prototypes. Each has spent over 10^9 dollars on the development of Maglev.

3.1 Japanese Superconducting Maglev

In 1970 the Japanese National Railway (JNR) started major development of superconducting Maglev, under the technical leadership of Kyotani (1975). They operated test vehicles in 1972 that demonstrated both levitation and LSM propulsion. In 1977 JNR began operating a large (10-t) vehicle, the ML-500, on a 7-km test track at Miyazaki. This and subsequent vehicles were based on the superconducting electrodynamic inventions of Powell and Danby.

Lift was generated by two lines of sequential multiturn horizontal loops of aluminum wire placed along the guideway. These loops interacted with eight superconducting levitation magnets on the underside of the vehicle. At the center vertical slab of the inverted-T–shaped guideway, additional aluminum loops were vertically mounted and cross connected. These provided lateral stability by null-flux interaction with eight additional superconducting magnets on the vehicle. These were vertically located on the sides of the slot in the vehicle that surrounded the vertical slab portion of the inverted-T guideway. Aluminum LSM drive windings on the guideway interacted with the superconducting magnets on the vehicle to propel it. Wheels supported the vehicle at low speed and at rest. Speeds well above 500 km/h were demonstrated.

The inverted-T guideway was modified to a U-shaped channel, and a new MLU series of vehicles were tested beginning in 1980. Coupled cars (up to 3) were operated, with capability for passengers. Speeds to 400 km/h with two cars and passengers were demonstrated. The eight superconducting magnet loops on the vehicle were vertically oriented, four on each side. Aluminum loops in the guideway underneath the vehicle provided lift. Horizontal stability and motor winding loops were located on the side walls of the U-shaped guideway. In later designs the vehicle magnets are placed on bogies at its ends, remote from the passengers, to reduce their exposure to stray magnetic field.

Figure 10 shows the planned Tokyo-to-Osaka route, which runs through the mountainous center of Japan. Most of the route will be located in deep tunnels. The first portion, a 43-km section in Yamanishi Prefecture, is now under construction with tunnels, switching, and stations. The Yamanishi track will provide a realistic full-scale demonstration of commercial system capability. The vehicles use a U-shaped guideway. Vertically oriented figure-of-eight null-flux loops on the sidewalls of the guideway provide combined horizontal stability and vertical levitation. The loops are compatible with the superimposed LSM drive windings. The guideway loops and windings interact with two rows of vertically oriented superconducting planar loops on each side of the vehicle bogies. Each 22-m-long vehicle weighs 18 t and carries 44 passengers. Trains with up to 14 coupled vehicles are planned for the commercial system.

JNR has carried out experiments in which vehicles moved past guideway loops that had

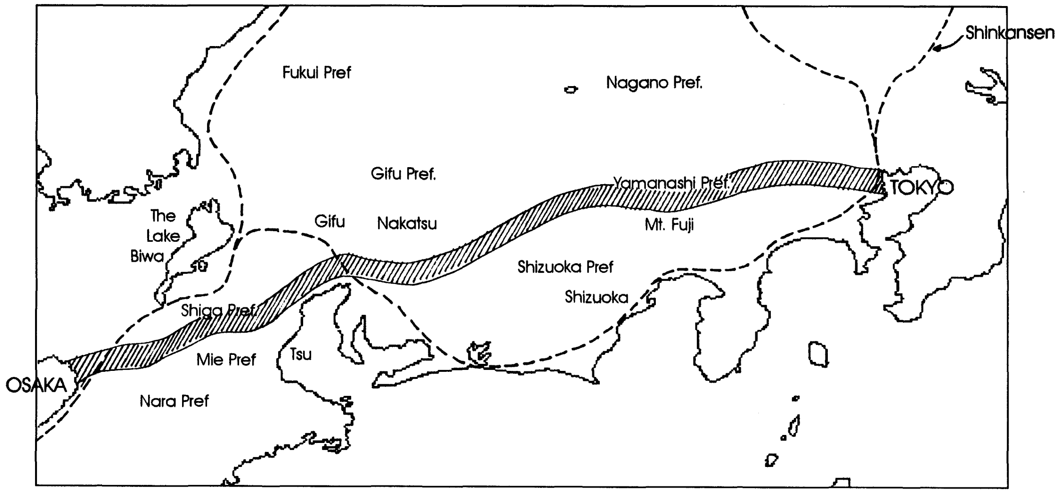

FIG. 10. Tokyo–Osaka route proposed for Japanese superconducting Maglev system.

large displacements from their normal design position to simulate the effects of earthquakes. A conventional rail train would have derailed upon encountering such large displacements. The Maglev vehicle did not experience any problems when it rode through the displaced sections. This unique safety capability, plus the advantages of low noise, minimum maintenance, and steep grade-climbing ability, make electrodynamic Maglev very attractive for a country like Japan that is organized for rail travel. Figure 11 shows a JNR demonstration vehicle.

3.2 Japanese Electromagnetic Maglev

Japan Air Lines in about 1970 initiated study of an electromagnetic Maglev system suitable for travel from Tokyo to the Narita airport. In 1973 they began construction of a prototype that attained 300 km/h in 1978. Their demonstration vehicle HSST-03 carried very large numbers of passengers at expositions in Japan and Canada. This small-gap (1 cm) system, similar in concept to the German Transrapid, is intended for moderate speeds up to 300 km/h. Such speeds do not necessarily require LSM propulsion but can use an onboard propulsion system (Suzuki *et al.*, 1987).

3.3 German Electromagnetic and Superconducting Maglev

Germany began development of both superconducting Maglev and servo-controlled electromagnetic Maglev in 1970. Their superconducting Maglev program culminated in 1976 with the test of a 12-m-long vehicle. The vehicle weighed 17 t, and it had a 10-cm gap along the guideway. It operated at speeds up to 230 km/h on a 280-m-diam circular track in Erlangen (Miller, 1987). The vehicle was propelled by a linear induction motor, which was separate from the levitation system.

In 1978 Germany discontinued work on superconducting Maglev and concentrated on the development of the electromagnetic Transrapid, because it was judged closer to commercial application. The 12-t TR02 attained 163 km/h on a 1-km track. The next step was the TR04 vehicle that weighed 18 t and carried 12 passengers at 250 km/h on a 3-km test track in the late 1970s. In 1979 a 70-passenger Transrapid demonstration vehicle at the Hamburg Fair carried passengers on a 1-km track. In the early 1980s a 32-km test track with loops at each end and a 12-km straight section was constructed at Emsland. The guideway on the end loops has a 12° bank angle.

The TR06 prototype vehicle consisted of two connected sections each 27 m long and 3.65 m wide. Total weight was 102 t without passengers or cargo. TR06 had a 20-t payload capacity and carried 196 passengers. A Linear Synchronous Motor propelled the vehicle, with guideway coils reacting against the levitation magnets. TR06 attained a maximum speed of 400 km/h (Wiescholek *et al.*, 1993). The latest design is the TR07 (Miller, 1987). It is slightly smaller in cross section and lighter than the TR06 (90 t for two sec-

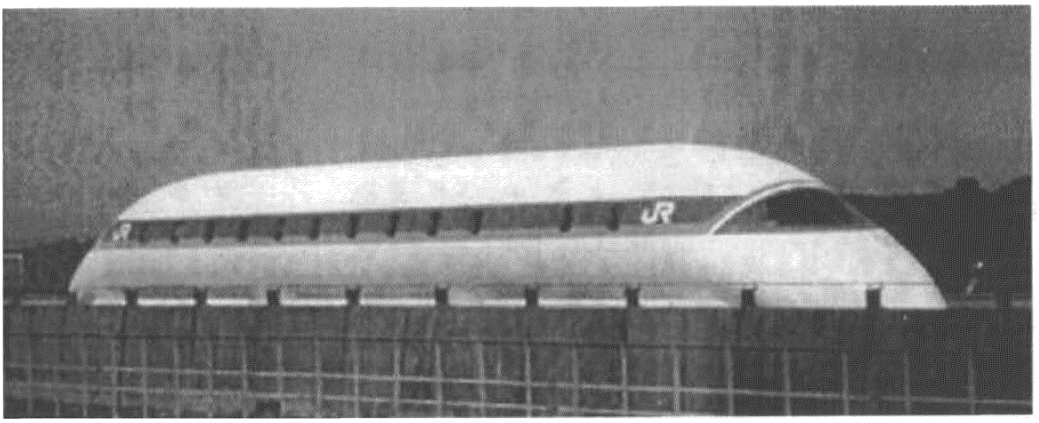

FIG. 11. Prototype JR superconducting Maglev vehicle.

tions as compared to 102 t). The air gap between the vehicle magnets and the guideway iron rails is 0.8 cm. Maximum design speed is 500 km/h.

Transrapid requires accurate position sensors and fast-acting servo control of the power fed to the vehicle electromagnets. For safety in case of guideway power loss, onboard batteries are employed. These are charged by a linear generator as the vehicle moves, picking up power from the active guideway. The electromagnets are attached to the vehicle by pneumatic springs and linkages. Figure 12 shows the Transrapid vehicle on its guideway. The vehicle rides above the T-shaped guideway shown in the photograph. The arms at the sides of the vehicle curl around under the guideway and hold the servo-controlled electromagnets, which are attracted upward to the two iron rails in the underside of the flat-topped guideway.

A mechanical switch that can transfer vehicles from one guideway to another has been demonstrated. Maximum vehicle speed on these switch sections is limited to 200 km/h. The switch section, which is 30 m in length, is pushed sideways when it is desired to transfer the vehicle from one guideway line to the other. The guideway must be constructed and maintained to very high tolerances because of the small (0.8 cm) air gap. Devices to help automate guideway fabrication and installation have been developed. In Germany, plans have been announced for a Hamburg-to-Berlin route.

3.4 U.S. Maglev Studies

After funding for U.S. Maglev development stopped in the early 1970s, individual nonfunded efforts continued on a sporadic basis; but these were limited to conceptual designs and analyses. In the early 1990s the United States resumed funding of Maglev at a low level under the National Maglev Initiative (NMI), following the favorable report by the U.S. Senate Task Force on Maglev (Powell and Danby, 1991). The NMI program was restricted to conceptual studies of generic components like guideways and power systems and system concept definition (SCD). Four SCD conceptual studies were completed, which are described below. Funding of $\$900 \times 10^6$ for Maglev prototype development was authorized as part of the Intermodal Surface Transportation Efficiency Act (ISTEA), but not appropriated, so that the United States had not yet (1994) undertaken the development of Maglev hardware.

The four SCD designs were primarily based on modifications of the existing Japanese and German Maglev programs and the U.S. efforts of two decades earlier. The Foster–Miller (1993) SCD design (Fig. 13) is a modification of the Japanese superconducting Maglev system to achieve a lighter-weight, more open guideway structure. Salient features of the design that are similar to those for the Japanese system include the placement of the superconducting magnets at the front and rear of the vehicle [Fig. 13(a)], to minimize the magnitude of stray fields in the passenger compartment, and the

use of the sidewall for the null-flux levitation/stability loops and the LSM drive windings [Fig. 13(b)]. The guideway structure is opened up to reduce weight and to inhibit the buildup of snow and ice in cold climates.

The Grumman SCD design (Proise *et al.*, 1993), shown in Fig. 14, is a modification of the German Transrapid Electromagnetic Maglev System. It uses superconducting windings to energize the vehicle electromagnets instead of the normal room-temperature copper windings used on Transrapid. This allows the gap between the vehicle magnets and the iron rails on the underside of the guideway to be considerably larger than that of Transrapid, i.e., 4 cm, compared to 0.8 cm, while keeping the weight of the vehicle magnets within reliable limits. However, the suspension is still inherently unstable, and an active servo system must control the attractive force exerted by the vehicle electromagnets in order to prevent contact with the guideway. In the Grumman concept the superconducting windings on the vehicle magnets supply most of the attractive levitation force, while servo-controlled copper auxiliary windings with adjustable current capability are used to vary the attractive force as required.

The Magneplane SCD design, proposed by Magneplane International (1992), retains the principal features of the original 1972 Magneplane concept (Kolm and Thornton, 1972), as illustrated in Fig. 15. The two arcs of the

conducting-sheet guideway are trough shaped, to allow the vehicle to bank when rounding a curve. Bank angle can be controlled so that the fixed guideway is compatible with coordinated turns at different vehicle speeds, without using a variable-tilt secondary suspension on the vehicle. A second set of superconducting magnets along the center of the vehicle is used for LSM propulsion; these are separate from those used for levitation. Separation of levitation and propulsion magnets is necessary with a conducting-sheet guideway, as discussed previously in this article.

vehicle, as illustrated in Fig. 16. A null-flux–type configuration is used to levitate and stabilize the vehicle, both vertically and horizontally. The vehicle superconducting magnets are arranged in an equivalent vertical figure-of-8 winding pattern. When the winding is at the central symmetry plane for the ladder-type aluminum guideway (a sequentially connected set of simple dipole loops), the net flux through the rectangular guideway loops is zero, and no current flows in them. When the vehicle is displaced upward or downward from the symmetry plane, the net flux through the guideway loops induces current in them that acts to push the vehicle back to the central symmetry plane. The Japanese and Bechtel–MIT designs are magnetically equivalent, with the first design using simple dipole superconducting vehicle magnets and figure-of-8 guideway loops, while the second design uses figure-of-8 superconducting magnets and simple dipole guideway loops.

4. FUTURE APPLICATION OF MAGLEV

The technical feasibility of Maglev as a transportation system has been demonstrated by the Japanese superconducting and German electromagnetic Maglev programs. Both systems are at the commercial prototype stage of development, and both plan to build first-generation operational routes.

However, the economic practicality of Maglev as a future transportation system has yet to be demonstrated. The present projected guideway costs for both types of Maglev systems are in the range of $\$20 \times 10^6$ per kilometer of two-way guideway, depending on the design and estimators. Engineering improvements are needed to reduce these costs significantly, to a level of $\$10 \times 10^6$/km or less, and to enhance the capability of Maglev vehicles to carry freight and to easily switch to off-line stations. These improvements,which appear achievable, are discussed in the next section of this article. Fundamental breakthroughs do not appear necessary for the successful large-scale application of Maglev—just the normal evolution of established basic concepts and technology.

4.1 Energy, Environmental, Economic, and Societal Benefits

Maglev can yield many important benefits. First, it is much more energy efficient than present transport. Figure 17 compares primary energy usage for Maglev, autos, and

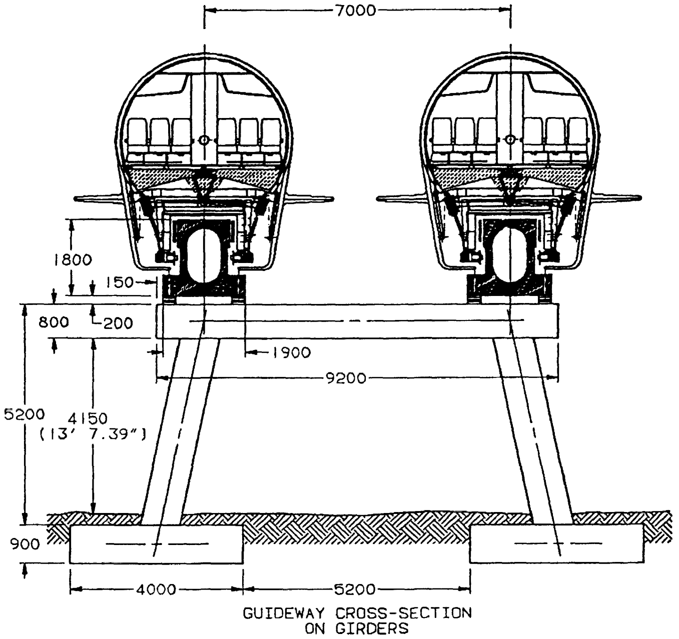

FIG. 16. Superconducting Maglev design concept proposed by MIT/Bechtel.

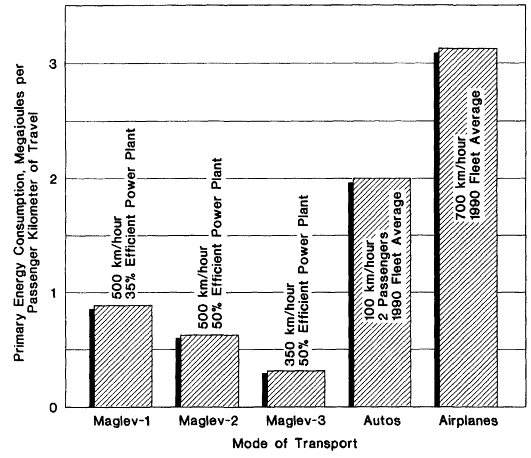

FIG. 17. Comparison of primary energy usage per passenger kilometer of travel for Maglev with other modes of transport.

airplanes, per passenger kilometer of travel. For Maglev, primary energy is defined as the thermal energy into the power plant that generates electricity; for autos or airplanes, it is the heating value of the fuel used. Current power plants operate at an average thermal efficiency of 35% (thermal energy to electricity). Per passenger kilometer of travel, Maglev at 500 km/h (~300 mph) uses 50% of the primary energy consumed by 100-km/h autos, and only 25% of that for 700-km/h airplanes. With the new more efficient (~50%) combined-cycle power plants that are beginning to come on line, Maglev primary energy consumption is only 35% of autos and 15% of airplanes. By operating at somewhat lower speed, e.g., 350 km/h (210 mph), Maglev primary energy consumption can be reduced to 18% of autos and 8% of airplanes.

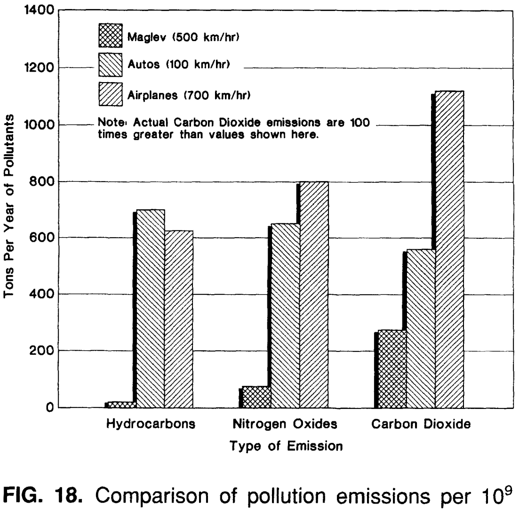
The much lower energy usage, plus the fact that electricity usually comes from nonpetroleum sources—that is, coal, hydro, and nuclear—makes Maglev very effective for reducing oil consumption. Transport accounts for approximately 50% of total U.S. oil consumption; implementing Maglev on a large scale would substantially reduce oil usage, lowering oil imports—now over 50% of total consumption—and helping balance of trade problems.

The transport sector is also the major contributor to air pollution, principally by autos and trucks. Maglev, because it uses much less primary energy, and because its electricity comes from central power plants where emissions can be controlled, will greatly reduce air pollution.

Figure 18 compares pollution emissions for Maglev and autos, per billion passenger kilometers of travel. In terms of emissions that are harmful to health (hydrocarbons, NO_x, sulfur dioxide, carbon monoxide), Maglev pollution is far less than autos. In terms of CO_2 emissions and global warming, Maglev is better, by approximately a factor of 3, than autos.

The economic benefits of Maglev appear to be very large. The United States currently spends about $\$10^{12}$ (one trillion) annually on auto, truck, airplane, and rail transport. Of this total, over 50% is spent in intercity transport—$\$2.5 \times 10^{11}$/y on autos, $\$1.6 \times 10^{11}$/y on trucks, $\$6 \times 10^{10}$/y on air, and the balance on bus and rail (primarily bulk freight).

The projected operating costs for Maglev, autos, trucks, and airplanes are illustrated in Fig. 19. These operating costs do not include capital costs associated with the construction of facilities, such as airports, highways, and guideways. In general, Maglev has much smaller operating costs. This results from Maglev's lower energy usage and equipment cost per unit of travel. To exploit these lower operating costs, Maglev routes need a large volume of traffic so that its expensive guideway can be paid for by revenues.



Note: Actual Carbon Dioxide emissions are 100 times greater than values shown here.

FIG. 18. Comparison of pollution emissions per 10^9 km of passenger travel for Maglev with other modes of transport.

TRANSPORT MODE	REVENUE MODE	
	PASSENGERS (Cents/Passenger km)	FREIGHT (Cents/Ton km)
MAGLEV	2	4.5
AUTOS (2 PASSENGERS)	10	-
TRUCKS	-	20
AIRPLANES	10	100

FIG. 19. Comparison of Maglev operating costs with those of other modes of transport.

An illustrative National Maglev Network for the United States is shown in Fig. 20. This example is based on the use of the rights of way along portions of the Interstate Highway System and is drawn so as to connect the major metropolitan areas in the United States. It has a total length of 28 000 km and 300 stations. The network directly serves 170 million persons (70% of U.S. population), who live within 25 km of a station. Over 90% (245 million) of the population live in states with Maglev routes. Capital investment for the network is approximately $\$200 \times 10^9$, including stations. This is less than the replacement cost in current dollars for the Interstate highways.

Figure 21 shows the payback time for this illustrative Maglev Network as a function of the fraction of the U.S. transport market that it captures. If the network carries 20% of intercity passenger and truck freight, for example, its investment could be recovered in only 3 years. Most infrastructure projects like highways, dams, and airports typically never recover their investment, or if they do, they take many years to do so.

Because the operating costs of Maglev transport will be much lower than those of competing modes, and because Maglev routes can carry extremely high traffic loads, a Maglev Network will always be able to carry goods and people at lower cost than other modes. Thus Maglev should ultimately capture a large share of the transport market, probably well above 20%.

Finally, many societal benefits can be expected from Maglev. The death rate on U.S. highways is 45 000 persons per year, with additional hundreds of thousands of major injuries. Many more thousands die or suffer

serious health problems as a result of pollution from autos and trucks. A large fraction of these deaths, injuries, and health problems would be eliminated if Maglev becomes a major mode of transport.

Another important societal benefit of Maglev is enhanced mobility—a result of faster travel speed and the elimination of delays due to congestion and bad weather. Improved mobility enables better industrial competitiveness through just-in-time manufacturing. It also enables people to live in smaller, more attractive population centers that are physically distant, but closely linked in time.

4.2 Engineering Developments Needed for Large-Scale Implementation of Maglev

To be implemented on a large scale, Maglev needs further development to reduce costs, increase potential markets, simplify and speed up the construction of guideways, and increase capability to serve effectively a wide network of many stations. These engineering developments are particularly needed for the United States, because of its many dispersed population centers.

No fundamental breakthroughs appear necessary. The three principal engineering developments needed are

1. lower-cost, easily erected guideways;
2. capability to carry truck-type freight; and
3. high-speed switching to off-line stations.

Lower guideway costs can be achieved by minimizing the amounts of material, and by using prefabricated beams and piers, rather than field construction. Figure 22 shows a narrow-beam guideway design using prefabricated, reinforced concrete beams and piers. The projected cost for this two-way guideway is $\$7 \times 10^6$/km, a factor of 3 lower than present costs. In this design, beams are 20 m long and weigh 15 metric tons; pier height is 10 m, with a weight of 15 metric tons.

The beams and piers would be mass produced at factories and shipped by road or rail to the construction site. To minimize traffic disruptions, the beams and piers would be transported along already completed sections of guideway, and erected on preinstalled footings. This eliminates the delays and detours normally associated with heavy construction. Guideways could then be installed on existing rights of way alongside highways, rail lines, and power lines, without major tie-ups.

Obtaining new rights of way for transport projects is very difficult in the United States. Maglev, unlike high-speed rail, can use existing rights of way because its elevated guideways will pass over existing structures, and readily adapt to changes in grade and curves. However, disruptions to existing facilities and traffic flow during construction must be minimal.

Capability to carry truck-type freight is very important, particularly in the United States, where intercity truck freight outlays are three times larger than those for air passengers. Maglev can be a "land ferry," transporting freight containers and trailers (Fig. 23) many hundreds of miles at lower cost and much faster than by highway or rail. Transporting truck-type freight across the United States in a few hours would facilitate just-in-time manufacturing. Maglev systems, with high magnetic lift-to-drag ratios and heavy lift capability, can efficiently transport freight long distances. A Maglev freight vehicle could carry a 40-metric-ton payload, with a gross loaded weight of 60 tons and a magnetic lift-to-drag ratio on the order of 100 to 1.

The third engineering development is the ability to switch Maglev vehicles at high speed from a main line guideway into off-

line stations, and then switch them back onto the guideway after loading. If Maglev vehicles stopped at every station on the route, stations would have to be spaced at intervals of 100 km or more to maintain reasonable average speed. Such a wide spacing would reduce accessibility and revenues, and lessen public support for Maglev.

Present Maglev vehicles either cannot switch to a secondary guideway at all or rely on low-speed mechanical switches. Superconducting Maglev vehicles should be able to switch electronically from one guideway to another at high speed, but this has not yet been demonstrated. With high-speed switching, "skip-stop" Maglev vehicles can bypass

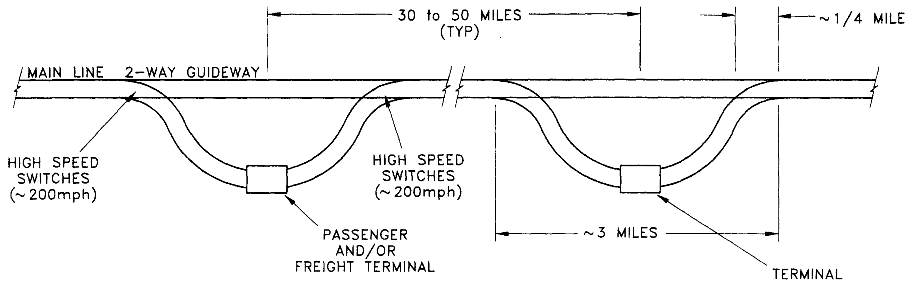
stations at high speed, stopping only where necessary (Fig. 24). Vehicles would switch from the high-speed guideway onto a secondary guideway leading to the station, decelerating in approximately 3 km. After unloading/loading, vehicles would then accelerate back to full speed and rejoin the main guideway. Many stations could then be located on the network, without penalizing speed.

The issue of high-temperature superconductors is sometimes raised in the belief that they are needed for Maglev. In fact, present niobium–titanium superconductors and liquid-helium cryogenic systems are technically and economically practical for Maglev. The vehicle superconducting magnets, cryostats, and closed-cycle refrigerators account for only 1% of system capital cost. Ninety percent of the cost is due to the guideway and propulsion system, with the remainder for stations, vehicle bodies, etc. A useful illustration is provided by the Superconducting Super Collider (SSC) Project, which was recently cancelled. The SSC magnets were far more technically demanding than those required for Maglev vehicles, because of their very stringent requirements on field quality, maximum field, conductor movement, cycling capability, radiation resistance, heat leaks, etc. Even with these very challenging requirements, the cost of the magnets in the 100 km SSC ring was projected to be on the order of $\$3 \times 10^9$. The same length of magnets in Maglev vehicles would transport 30% of U.S. intercity passenger traffic. Even if Maglev magnets cost as much as SSC magnets, which is unlikely, their amortized cost would be 0.1 cent per passenger mile, a trivial amount.

4.3 Environmental and Safety Aspects

High-speed rail transport is exceptionally safe. In over 20 years of travel, the Japanese Shinkansen system has never had a fatal accident, even though it carries hundreds of thousands of passengers each day. Maglev should be even safer than high-speed rail: First, the guideways will be elevated, reducing access. Second, the Maglev vehicles will float 10–20 cm above the guideway, reducing hazards from small objects on the guideway. Third, track damage and wear will be negligible compared to high-speed rail, because the vehicles do not contact the guideway, and because the magnetic loadings are distributed under the vehicle rather than concentrated at wheels. The magnetic levitation system will use highly redundant and independent magnets. The probability of enough magnets failing that levitation is infinitesimally small—less than 10^{-10} per year. Even if levitation were to fail, a backup mechani-



WHY OFF–LINE STATIONS?

- STATION SPACING WILL BE REALTIVELY CLOSE
  - MAXIMIZE PASSENGER/FREIGHT REVENUES
  - POLITICAL REASONS
- ON–LINE STATIONS SERIOUSLY DEGRADE AVERAGE SPEED
- MAXIMIZE GUIDEWAY TRAFFIC CAPACITY

WHAT ARE REQUIREMENTS FOR OFF–LINE CAPABILITY?

- HIGH SPEED SWITCHING (~200 mph)
- COMPUTER CONTROL OF TRAFFIC WITH PLAN–AHEAD CAPABILITY
- PRESET LOAD/UNLOAD INTERVALS FOR MAGLEV VEHICLES

FIG. 24. Schematic view of Maglev guideway system designed for high-speed switching to off-line stations.

cal skid system would take over and bring the vehicle to a safe stop. Vehicle levitation does not require external power but is inherently generated by motion. If the LSM propulsion were to cease, the levitated vehicle would simply coast until its speed dropped to approximately 30 km/h and then settle on the guideway. LSM propulsion inherently keeps fixed spacing between all vehicles regardless of local variations in force due to winds, grades, etc. Vehicles cannot gain on or collide with one another.

Maglev is pollution free and quiet, and has minimal impact on its surroundings, compared to other modes of ground transport. A two-way guideway, for example, can carry more passengers and freight than a 12-lane highway. Recently, there has been concern and dispute about the possible health effects of weak ac electromagnetic fields near power lines. It is important to distinguish between dc and ac magnetic fields. The fringing fields from the superconducting magnets on a Maglev vehicle are dc, not ac. So far, the health effects of weak dc magnetic fields have not been of concern. To ease potential concern of the riding public, the weak fringing fields in the passenger compartment can be reduced to the natural ambient magnetic field on Earth (approximately 0.5 G), using both active (distributed electrical currents) and passive (ferromagnetic materials) shielding. Without shielding, the fringing field is about 10 G. Such shielding would also screen out weak ac fields from the LSM propulsion system and fluctuations in the induced guideway currents. These fluctuations are caused by time variations of inductive coupling between the SC magnets and the guideway loops. Maglev can reduce fringe magnetic fields in the passenger compartment to whatever level is required by future standards. Weak magnetic fields are omnipresent in human society, however, and are found in subways, rail trains, work places, homes, city streets, etc. Minimizing weak magnetic fields in these areas would be much more difficult than in Maglev vehicles.

4.4 Broader Applications of Maglev

Maglev with its unique technical capabilities is attractive for easing greatly the increasing problems of suburban traffic congestion and pollution. Rapid acceleration and banking on curves is practical, limited only by passenger comfort. Lightweight economical guideway structures can be sited to coexist with the rights of way of existing transportation systems or along utility rights of way in a very flexible and adaptable manner. At the intermediate speeds required for urban transit, for example, less than 200 km/h, Maglev can be essentially noise free as well as locally pollution free.

The ability to electromagnetically switch safely and swiftly at full operating speeds without mechanical moving parts permits a high density of single vehicles to operate at high speed on a network with a large number of stations as required for convenient suburban transport. Highly flexible and individualized programming of even small numbers of passengers to a specific station can be carried out while the great majority of passengers pass by at full operating speed. In fact, this "skip-stop" fleet can include some smaller vehicles. At rush hours vehicles can be combined or "entrained" if required by ultrahigh volume to some stations.

The technical characteristics of Maglev enabling highly flexible and adaptable commuter service dovetail strongly with those that permit "land ferry" transport of freight and autos, conveniently interfaced with our existing highway-dominated transport system.

The authors expect that when Maglev comes fully of age it will have three major components:

1. 500-km/h, energy-efficient transport of people and freight over large distances;
2. urban and suburban Maglev transport with a large commuter component to complement existing networks; and
3. ultrahigh-speed transcontinental or intercontinental transport in evacuated tubes with extremely low energy consumption and with speeds of several thousand km/h.

GLOSSARY

Magnetic Spring: The magnetic restoring force that develops to push a vehicle back to its equilibrium suspension point if an external force acts to displace the vehicle from equilibrium.

Magnetic Well: A five-dimensional potential well in which the vehicle is held with the normal equilibrium suspension point at the bottom of the well. External energy input is required to make the vehicle climb up in its potential well. The five dimensions are vertical, lateral, pitch, yaw, and roll. The vehicle is unconstrained in the sixth dimension—that is, along the guideway.

Null Flux: An arrangement of loops in the guideway such that the *net* flux through the complete loop circuit is zero when the superconducting magnet on the vehicle is at the center of symmetry of the loop circuit. If the vehicle magnet moves away from the center of symmetry, a net flux and current develop in the circuit that act to push the vehicle magnet back to the center of symmetry.

Pole Pitch: The center-to-center distance between magnets of like polarity along the vehicle. The vehicle magnets alternate in polarity so that the pole pitch is twice the center-to-center distance between sequential magnets.

Superconducting Maglev: Magnetic levitation based on the repulsive force between superconducting magnets on a moving vehicle and the currents induced in conducting loops or sheets located on the guideway underneath.

INTRODUCTION

Transport phenomena pervade all of physics. A major part of the current research on metals and semiconductors involves the conduction of electricity under a variety of conditions. The theoretical description of transport processes in condensed matter is carried out at many different levels of sophistication, ranging from the use of pure phenomenology to the application of quantum-field-theoretical methods. Modern transport theory is rooted in the kinetic theory of the nineteenth century, founded by Clausius, Maxwell, Boltzmann, and others. Historically, kinetic theory deals with nonequilibrium phenomena in dilute gases, in which the range of interaction between the molecules is much less than their average separation. Then the interaction between the particles may be considered to be essentially instantaneous, with the particle motion consisting of straight paths that change direction as a result of each instantaneous scattering process. An external field may cause the paths to be curved, but this does not change the fundamental separation between free-particle motion and collision.

In this article we discuss the use of the Boltzmann equation for describing transport phenomena such as electrical or thermal conduction, including collective motion such as sound or plasma oscillations. The theory is semiclassical in the sense that it involves a single-particle distribution function that depends on both position and momentum variables. Despite this limitation the Boltzmann approach to transport has been very fruitful. It can account for a variety of scattering processes, including those that involve emission or absorption of other particles such as electron–phonon scattering in metals and semiconductors. The transport of neutrons in nuclear reactors is described by a simplified Boltzmann equation, obtained by exploiting the fact that the neutron–neutron collision rate is much smaller than the rate of neutrons colliding with other particles. Strongly interacting particles or systems exhibiting a

condensate—such as electrons in superconductors—may also be described by a Boltzmann equation, suitably modified to allow for the effects of interaction.

The first section discusses the derivation of the Boltzmann equation and summarizes its most important properties. It describes the relaxation-time approximation and different methods for obtaining solutions to the general integro-differential equation. The following sections discuss the use of the kinetic equation for different physical systems. Since these include plasmas, metals, semiconductors, and superconductors, it is of course impossible to discuss their transport properties in detail. Instead, the attention is confined to the important features that must be considered when the Boltzmann equation is applied to systems other than the classical gas for which it was invented.

1. THE BOLTZMANN EQUATION

For a classical gas of particles the distribution function $f(\mathbf{r},\mathbf{p},t)$ is defined such that $f(\mathbf{r},\mathbf{p},t)d^3r\, d^3p/(2\pi\hbar)^3$ is the mean number of particles at time t in the phase-space element $d^3r\, d^3p$ of the six-dimensional phase space of a single particle, with $\mathbf{r}$ being the position vector of the particle and $\mathbf{p}$ its canonical momentum. The factor $(2\pi\hbar)^3$ serves to make f dimensionless, equal to the mean occupation number per quantum state for particles in a definite internal state.

The Boltzmann equation is a continuity equation with source terms in the six-dimensional phase space. In its general form it is an integro-differential equation for the distribution function f. If collisions are neglected, the rate of increase of f in a given phase-space volume element must equal the net number of particles that stream from outside to inside this phase-space volume element. This implies the continuity equation

$$\frac{\partial f}{\partial t} + \frac{\partial}{\partial x_\mu}(v_\mu f) = 0. \tag{1}$$

Here $v_\mu = (\dot{\mathbf{r}},\dot{\mathbf{p}}) = (\mathbf{v},\dot{\mathbf{p}})$ is the six-dimensional velocity, the dot denoting differentiation with respect to time, while the six-dimensional gradient operator is $\partial/\partial x_\mu = (\partial/\partial\mathbf{r}, \partial/\partial\mathbf{p})$. The balance expressed by (1) neglects, however, the effects of collisions, which are considered to be instantaneous. Such collisions move particles from other regions of the phase space *into* the one under consideration, or they move particles *away* from this region. It is therefore necessary to add a source term to the right-hand side of (1):

$$\frac{\partial f}{\partial t} + \frac{\partial}{\partial x_\mu}(v_\mu f) = \left(\frac{\partial f}{\partial t}\right)_{\text{coll}}. \tag{2}$$

The source term represents the rate of change of the distribution function due to collisions. Equation (2) is a generalized conservation law. It expresses that the number of particles in a given phase-space volume element changes

1. as a result of the motion of the particles under the influence of the fields and
2. as a result of collisions between the particles.

The left-hand side of (2) may be simplified, when the motion of the particles is determined by Hamilton's equations

$$\dot{\mathbf{r}} = \frac{\partial H}{\partial \mathbf{p}}, \quad \dot{\mathbf{p}} = -\frac{\partial H}{\partial \mathbf{r}}, \tag{3}$$

which imply that $\partial v_\mu/\partial x_\mu = 0$. This means that (2) may be written in the simpler form

$$\frac{\partial f}{\partial t} + \mathbf{v}\cdot\frac{\partial f}{\partial \mathbf{r}} + \dot{\mathbf{p}}\cdot\frac{\partial f}{\partial \mathbf{p}} = \left(\frac{\partial f}{\partial t}\right)_{\text{coll}}. \tag{4}$$

The momentum $\mathbf{p}$ in (4) is the canonical momentum $\mathbf{p}_c$. In the presence of a magnetic field, it is convenient to transform to $(\mathbf{r},\mathbf{p}_k)$ as phase-space coordinates instead of $(\mathbf{r},\mathbf{p}_c)$, where $\mathbf{p}_k$ is the kinetic momentum given by $\mathbf{p}_k = \mathbf{p}_c - q\mathbf{A}$, with q being the charge of the particle. The reason is that the kinetic momentum is related in a simple way to the force according to

$$\dot{\mathbf{p}}_k = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}), \tag{5}$$

where $\mathbf{B} = \nabla \times \mathbf{A}$. Now (4) is readily seen to be form-invariant under this transformation: For fixed $\mathbf{r}$ and t one has $d^3p_c = d^3p_k$, which implies that the distribution function is invariant. Furthermore, the left-hand side of (4) is the substantial derivative df/dt, which may be expressed in either set of coordinates. With $\mathbf{p}$ interpreted as $\mathbf{p}_k$, we can thus use (4) together with the equation of motion (5).

1.1 The Collision Integral

The form of the collision term $(\partial f/\partial t)_{\text{coll}}$ depends on which particular scattering processes are being considered. We shall here discuss two specific examples:

1. elastic scattering of particles from fixed impurities and
2. collisions between the particles themselves.

For the following, it is convenient to introduce the abbreviation $d\tau = d^3p/(2\pi\hbar)^3$.

1. In the case of elastic impurity scattering the collision integral is determined by processes that move particles from the phase-space element $d\tau$ to the phase-space element $d\tau'$ as well as the inverse processes that move particles from $d\tau'$ to $d\tau$. Let us first consider scattering processes from $d\tau$ to $d\tau'$: The statistical description of the effect of collisions implies that the rate of change of $f(\mathbf{p})$ due to such processes is proportional to $f(\mathbf{p})$ as well as $d\tau'$. The rate of change is therefore written as $-d\tau' w(\mathbf{p}',\mathbf{p})f(\mathbf{p})$, where $d\tau' w(\mathbf{p}',\mathbf{p})dt$ is the probability of scattering of a particle with momentum $\mathbf{p}$ to the element $d\tau'$ during the time interval dt. With a similar expression for the rate of change of $f(\mathbf{p})$ due to the inverse process, scattering from $d\tau'$ to $\mathbf{p}$, the collision integral becomes

$$\left(\frac{\partial f}{\partial t}\right)_{\text{coll}} = \int d\tau'[w(\mathbf{p},\mathbf{p}')f(\mathbf{p}') - w(\mathbf{p}',\mathbf{p})f(\mathbf{p})]$$
$$= -\int d\tau' w(\mathbf{p},\mathbf{p}')[f(\mathbf{p}) - f(\mathbf{p}')]. \qquad (6)$$

The second equality in (6) holds true when the collision probability is invariant under time reversal and spatial inversion, which together imply the symmetry $w(\mathbf{p}',\mathbf{p}) = w(\mathbf{p},\mathbf{p}')$.

2. Next we consider the case of particle–particle scattering. The probability that a particle of momentum $\mathbf{p}$ will be scattered during the time interval dt by a particle in the element $d\tau_1$, resulting in the particles ending up in $d\tau'$ and $d\tau_1'$, is $d\tau_1 d\tau' d\tau_1' \times w(\mathbf{p}',\mathbf{p}_1';\mathbf{p},\mathbf{p}_1)f(\mathbf{p}_1)dt$, since it is proportional to the number density of particles in $d\tau_1$, $f(\mathbf{p}_1)d\tau_1$. When the reverse process is taken into account, the collision integral is seen to be

$$\left(\frac{\partial f}{\partial t}\right)_{\text{coll}} = \int d\tau_1 d\tau' d\tau_1' w(\mathbf{p},\mathbf{p}_1;\mathbf{p}',\mathbf{p}_1')$$
$$\times [f(\mathbf{p}')f(\mathbf{p}_1') - f(\mathbf{p})f(\mathbf{p}_1)], \qquad (7)$$

provided the collision probability is invariant under time reversal and spatial inversion.

It is clear that the Boltzmann approach is not limited to these two examples but applies equally well to systems containing different kinds of particles such as two-component mixtures. One important example is the transport of neutrons in a reactor, the second component being the atoms of the moderator. Since the number density of neutrons—as well as the range of their mutual interaction—is many orders of magnitude smaller than that of the atoms, the collisions between the neutrons may be neglected and the atoms assumed to be in equilibrium. This results in a collision integral of a form similar to (6), as discussed in detail by Cercignani (1988).

Our discussion has so far relied on the properties of a dilute classical gas, in which the range of interaction is much less than the interparticle distance. It is possible to generalize the classical Boltzmann equation in a number of ways. Apart from changes from Maxwell–Boltzmann (equilibrium) distributions to Fermi–Dirac or Bose–Einstein distributions, one may consider collision processes that involve emission or absorption of other elementary excitations such as phonons or magnons. In superfluids and superconductors the collision integral contains terms that correspond to the creation or annihilation of particles from a condensate. The validity of the Boltzmann equation is not restricted to dilute systems, but it may be applied to the elementary excitations in a dense and strongly interacting system.

1.2 The *H* Theorem

The development in time of the distribution function $f(\mathbf{r},\mathbf{p},t)$ is governed by the Boltzmann equation. The famous H theorem, derived by Boltzmann, demonstrates that this development in time is consistent with the law of increasing entropy for a closed macroscopic system of particles that is left to itself in a nonequilibrium state.

Let us consider the quantity $\phi(\mathbf{p},f)$, which may be any function of the momentum variable $\mathbf{p}$ and the distribution function $f(\mathbf{r},\mathbf{p},t)$. We may associate with it a space- and time-dependent density $\rho_\phi(\mathbf{r},t)$ by the definition

$$\rho_\phi(\mathbf{r},t) = \int d\tau \phi(\mathbf{p},f) f(\mathbf{r},\mathbf{p},t). \tag{8}$$

It is then a straightforward consequence of the form of the collision integral (7) as well as the symmetries obeyed by w that the rate of change of ρ_ϕ due to collisions is given by

$$\left(\frac{\partial \rho_\phi}{\partial t}\right)_{\text{coll}} = -\tfrac{1}{4}\int d\tau d\tau_1 d\tau' d\tau_1' w(\mathbf{p},\mathbf{p}_1;\mathbf{p}',\mathbf{p}_1') \times [\bar{\phi} + \bar{\phi}_1 - \bar{\phi}' - \bar{\phi}_1'](ff_1 - f'f_1'), \tag{9}$$

where $\bar{\phi} = \phi + f\partial\phi/\partial f$. Let us choose ϕ to be the natural logarithm of the distribution function, $\phi = \ln f$. Then we have $\bar{\phi} = \phi + 1$ and

$$\left(\frac{\partial}{\partial t}\int d\tau f \ln f\right)_{\text{coll}} = -\tfrac{1}{4}\int d\tau d\tau_1 d\tau' d\tau_1' w(\mathbf{p},\mathbf{p}_1;\mathbf{p}',\mathbf{p}_1') \times (ff_1 - f'f_1') \ln \frac{ff_1}{f'f_1'}. \tag{10}$$

Since w is positive and $(x - y)\ln(x/y)$ is positive or zero, the right-hand side of (10) is never positive. The quantity $\int d\tau f \ln f$ is named H, and the result (10) establishes the H theorem: that the H production due to collisions is never positive.

In order to elucidate the physical significance of this result, let us consider the entropy in a general nonequilibrium state specified by the distribution function $f(\mathbf{r},\mathbf{p},t)$. The entropy density s is obtained as the Boltzmann constant k times the logarithm of the statistical weight or

$$s = -k\int d\tau [f\ln f \mp (1 \pm f)\ln(1 \pm f)], \tag{11}$$

where the upper (lower) sign refers to bosons (fermions). The expression (11) for the entropy density follows from combinatorial arguments and hence applies to equilibrium as well as nonequilibrium situations. For a dilute gas, $f \ll 1$, and one obtains

$$s = k\int d\tau (f - f\ln f). \tag{12}$$

This shows that H equals minus the entropy density divided by the Boltzmann constant, apart from the first term in (12) involving the number density of particles, $\int d\tau f$. When the entropy density is integrated over the entire volume of the system, the first term in (12) yields k times the number of particles, which is constant and may therefore be disregarded. This proves the H theorem, and one concludes that the statistical description of the collision processes implies that the collisions cannot reduce the total entropy.

1.3 Conservation Laws

We shall now turn to a discussion of the significance of the conservation laws that apply to particle–particle scattering. In (9) we have obtained a general expression for the rate of change of the density ρ_ϕ due to collisions. If ϕ does not depend on the distribution function, we have $\bar{\phi} = \phi$. It then follows from (9) that $\partial\rho_\phi/\partial t$ is zero, if

$$\phi + \phi_1 = \phi' + \phi_1'. \tag{13}$$

A quantity satisfying (13) is called a collision invariant. Since momentum is conserved in a collision between two particles, $\phi = p_x, p_y, p_z$ are three collision invariants. In addition the kinetic energy $E = p^2/2m$ is conserved as well as the particle number. Thus $\mathbf{p}$, E, and 1 are the five collision invariants, corresponding to the conservation of momentum, energy, and particle number. The angular momentum is also a collision invariant, but this is important only for rotating systems.

The identification of the collision invariants allows one to determine the equilibrium distribution function, since in equilibrium the entropy production must be zero. This means that the right-hand side of (10) must vanish, yielding the condition $ff_1 = f'f_1'$. Therefore,

$$\ln f + \ln f_1 = \ln f' + \ln f_1', \tag{14}$$

which shows that $\ln f$ belongs to the class of functions satisfying (13). It follows that ln f must be a linear combination of the collision invariants, that is,

$$\ln f = A + \mathbf{B}\cdot\mathbf{p} + CE, \qquad (15)$$

where A, $\mathbf{B}$, and C are constants. The values of these constants are known from equilibrium statistical mechanics, $A = \mu/kT$, $\mathbf{B} = \mathbf{u}/kT$, $C = -1/kT$, where μ is the chemical potential, T the temperature, and $\mathbf{u}$ the drift velocity. We have thus established the form of the equilibrium distribution function,

$$f = \exp\{(-E + \mathbf{u}\cdot\mathbf{p} + \mu)/kT\}. \qquad (16)$$

In the fermion case, when f is not small, (16) is replaced by

$$f(1 - f) = \exp\{(-E + \mathbf{u}\cdot\mathbf{p} + \mu)/kT\}, \qquad (17)$$

which yields the Fermi–Dirac equilibrium distribution

$$f = \frac{1}{e^{(E-\mathbf{u}\cdot\mathbf{p}-\mu)/kT} + 1}. \qquad (18)$$

1.4 Linearization

In its general form the Boltzmann equation is a nonlinear, integro-differential equation. In many cases, it is sufficient to consider a linearized version, when the deviation from a local equilibrium distribution function $f^0(\mathbf{p})$ is small.

Let us consider a homogeneous system, in which the distribution function $f(\mathbf{p})$ decays toward its equilibrium value $f^0(\mathbf{p})$. In the absence of external forces, f is changed by collisions only. The Boltzmann equation is linearized by writing $f = f^0 + f^0\psi$ and keeping only terms of order ψ. One gets

$$\frac{\partial\psi}{\partial t} = L\psi, \qquad (19)$$

where

$$L\psi = -\int d\tau_1 d\tau' d\tau_1' w(\mathbf{p},\mathbf{p}_1;\mathbf{p}',\mathbf{p}_1') \times [\psi + \psi_1 - \psi' - \psi_1'] f^0(\mathbf{p}_1). \qquad (20)$$

We have used the equilibrium condition $f^0(\mathbf{p})f^0(\mathbf{p}_1) = f^0(\mathbf{p}')f^0(\mathbf{p}_1')$. The linear differential equation (19) admits solutions of the form

$$\psi = e^{-\lambda t}g_\lambda(\mathbf{p}), \qquad Lg_\lambda = -\lambda g_\lambda. \qquad (21)$$

The constant λ determines the decay in time associated with the eigenfunction g_λ of the L operator. Because of the symmetry relations obeyed by w under interchange of its momentum variables, the linear operator L is symmetric in the sense that

$$(g_1,Lg_2) = (g_2,Lg_1). \qquad (22)$$

Here we have defined a scalar product by

$$(g_1,g_2) = \int d\tau f^0(\mathbf{p})g_1(\mathbf{p})g_2(\mathbf{p}). \qquad (23)$$

The operator L is negative semidefinite, which means that its eigenvalues are all negative or zero. This is seen by writing $(g_\lambda,Lg_\lambda) = -\lambda(g_\lambda,g_\lambda)$ and using the symmetries and positivity of w.

It is often of interest to linearize the Boltzmann equation in an external field, a temperature gradient, or the like, in order to determine the linear response of the system to such a disturbance. One then linearizes the Boltzmann equation with respect to the "driving gradient," which could be the temperature gradient or a spatial derivative of the drift velocity. The function ψ is assumed to be linear in the driving gradient, and the left-hand side of the Boltzmann equation may then be approximated by replacing the distribution function f with the local equilibrium distribution f^0 and expanding it to first order in the gradients. This results in a Boltzmann equation that is an inhomogeneous, linear integral equation.

As an example of this linearization procedure let us consider heat conduction in a dilute classical gas due to the presence of a temperature gradient ∇T, assuming the absence of convection ($\mathbf{u} = 0$). In the stationary case the left-hand side of the Boltzmann equation becomes

$$\mathbf{v}\cdot\frac{\partial f^0}{\partial\mathbf{r}} = -\frac{\partial f^0}{\partial E}\mathbf{v}\cdot\left(\frac{E-\mu}{T}\nabla T + \nabla\mu\right). \qquad (24)$$

In the convectionless case under consideration the pressure is independent of position. The gradient of the chemical potential is therefore proportional to the temperature gradient [$\nabla\mu = (\partial\mu/\partial T)_p \nabla T$], and (24) takes the form

$$\mathbf{v}\cdot\frac{\partial f^0}{\partial \mathbf{r}} = -\frac{\partial f^0}{\partial E}\mathbf{v}\cdot\nabla T\frac{E-h}{T}, \tag{25}$$

where h is the enthalpy per particle, given by

$$h = \mu - T\left(\frac{\partial\mu}{\partial T}\right)_p. \tag{26}$$

We shall use this linearized form of the driving term below to calculate the heat conductivity of a classical gas.

1.5 Methods of Solution

Since the linear operator L is symmetric and negative semidefinite, it is possible to derive a variational principle that applies to the linearized Boltzmann equation. Let us define the positive semidefinite operator H by

$$L = -H. \tag{27}$$

The linear, inhomogeneous Boltzmann equation has thus the form

$$X = H\psi, \tag{28}$$

where X is the inhomogeneous driving term. In the case of electrical conduction, X will be proportional to the component of the particle velocity along the electric field. The reason is that the $\dot{\mathbf{p}}\cdot\partial f/\partial\mathbf{p}$ term in (4), when linearized in the driving force $q\mathbf{E}$, becomes $q\mathbf{E}\cdot\partial f^0/\partial\mathbf{p} = q(\mathbf{E}\cdot\partial\epsilon/\partial\mathbf{p})\partial f^0/\partial\epsilon$. The current density is given by an integral over $\mathbf{p}$ of the velocity $\partial\epsilon/\partial\mathbf{p}$ weighted by the nonequilibrium distribution $f - f^0$, and the current density (and hence the conductivity) is therefore proportional to the scalar product (X,ψ). This is a common feature, which is not limited to electrical conduction: the transport coefficient may in general be related to the scalar product (X,ψ). We now derive a bound on (X,ψ) using the Schwarz inequality

$$(\psi,H\psi)(U,HU) \geq (U,H\psi)^2, \tag{29}$$

where U is an arbitrary trial function. Since $X = H\psi$, it follows that

$$(X,\psi) \geq \frac{(U,X)^2}{(U,HU)}. \tag{30}$$

One often uses the driving term X itself as a trial function. Then $(X,X)^2/(X,HX)$ becomes a lower bound on the conductivity. The determination of the lower bound may be improved by choosing U as a linear combination of a particular set of basis functions and solving the resulting matrix equation for the coefficients.

It is also possible to solve the integral equation directly, by the use of numerical methods. If the integral equation effectively involves only one variable, such numerical calculations may be relatively simple. If account is taken of the complexities of a real metal, such as anisotropy of the Fermi surface and phonon spectra, a straightforward integration may become prohibitively difficult. It should also be emphasized that the complexities of a real metal are in general not known well enough to justify the effort involved in obtaining detailed numerical solutions to the Boltzmann equation, starting from the complete collision integral.

In a few cases it is possible to determine the eigenfunctions of the collision operator and use the method of eigenfunction expansion to obtain exact solutions. Provided the eigenfunctions of L form a complete, orthonormal set, we can write down the general solution to the Boltzmann equation (19) in the form

$$\psi = \sum_i A_i g_i(\mathbf{p}) e^{-\lambda_i t}. \tag{31}$$

If a particular eigenvalue λ_i is zero, corresponding to a collision invariant, the coefficient A_i in the expansion must be zero, since ψ is assumed to vanish as $t \to \infty$. If the eigenvalues and eigenfunctions are known, the transport coefficient may then be obtained directly. This is true only in special cases. A famous example is Maxwell's r^{-5} molecules, that is, molecules repelling each other by a force inversely proportional to the fifth power of their mutual distance.

1.6 The Relaxation-Time Approximation

Since the linearized Boltzmann equation is an inhomogeneous integral equation, which may be difficult to solve analytically or numerically, it may be useful to treat the collision operator in a simple relaxation-time approximation. This amounts to replacing the spectrum of different relaxation times by a single time τ. The resulting equation has the form

$$\frac{\partial f}{\partial t} + \mathbf{v}\cdot\frac{\partial f}{\partial \mathbf{r}} + \dot{\mathbf{p}}\cdot\frac{\partial f}{\partial \mathbf{p}} = -\frac{f - f^0}{\tau}. \tag{32}$$

One usually assumes that τ is independent of $\mathbf{p}$, while the local equilibrium function f^0 may depend on $\mathbf{r}$ and t. Below we give two examples of the use of the relaxation-time approximation.

1.6.1 Thermal Conductivity A stationary temperature gradient ∇T in a gas of particles causes a heat current density given by $\mathbf{j}_{\text{th}} = -\kappa\nabla T$, where κ is the thermal conductivity. The thermal conductivity is obtained by solving the linearized Boltzmann equation. The driving term was obtained for a classical gas in (25) above. Treating the collisions in the relaxation-time approximation, we thus obtain

$$-\frac{\partial f^0}{\partial E}\frac{E - h}{T}\mathbf{v}\cdot\nabla T = -\frac{f - f^0}{\tau}. \tag{33}$$

The heat-current density is identical to the energy-current density given by

$$\mathbf{j}_\epsilon = \int d\tau E\mathbf{v}f, \tag{34}$$

since we are considering the case when there is no convection and hence no macroscopic motion of the gas. For a monatomic gas one obtains, after carrying out the integration over energy and angle in momentum space,

$$\kappa = nc_p\tau\frac{kT}{m}, \tag{35}$$

where n is the particle density and $c_p = 5k/2 = h/T$ is the specific heat per particle at constant pressure.

The use of the relaxation-time approximation is not, of course, limited to classical gases. For a degenerate gas of fermions, one finds that (35) is replaced by

$$\kappa = \tfrac{1}{3}nc_V v_{\text{F}}^2\tau, \tag{36}$$

where the Fermi velocity v_{F} is related to the Fermi momentum—and hence the particle density—by $v_{\text{F}} = \hbar k_{\text{F}}/m$, with $n = k_{\text{F}}^3/3\pi^2$, while c_V is the specific heat per particle at constant volume.

1.6.2 Viscosity According to hydrodynamics, a spatially varying flow velocity $u_x(y)$ causes a momentum-current density Π_{xy} given by $\Pi_{xy} = -\eta\partial u_x/\partial y$, where η is the (shear) viscosity. The viscosity of a classical gas is determined by linearizing the Boltzmann equation in terms of the spatial derivative of the flow velocity. With the flow velocity along the x axis and depending only on y, the Boltzmann equation becomes

$$-p_x v_y\frac{\partial f^0}{\partial E}\frac{\partial u_x}{\partial y} = -\frac{f - f^0}{\tau}. \tag{37}$$

From this the momentum current density Π_{xy} and hence the shear viscosity are obtained as

$$\Pi_{xy} = \int d\tau p_x v_y f = -\int d\tau\frac{v_x^2 p_y^2}{kT}f^0\tau\frac{\partial u_x}{\partial_y}, \tag{38}$$

resulting in the viscosity

$$\eta = n\tau kT. \tag{39}$$

Note that $\eta/nm = \tau kT/m$, while $\kappa/nc_p = \tau kT/m$. This means that the Prandtl number, which is defined as $N_{\text{Pr}} = \eta c_p/m\kappa$, is 1 within the relaxation-time approximation, contrary to the measured values which for monatomic gases are very close to $\frac{2}{3}$.

For a degenerate gas of fermions one finds that (39) is replaced by

$$\eta = \tfrac{1}{5}nmv_{\text{F}}^2\tau, \tag{40}$$

which shows that the temperature T in the classical case is replaced by a numerical factor times the Fermi temperature $mv_{\text{F}}^2/2k$.

1.6.3 Electrons in Metals The relaxation-time approximation is widely used in metals and semiconductors. Its formal validity is, however, restricted to situations where

1. the energy bands are spherical,
2. the scattering is elastic, and
3. the collision probability only depends on

the angle between the incoming and outgoing momentum.

As an example we mention the case when the electrons in a metal are scattered by fixed impurities. The linearized Boltzmann equation for electrical conduction then becomes [with $g(\mathbf{k}) = f - f^0$]

$$-e\mathbf{E}\cdot\mathbf{v}\frac{\partial f^0}{\partial \epsilon} = -\int \frac{d\mathbf{k}'}{(2\pi)^3} w(\mathbf{k},\mathbf{k}')[g(\mathbf{k}) - g(\mathbf{k}')]. \tag{41}$$

Here the energy of an electron is $\epsilon(\mathbf{k})$, and its velocity $\mathbf{v} = (1/\hbar)\partial\epsilon(\mathbf{k})/\partial\mathbf{k}$.

Under isotropic conditions it is possible to replace the right-hand side of (41) by a simple relaxation-time expression for the collision integral by virtue of the identity

$$\cos\theta_{k'} = \cos\theta \cos\theta_k + \sin\theta \sin\theta_k \cos(\phi_k - \phi), \tag{42}$$

where ϕ and θ are the polar angles of $\mathbf{k}'$ relative to the direction of $\mathbf{k}$, while ϕ_k and θ_k denote polar angles relative to the direction of $\mathbf{E}$. This is a consequence of (41) having its solution $g(\mathbf{k})$ proportional to $\cos\theta_k$, as may be verified by insertion and use of (42): since the term involving $\cos(\phi_k - \phi)$ vanishes upon integration over ϕ (as w is assumed to depend only on θ, not on ϕ), one has

$$\left(\frac{\partial f}{\partial t}\right)_{\text{coll}} = -\frac{1}{\tau}(f - f^0), \tag{43}$$

where the relaxation time is given by

$$\frac{1}{\tau} = \int \frac{d\mathbf{k}'}{(2\pi)^3} w(\mathbf{k},\mathbf{k}')(1 - \cos\theta). \tag{44}$$

The appearance of $\cos\theta$ in this expression for τ derives from the fact that the driving term in the case of electrical (or thermal) conduction involves the component of the particle velocity along the electric field (or temperature gradient).

Despite the restrictions mentioned above on the validity of the relaxation-time approximation, it remains widely used. This is due to its simplicity and the physical insight it provides under conditions when one is not interested in the accurate value of a given transport coefficient or uses τ as a fitting parameter entering other physical quantities. The use of the relaxation-time approximation may also be justified in cases when the departure from the equilibrium distribution is localized to a small region of **k** space.

1.7 Mean Free Paths

The *mean free path* is a measure of the average distance that the particles travel between consecutive collisions. It is obtained from the relaxation time by multiplying τ by a characteristic velocity v of the carriers, $l = v\tau$. In the classical gas v is a thermal velocity of order $(kT/m)^{1/2}$, while in the degenerate case v should be identified with the Fermi velocity.

The mean free path may be estimated from the relation $l \simeq 1/n\sigma$, where n is the number density of scatterers, while σ is the total scattering cross section for a single scatterer. For a gas of hard spheres with diameter d one finds $\sigma = \pi d^2$ and hence $\tau \simeq 1/vnd^2$. Thus τ depends on temperature according to $\tau \propto T^{-1/2}$, while the mean free path is temperature independent.

Different transport properties are generally characterized by different mean free paths or relaxation times. One may write a transport coefficient such as the electrical conductivity σ of a metal in the form suggested by the Drude model, $\sigma = ne^2\tau_\sigma/m$, while the thermal conductivity may be written as $\kappa = nc_V v_F^2 \tau_\kappa/3$. The two relaxation times τ_σ and τ_κ need not, however, be equal in magnitude and may even differ in their temperature dependence, as in the case of electrons scattering against phonons. For a simple Debye model with spherical energy bands one finds $\tau_\sigma \propto T^{-5}$, while $\tau_\kappa \propto T^{-3}$, when T is much less than the Debye temperature. The physical reason for this difference is that small-angle scattering, caused by long-wavelength phonons, is much less effective in degrading an electrical than a thermal current.

2. CLASSICAL GASES

Kinetic theory was developed in the latter half of the 19th century with the aim of explaining the observed magnitude and temperature dependence of transport coefficients such as viscosity or thermal conductivity of air. The contributions by Maxwell and Boltzmann laid the foundation for the kinetic theory of gases and its generalizations to other dilute systems. Via solutions to the appropriate Boltzmann equation (obtained by variational or other methods), the calculated transport coefficients are related directly to the intermolecular potential. A transport coefficient such as the shear viscosity of monatomic gases may be measured and calculated with great accuracy, resulting in excellent agreement between experimental and theoretical values, as discussed below and—in much more detail—by Smith and Jensen (1989).

When the mean free path becomes comparable to or larger than other dimensions characterizing the flow, such as the diameter of a tube or a hole in a container, one enters a regime in which hydrodynamics no longer holds. Kinetic theory, however, retains its validity, but the solution of the Boltzmann equation must incorporate boundary conditions that describe how the particles are scattered by the wall.

2.1 Transport Coefficients

In the following we consider only monatomic gases, on account of the simplicity of their interatomic potential U, which may be quite accurately represented by the Lennard–Jones potential

$$U(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^{6}], \tag{45}$$

with ϵ and σ positive constants. For all but the lightest atoms, it is possible with such a two-parameter model to obtain good fits to the magnitude and temperature dependence of the transport coefficients, using values of the parameters ϵ and σ that are consistent with other experiments.

2.1.1 Heat Conductivity In the previous section we found the thermal conductivity within the relaxation-time approximation to be $\kappa = nc_pkT\tau/m$, while the corresponding value of the shear viscosity was found to be $\eta = nkT\tau$. This does not imply that these transport coefficients are proportional to the absolute temperature, since τ is an undetermined parameter. Furthermore the measured Prandtl number $N_{\mathrm{Pr}} = \eta c_p/m\kappa$ differs considerably from the value 1 predicted by the relaxation-time approximation. It is therefore necessary to abandon the relaxation-time approximation and return to the linearized integral equation.

Let us for simplicity assume that the molecules may be represented by hard spheres of diameter d. It is then not difficult to show, using as variational solution to the Boltzmann equation a trial function proportional to X [cf. (30) above], that κ is given by the lower bound

$$\kappa \geq \frac{75k}{64d^2}\sqrt{\frac{kT}{m\pi}}. \tag{46}$$

While (46) only constitutes a lower bound on κ, subsequent improvements of the trial function (obtained by linear combinations that include the second, third, and fourth eigenfunctions belonging to the exactly solvable case of "Maxwellian molecules" with interatomic forces proportional to r^{-5}, r being their mutual separation) yield only relative corrections $\Delta\kappa/\kappa$ of order 2.3×10^{-2}, 2.1×10^{-3}, and 3×10^{-4}, respectively. The procedure thus converges very rapidly, and the inequality in (46) may be considered an equality with an accuracy of 2–3%.

While it is simpler to carry out the calculation of the thermal conductivity for an interatomic potential corresponding to hard spheres, the use of the Lennard–Jones expression (45) involves no conceptual changes, only somewhat more laborious expressions. It is a general feature of the variational method of solution that the result obtained from the simplest trial function proportional to the driving term X is quite accurate, the reason being that a first-order error in the choice of trial function yields a second-order error in the calculated value of the transport coefficient.

2.1.2 Viscosity Let us now calculate the viscosity η within the same model where the molecules are represented by hard spheres of diameter d. With a trial function proportional to the driving term X appropriate to viscosity, one finds

$$\eta \geq \frac{5}{16d^2}\sqrt{\frac{mkT}{\pi}}. \tag{47}$$

As before, (47) constitutes a lower bound on η, but subsequent improvements of the trial function yield again only corrections at the 1% level. The Prandtl number $\eta c_p/m\kappa$ is seen from (46) and (47) to be $\frac{2}{3}$, in excellent agreement with the measured value for the noble gases, which is found to be 0.666 for both Ne and Ar at room temperature.

The value of $\frac{2}{3}$ for the Prandtl number is always obtained within the first variational approximation, with a trial function proportional to X, irrespective of the form of the interatomic potential. Its agreement with experiment is therefore not a stringent test of the model potential or the validity of kinetic theory. To obtain this one must compare the calculated temperature dependence of the transport coefficients with the measured one. The temperature dependence predicted by (47) is not the one observed experimentally: the observed viscosity is proportional neither to T (as predicted for Maxwellian molecules with the interatomic forces proportional to r^{-5}) nor to $\sqrt{T}$ as predicted by the hard-sphere model according to (47). The observed temperature dependence is intermediate between these simple power laws. To illustrate the level of agreement between theory and experiment, we quote measured (calculated) values of the shear viscosity of Ne at a few selected temperatures, in units of 10^{-6} Pa·s: 11.98 (11.77) at $T = 80$ K, 23.76 (23.79) at $T = 200$ K, and 30.97 (30.65) at $T = 290$ K. The calculated values in parenthesis were obtained from a potential of the form (45). This level of agreement by far surpasses that which can be achieved when kinetic theory is applied to the transport properties of metals or semiconductors.

Other transport coefficients such as the second viscosity ζ or the self-diffusion coefficient D may be obtained in a similar fashion. One finds that the ratio of the kinematic viscosity $\nu = \eta/nm$ to the self-diffusion coefficient D (the so-called Schmidt number) depends somewhat on the assumed intermolecular potential. For hard spheres the first variational approximation yields a Schmidt number of 0.833, while one obtains the exact value 0.645 for atoms repelling each other by forces proportional to r^{-5} ("Maxwellian molecules").

2.1.3 Quantum Effects A gas is nondegenerate if the mean interparticle distance is much greater than the thermal deBroglie wavelength λ_{th} given by $\lambda_{\text{th}} = h/\sqrt{2\pi mkT}$. However, quantum effects may be important if λ_{th} is comparable with the "size" of the particles, specified, for instance, by the parameter σ in the potential (45). In such cases the scattering cross section must be calculated according to the laws of quantum mechanics, by determining the phase shifts associated with each angular momentum component of the incident wave. It is also necessary to allow for the indistinguishability of the molecules undergoing collisions. A quantitative measure of the importance of quantum effects is furnished by the deBoer parameter $h/\sigma\sqrt{m\epsilon}$, which is the square root of the ratio of the zero-point energy of a particle confined to a region of size σ and the well depth ϵ. For He this parameter is 2.60, for Ne 0.54, and for Ar 0.17.

2.2 Knudsen Flow

When a gas of particles is very dilute, the mean free path l between collisions may become comparable with characteristic lengths such as the diameter d of a tube through which the gas is flowing. Hydrodynamics then ceases to be applicable. When l/d is somewhat less than unity, it is possible to treat the leading correction to hydrodynamics by introducing a slip boundary condition in the hydrodynamic equations, relating the extrapolated flow velocity u_0 at the surface to the velocity gradient near the surface according to $u_0 = \zeta\partial u/\partial x$, where the x axis points normal to the boundary. The length ζ is called the slip length. It is of the same order of magnitude as the bulk mean free path, provided the boundary scattering is diffuse. If the boundary scattering is partly specular, the slip length is increased accordingly.

The *Knudsen number* is the ratio of the mean free path to a characteristic dimension. When it is large compared to unity, the concept of a slip length loses its meaning, and one enters the regime of rarefied gas dynamics important for vacuum technology and space research. Under these circumstances the Boltzmann equation must be solved for the geometry in question, with boundary conditions specifying the scattering properties of the walls of the container in which the gas is enclosed.

3. PLASMAS

In the previous section we considered transport phenomena in gases consisting of neutral particles interacting via forces that fall off rapidly with the distance between particles. If the gas is ionized, a very different situation occurs because of the $1/r$ dependence of the Coulomb interaction between the charged particles. A completely ionized gas is called a plasma. We here consider a two-component plasma consisting of electrons with charge $-e$ and ions with charge ze. The characteristic plasma densities and plasma temperatures span an enormous range, from those of a fusion plasma to an electron or hole plasma in a semiconductor. The unifying feature of these different physical systems is the role of the Coulomb interaction and the screening properties of the mobile charge carriers.

The screening properties of the plasma and its collective oscillations are obtained by solving the Maxwell equations together with the collisionless Boltzmann equation for the electrons and for the ions (often called the Vlasov equations). The conductivity is obtained from the Boltzmann equation and used in the Maxwell equations for the electromagnetic fields associated with the charge carriers. The Coulomb interaction between the particles is thus included in the collisionless Boltzmann equation via the self-consistent fields that determine the motion of the charged particles.

The reader may find a thorough treatment of the properties of a two-component plasma in the textbook by Lifshitz and Pitaevskii (1981).

3.1 Collective Oscillations

The charge and current induced by an external electrical field that varies in space and time according to $\exp(i\mathbf{q}\cdot\mathbf{r} - i\omega t)$ may be described in terms of a permittivity tensor $\epsilon_{ij}(\mathbf{q},\omega)$, which relates the displacement field **D** to the electric field **E** by

$$D_i = \epsilon_0\epsilon_{ij}E_j. \tag{48}$$

By inserting plane-wave solutions in the Maxwell equations and using the fact that $\mathbf{B} = \mu_0\mathbf{H}$, one arrives readily at the condition for propagation of electromagnetic waves,

$$\det\left(q_iq_j - q^2\delta_{ij} + \frac{\omega^2}{c^2}\epsilon_{ij}\right) = 0. \tag{49}$$

The condition (49) is obtained by eliminating the magnetic field from the Maxwell equations and inserting (48), using $1/\mu_0\epsilon_0 = c^2$. In empty space ($\epsilon_{ij} = \delta_{ij}$) it implies that $\omega^2 = c^2q^2$, corresponding to the propagation of electromagnetic waves with the electric and magnetic fields perpendicular to each other and to the direction of propagation.

In a medium such as a plasma, the dielectric tensor may have both a real and an imaginary part. Then (49) can only be satisfied by a complex ω, assuming that we have chosen the wave vector **q** to be real. The real part of ω yields the angular frequency of the wave, while the imaginary part determines its damping.

The dielectric tensor may be written in terms of the conductivity,

$$\epsilon_{ij} = \delta_{ij} - (1/i\omega\epsilon_0)\sigma_{ij}, \tag{50}$$

since the induced current density **j** is included with the displacement field in the Maxwell equation. The current density **j** is given by the distribution function according to

$$\mathbf{j} = \sum_{\alpha=e,i}\int d\mathbf{v}e_\alpha\mathbf{v}_\alpha f_\alpha. \tag{51}$$

We have introduced an index α, which indicates whether the corresponding quantity involves the electrons (e) or the ions (i). The quantity e_α is the charge of the particle in question ($e_e = -e$, where e is the elementary charge).

In order to linearize the collisionless Boltzmann equation in the electric field strength E we write $f = f^0 + \delta f$, with δf proportional to E, and obtain

$$-i\omega\delta f_\alpha + i\mathbf{q}\cdot\mathbf{v}_\alpha\delta f_\alpha + \frac{e_\alpha}{m_\alpha}\mathbf{v}_\alpha \times \mathbf{B}_0\cdot\frac{\partial}{\partial\mathbf{v}_\alpha}\delta f_\alpha = -\frac{e_\alpha}{m_\alpha}\mathbf{E}\cdot\frac{\partial f^0_\alpha}{\partial\mathbf{v}_\alpha}. \tag{52}$$

We have assumed the presence of a static magnetic field $\mathbf{B}_0$. The oscillatory part does not contribute, since the associated Lorentz force, which is proportional to E, is perpendicular to the velocity. For the same reason

(52) cannot be linearized in the static magnetic field, since this would make $\mathbf{B}_0$ vanish altogether from the equation.

We shall illustrate the use of the Boltzmann equation (52) by a few examples. The procedure is the following: First we determine σ_{ij} from the kinetic equations for the distribution functions of the electrons and ions. Then ϵ_{ij} is obtained from (50) and inserted into (49). The collective modes are found by setting the determinant of (49) equal to zero. The discussion may be divided into four cases, according to whether the wave vector $\mathbf{q}$ and the static magnetic field $\mathbf{B}_0$ are taken to be zero or nonzero in (52).

(a) $\mathbf{q} = 0$, $\mathbf{B}_0 = 0$. When we set $\mathbf{q} = 0$ in the Boltzmann equation, the dielectric tensor in (49) becomes independent of $\mathbf{q}$. Since the electrons are much lighter than the ions, we may neglect the contribution of the latter. The conductivity tensor is then given by the familiar Drude expression

$$\sigma_{ij} = -\frac{ne^2}{mi\omega}\delta_{ij}, \tag{53}$$

where n is the electron density. The corresponding solutions to (49) are given by $\omega^2 = c^2q^2 + \omega_{pe}^2$, if $\mathbf{E}$ is perpendicular to $\mathbf{q}$, and $\omega^2 = \omega_{pe}^2$, if $\mathbf{E}$ is parallel to $\mathbf{q}$. Here the plasma frequency $\omega_{p\alpha}$ is defined by $\omega_{p\alpha}^2 = n_\alpha e_\alpha^2/m_\alpha\epsilon_0$. The ion plasma frequency is much less than the electron plasma frequency because of the smallness of the ratio m_e/m_i.

(b) $\mathbf{q} \neq 0$, $\mathbf{B}_0 = 0$. If we keep $\mathbf{q}$ in the Boltzmann equation, we may determine the dispersion and damping of a plasma wave, neglecting the ion motion. We assume that the electrons and ions in equilibrium are described by classical distribution functions characterized by the electron temperature T_e and the ion temperature T_i, respectively. By expanding the conductivity to second order in q one finds the dispersion of the plasma wave given by

$$\omega^2 = \omega_{pe}^2 + \frac{3kT_e}{m}q^2, \tag{54}$$

while the damping is

$$\mathrm{Im}\,\frac{\omega}{\omega_{pe}} = -\frac{\pi^{1/2}}{8^{1/2}}\frac{e^2nm^{1/2}\omega}{\epsilon_0q^3(kT_e)^{3/2}}\exp\left(-\frac{m\omega^2}{2kT_eq^2}\right). \tag{55}$$

This *Landau damping* is reversible, caused by the transfer of energy from the electromagnetic wave to the motion of the individual particles.

We may also consider the motion of ions and electrons together, treating the dielectric screening due to electrons in the static limit, and that due to the ions in the dynamic limit. In the longitudinal case ($\mathbf{q}$ parallel to the electric field, which we take to be along the z axis), the vanishing of the determinant of (49) implies that $\epsilon_{zz} \equiv \epsilon_\parallel = 0$. The longitudinal part of the dielectric tensor then becomes

$$\epsilon_\parallel \simeq 1 - \frac{\omega_{pi}^2}{\omega^2}\left(1 + \frac{3q^2kT_i}{\omega^2m_i}\right) + \frac{\omega_{pe}^2m}{q^2kT_e}. \tag{56}$$

In the long-wavelength limit $q \to 0$, the condition $\epsilon_\parallel = 0$ yields the sound velocity of the ion-acoustic wave,

$$\omega^2 = q^2\frac{kT_e + 3kT_i}{m_i}. \tag{57}$$

The damping of the wave is found by taking into account the imaginary part of $\epsilon_\parallel$.

(c) $\mathbf{q} = 0$, $\mathbf{B}_0 \neq 0$. By solving the first-order differential equation (52), using cylindrical coordinates in velocity space, we find the dielectric tensor

$$\epsilon_{xx} = \epsilon_{yy} \equiv \epsilon_\perp = 1 - \sum_\alpha \frac{\omega_{p\alpha}^2}{\omega^2 - \omega_{c\alpha}^2}, \tag{58}$$

while

$$\epsilon_{xy} = -\epsilon_{yx} \equiv i\epsilon_a = i\sum_\alpha \frac{\omega_{p\alpha}^2\omega_{c\alpha}}{\omega(\omega^2 - \omega_{c\alpha}^2)}. \tag{59}$$

and

$$\epsilon_{zz} \equiv \epsilon_\parallel = 1 - \sum_\alpha \frac{\omega_{p\alpha}^2}{\omega^2}, \tag{60}$$

with $\omega_{c\alpha} = e_\alpha B_0/m_\alpha$ denoting the cyclotron frequency for electrons ($\alpha = e$) or ions ($\alpha = i$).

We return to the solution of the determinantal equation (49) and choose $\mathbf{q}$ in the xz plane, with θ denoting the angle between $\mathbf{q}$ and $\mathbf{B}_0$,

$$\mathbf{q} = (q\sin\theta, 0, q\cos\theta). \tag{61}$$

From the dielectric tensor given above together with (49) we find a quadratic equation in q^2c^2/ω^2 for the determination of ω as a function of $\mathbf{q}$:

$$(\epsilon_\perp \sin^2\theta + \epsilon_\| \cos^2\theta)\left(\frac{q^2c^2}{\omega^2}\right)^2 - [\epsilon_\perp\epsilon_\|(1 + \cos^2\theta) + (\epsilon_\perp^2 - \epsilon_a^2)\sin^2\theta]\frac{q^2c^2}{\omega^2} + (\epsilon_\perp^2 - \epsilon_a^2)\epsilon_\| = 0. \tag{62}$$

From this we get for a given θ a solution $q(\omega)$, which determines $\omega(\mathbf{q})$, since $\epsilon_\|$, $\epsilon_\perp$, and ϵ_a are given by (60), (58), and (59), respectively. Those frequencies that make the coefficient of $(q^2c^2/\omega^2)^2$ vanish are called *plasma resonances*. They evidently correspond to solutions for which $qc/\omega \to \infty$.

Let us examine whether there are oscillations with a linear dependence of ω on q for $q \to 0$. In the limit of low frequencies and with $m_e \ll m_i$, we have $\epsilon_\perp \simeq 1 + \omega_{pi}^2/\omega_{ci}^2$ and $\epsilon_\| \simeq -\omega_{pe}^2/\omega^2$. Since ϵ_a is proportional to ω in the limit $\omega \to 0$, we can neglect it, and we get two solutions, ω_1 and ω_2. One of the solutions is the magnetosonic wave, which has a frequency given by

$$\omega = \omega_1 = v_A q(1 + v_A^2/c^2)^{-1/2}. \tag{63}$$

Here we have introduced the Alfvén velocity v_A by the definition

$$v_A^2 = c^2\omega_{ci}^2/\omega_{pi}^2. \tag{64}$$

The other solution is the Alfvén wave

$$\omega = \omega_2 = v_A q|\cos\theta|(1 + v_A^2/c^2)^{-1/2}. \tag{65}$$

Another type of solution to (62) are the *whistlers* that propagate at frequencies intermediate between the ion and the electron cyclotron frequency with the dispersion relation $\omega^2 = c^4q^4\cos^2\theta\omega_{ce}^2/\omega_{pe}^4$. In solids they are named *helicon waves*.

(d) $\mathbf{q} \neq 0$, $\mathbf{B}_0 \neq 0$. When both the magnetic field and the wave vector are different from zero, the Boltzmann equation may be solved by a Fourier expansion, based on the eigenfunctions for the differential operator associated with the magnetic field. The significance of the additional term $i\mathbf{q}\cdot\mathbf{v}\delta f$ in the Boltzmann equation may be seen by considering the contribution of the electrons to the dielectric tensor when $\omega \simeq \omega_c$, provided both q_x and q_z are sufficiently small. In this case one finds that the singular behavior $\epsilon_{xx} - 1 \propto (\omega - \omega_c)^{-1}$ given by (58) is replaced by $\epsilon_{xx} - 1 \propto (\omega - \omega_c)$, provided $(\omega - \omega_c)^2 \ll kTq_z^2/m$. In addition ϵ_{xx} acquires an imaginary part.

3.2 Dielectric Screening

In the static limit ($\omega = 0$) the longitudinal dielectric function $\epsilon_\|$ obtained from the Boltzmann equation for a classical electron gas at temperature T, with neglect of the ion motion, is

$$\epsilon_\| = 1 + \frac{ne^2}{\epsilon_0 kTq^2} = 1 + \frac{q_D^2}{q^2}, \tag{66}$$

where we have introduced the Debye screening wave vector $q_D = (ne^2/\epsilon_0 kT)^{1/2}$. For degenerate electrons one obtains a similar result,

$$\epsilon_\| = 1 + \frac{3ne^2}{2\epsilon_0\epsilon_F q^2} = 1 + \frac{k_s^2}{q^2}, \tag{67}$$

where ϵ_F is the Fermi energy. Here k_s is called the Thomas–Fermi screening wave vector, and it is seen to be given by $k_s^2 = 4k_F/a_0$, where a_0 is the Bohr radius. This form of the dielectric function causes the infinite-range Coulomb interaction in a plasma of freely moving charged particles to be screened over distances of order q_D^{-1} or k_s^{-1}, depending on whether the plasma is nondegenerate or degenerate. The screening effect may be understood by dividing the Fourier transform of the unscreened Coulomb interaction, which is proportional to q^{-2}, by the dielectric function $\epsilon_\|$. This results in the replacement of q^{-2} by $1/(q^2 + k_s^2)$ (in the degenerate case), which after Fourier transformation yields a real-space potential proportional to $e^{-k_s r}/r$ of range k_s^{-1}. The magnitude of the screening length depends on the density of the plasma and—in the nondegenerate case—on the temperature. For a fusion plasma at a temperature $T = 10^8$ K and density $n = 10^{20}$ m^{-3} it is $q_D^{-1} = 7 \times 10^{-5}$ m. In metals the screening length is of the same order of magnitude as the mean interelectronic distance.

4. METALS AND SEMICONDUCTORS

Since the transport properties of metals and semiconductors have been covered in other articles (see ELECTRONIC TRANSPORT IN SOLIDS; METALS AND ALLOYS, CONDUCTIVITY IN; INSULATORS AND SEMICONDUCTORS, CONDUCTIVITY IN), we limit ourselves to a brief discussion of the use of the Boltzmann equation for the description of transport phenomena in normal and superconducting metals and in semiconductors. In doing so we merely point out the novel features that must be taken into account when using the semiclassical Boltzmann equation for such systems. While the Boltzmann equation is applicable to clean superconductors under conditions of slow variations in time and space, there exists a much more general framework for treating nonequilibrium properties of superconductors. This is the *quasiclassical method* pioneered by Eilenberger (1968) and Larkin and Ovchinnikov (1968). A review of the quasiclassical approach and the Keldysh method (Keldysh, 1964) of deriving kinetic equations has been given by Rammer and Smith (1986).

4.1 Normal Metals

The conduction electrons in a metal form a highly degenerate Fermi system of particles, which move in the periodic potential due to the ions. It is therefore essential to take quantum mechanics into account in describing their motion. In quantum mechanics it has strictly speaking no meaning to introduce a distribution function $f(\mathbf{r},\mathbf{p},t)$ that depends on the position $\mathbf{r}$ and the momentum $\mathbf{p}$ of a particle, since this would contradict the Heisenberg uncertainty relations. We may however take over the classical concept of a distribution function by interpreting particles in terms of wave packets centered around the position $\mathbf{r}$ and momentum $\mathbf{p}$ with corresponding uncertainties that satisfy the Heisenberg relations $\Delta x \Delta p_x \geq \hbar/2$ etc. With such an interpretation the classical concept of a distribution function may be taken over in quantum mechanics, provided the applied fields vary sufficiently slowly. The periodic potential, however, varies rapidly on the scale given by the extent of wave packets in real space. It is therefore necessary to treat the periodic potential according to quantum mechanics, while the external fields are treated classically. This semiclassical description of electron dynamics in a periodic lattice is obtained from the equation of motion (5) by replacing the kinetic momentum $\mathbf{p}_k$ by $\hbar\mathbf{k}$, where $\mathbf{k}$ is the Bloch vector, and identifying the velocity $\mathbf{v}$ with the group velocity $(1/\hbar)\partial\epsilon/\partial\mathbf{k}$, where $\epsilon(\mathbf{k})$ is the Bloch energy.

The Boltzmann equation for the distribution function $f(\mathbf{r},\mathbf{k},t)$ then assumes the usual form [cf. (4)], but its analysis is complicated by the fact that the energy $\epsilon(\mathbf{k})$ in general depends on the direction of $\mathbf{k}$ as well as its magnitude.

In simple cases the transport properties of a metal bear close resemblance to those of a plasma. As an example, the frequency-dependent conductivity of a metal is given by (53), if the frequency is sufficiently high that collisions may be neglected and if the energy bands are spherical. When the anisotropy is taken into account, one obtains for a cubic metal in the collisionless limit a result similar to (53), but with m replaced by an optical mass, which is inversely proportional to the velocity averaged over the Fermi surface. Similarly, the Hall effect at high magnetic fields may be obtained from the static limit ($\omega = 0$) of the conductivity tensor resulting in (58)–(60). The ion-acoustic waves given by (57) have their counterpart in the phonons of the metal, once the electrons are treated as a degenerate gas, resulting in the electron temperature in (57) being replaced by the Fermi temperature times a numerical constant.

In general, however, the transport properties of metals are much harder to analyze, because of the complexities introduced by the band structure. The collision processes limiting the electronic transport include scattering against impurities and other defects as well as electron–phonon scattering. Because of the periodic potential, the quasimomentum $\hbar\mathbf{k}$ is only conserved in collisions between electrons and phonons up to the addition of a reciprocal lattice vector. In performing realistic calculations of electrical and thermal conductivity, it is often necessary to include such *Umklapp* processes characterized by a nonzero reciprocal lattice vector.

Since the conduction electrons in a metal form a degenerate gas with a Fermi temperature that is typically a hundred times larger than room temperature, the electrical and thermal conductivities reflect the properties of the electronic states at the Fermi surface. The calculation of the thermoelectric properties of a metal requires one to take into account also the *variation* of the density of states, the group velocity, and the collision probability in the vicinity of the Fermi surface. The electrical current set up by a temperature gradient ∇T may be canceled by applying an electric field $\mathbf{E} = Q\nabla T$. The *Seebeck* coefficient Q may in a free-electron model (with energy-independent relaxation time) be shown to be equal to the entropy per particle divided by the electronic charge, but for metals with anisotropic band structure, with electrons being scattered by phonons and impurities, such thermoelectric coefficients are very difficult to calculate reliably.

4.2 Superconductors

The nonequilibrium properties of superconductors differ in several fundamental ways from those of normal metals. The most striking difference is the infinite conductivity characterizing the superconducting state. The thermal conductivity is finite, but its size and temperature dependence differ from that of normal metals, as a result of the existence of an energy gap for the excitations in the superconducting state. The thermoelectric properties differ qualitatively from those of normal metals, on account of the infinite electrical conductivity. The presence of a condensate means that the number of excitations is not a conserved quantity in a collision. This gives rise to novel relaxation phenomena that have no counterpart in normal metals. Also the magnitude of the energy gap depends on the distribution of excitations and may relax under nonequilibrium conditions.

Compared to the normal metallic state the most important novel features are thus

1. the change in the dispersion relation for the excitations due to the existence of an energy gap and
2. the coherence factors that relate the normal-state excitations to those of a superconductor.

It should also be emphasized that the conditions for the validity of the Boltzmann equation are much more stringent than in a metal, because of the existence of an energy gap Δ that is much less than the Fermi energy. The superconducting state is characterized by a coherence length of order $\hbar v_F/\Delta$, which is much longer than the interatomic distance. It is therefore necessary to restrict spatial variations to scales longer than the coherence length and temporal variations to scales longer than $\hbar/\Delta$. There are other conditions related to the phenomenon of *pair-breaking*, restricting, e.g., the inelastic scattering rate to being much less than $\Delta/\hbar$ in order that a Boltzmann description is applicable.

4.3 Semiconductors

Semiconductors are characterized by a conductivity that at room temperature is much smaller than that of metals, but much larger than that of typical insulators. In addition the conductivity of a semiconductor increases with increasing temperature, in contrast to the usual behavior observed in metals. When the temperature approaches zero, the conductivity of a semiconductor becomes vanishingly small. The presence of an energy gap for the excitation of particles (or holes) is the reason for this very different behavior of metals and semiconductors. As a result the density of current carriers is much lower in a semiconductor than in a metal, and the charge carriers may therefore usually be considered to be a nondegenerate gas. For this reason, transport in semiconductors bears some resemblance to transport in classical gases. The unique features of transport in semiconductors derive from the existence of two different kinds of charge carriers, electrons and holes. Certain aspects represent a simplification compared to metals. Thus it is often possible to use a quadratic relation between the energy and the Bloch wave vector for the states of relevance to the transport process. In both metals and semiconductors the important scattering processes limiting the transport of electricity are electron–impurity and electron–phonon scattering. Also electron–electron interaction plays a role insofar as it leads to screening of the electron–impurity and electron–phonon interaction.

In semiconductors an energy-dependent

relaxation time $\tau(\epsilon)$ is often used to account for the effect of collisions with impurities and phonons. The specific form of $\tau(\epsilon)$ depends on whether the scattering is due to, e.g., ionized impurities or deformation-potential coupling to acoustic phonons. As a result of the energy dependence of the relaxation time, even the simplest model based on a quadratic dispersion relation yields transport properties that differ qualitatively from those of the free-electron model in metals, by exhibiting, e.g., a finite magnetoresistance. For metals, the ratio between the thermal conductivity and T times the electrical conductivity is given by the universal Lorenz number $\pi^2k^2/3e^2$, provided elastic scattering dominates. In semiconductors the corresponding ratio is affected by the specific energy dependence of the relaxation time, because the charge carriers in equilibrium are described by a Maxwell–Boltzmann rather than a Fermi–Dirac distribution.

5. INSULATORS

The transport properties of insulators are dominated by the phonons, on account of the absence of free charge carriers. The heat conductivity is limited by the mutual interaction between phonons and by their scattering from defects and boundaries. The existence of independent normal modes, characterized by a wave vector $\mathbf{q}$ and frequency $\omega(\mathbf{q})$, depends on the validity of the harmonic approximation to the lattice Hamiltonian. Each normal mode is quantized as an ordinary harmonic oscillator, its excited states being specified by the number of vibrational quanta, phonons, of energy $\hbar\omega(\mathbf{q})$. If anharmonic forces are taken into account, the normal modes become coupled, but they still form a useful basis for the description of thermodynamic and transport properties of insulating crystals.

5.1 Heat Conductivity

While the thermodynamic properties of an insulating crystal are reasonably well described by treating the solid as a collection of independent phonons, the interaction between phonons is decisive in determining the transport of heat. In the absence of phonon–phonon interactions (as well as other scattering processes such as those due to impurities or boundaries), the thermal conductivity of an insulating crystal would be infinite, since nothing prevents the free flow of the phonon gas. So it is necessary to take into account anharmonicity, not as a correction, but as the dominant effect that limits the conduction of heat. The anharmonic terms in the lattice Hamiltonian give rise to both three- and four-phonon processes, since the number of phonons is not conserved in a collision. As a result of the periodicity of the lattice, the total quasimomentum in a scattering process is conserved up to the addition of a reciprocal lattice vector $\mathbf{G}$. The *normal* processes are characterized by $\mathbf{G} = 0$, while *Umklapp* processes have $\mathbf{G} \neq 0$. Only Umklapp processes may cause a heat current to decay toward zero, since the total quasimomentum is conserved by normal collisions.

The phonon spectra are anisotropic in the sense that the frequency $\omega(\mathbf{q})$ depends on the direction of $\mathbf{q}$, not just on its magnitude, in accordance with the symmetry of the underlying crystal lattice. It is therefore difficult to carry out realistic calculations of the phonon heat conductivity starting from the Boltzmann equation for the phonon distribution $N_{\mathbf{q}}$. In certain simple cases such as scattering by isotopic impurities or by boundaries, it is possible to obtain explicit answers that may be compared with experiment.

If a crystal contains isotopic impurities that are randomly distributed on the lattice sites, the elastic scattering of phonons from the isotopic impurities gives rise to an additional thermal resistance, apart from the contribution due to phonon–phonon scattering. The transition probability may be obtained from the change in kinetic energy $\Delta E = \Delta M \delta\dot{R}_i^2/2$ due to a single impurity situated at the lattice site $\mathbf{R}_i$. Here $\delta\dot{R}_i$ denotes the velocity of the isotopic impurity, with δR_i being the displacement from the lattice site. The difference in mass between the impurity and the host atom is ΔM. By introducing phonon coordinates it is then possible to determine the matrix element for scattering from $\mathbf{q}$ to $\mathbf{q}'$. The transition probability entering the Boltzmann equation is given within the Born approximation by the square of the matrix element for the scattering from a single impurity, multiplied by the number of impurities N_{imp}.

Another situation in which it is possible to derive simple expressions for the transport coefficients is thermal conduction at very low temperatures when the mean free path is so long that the important scattering mechanism is that due to the boundaries of the crystal. Under these conditions one can use expressions analogous to those derived for free molecular flow in gases. For a circular cylinder with diameter d one finds that the thermal conductivity κ is given by $\kappa = Csd/3$, where s is the sound velocity (assumed to be isotropic) and C the heat capacity per unit volume, in good agreement with experiment.

5.2 Second Sound

The phonon gas in insulators may support collective oscillations that are analogous to sound waves in an ordinary gas. Since the number density of phonons in equilibrium is determined by the temperature, the collective mode in the phonon gas is an oscillation in temperature. At sufficiently long wavelength the acoustical phonons have the same dispersion relation as the sound modes given by the equations of elasticity. The collective motion can therefore be thought of as a number-density wave in the gas of sound quanta, a "second sound." The collective temperature wave in solids only exists if the quasimomentum-destroying Umklapp processes are sufficiently *rare.* The existence of second sound in solids requires that the rate of quasimomentum-destroying processes is much less than the frequency of the collective mode, while at the same time the frequency should be much less than the rate of normal scattering processes. For this reason, second sound has only been observed in a few solids, namely, solid ^{3}He, solid ^{4}He, NaF, and Bi.

6. QUANTUM FLUIDS

With suitable modifications the Boltzmann equation may be used for the description of transport properties of quantum fluids. The two classic examples of quantum fluids are ^{3}He, which is a Fermi liquid, and ^{4}He, which is a Bose liquid. We here restrict ourselves to the discussion of Fermi liquids. For a general discussion of the concepts of Fermi-liquid theory, the reader may consult Pines and Nozières (1989).

6.1 Fermi Liquids

In liquid ^{3}He the interaction between the atoms is sufficiently strong that the specific heat at low temperatures is enhanced to a value several times that of the noninteracting system. The compressibility is strongly reduced by the repulsive interaction, yielding a sound velocity that is considerably larger than the Fermi velocity. The theory of Fermi liquids is due to Landau (1956), who assumed that the low-lying excited states, the elementary excitations, of an interacting Fermi system could be obtained by the gradual turning-on of the interaction between the particles in an ideal Fermi gas, with a one-to-one correspondence between the states of the ideal gas and those of the interacting system. These elementary excitations behave as quasiparticles in the sense that they possess a definite energy and momentum. The quasiparticle energy is a *functional* of the quasiparticle distribution function, implying that the energy of a quasiparticle depends on the occupation of the other quasiparticle states.

6.1.1 The Landau–Boltzmann Equation Formally, the energy $\epsilon_{\mathbf{p}\sigma}$ of a quasiparticle with momentum $\mathbf{p}$ and spin σ is introduced as the functional derivative of the total energy with respect to the quasiparticle distribution $f_{\mathbf{p}\sigma}$. The second functional derivative of the total energy yields the quasiparticle interaction function $f_{\mathbf{p}\sigma\mathbf{p}'\sigma'}$. The energy may thus be written as

$$\epsilon_{\mathbf{p}\sigma} = \epsilon^0_{\mathbf{p}\sigma} + \sum_{\sigma'} \int d\tau' f_{\mathbf{p}\sigma\mathbf{p}'\sigma'} \delta f_{\mathbf{p}'\sigma'}, \tag{68}$$

where $\delta f_{\mathbf{p}\sigma}$ is a small change in the distribution function. The energy ϵ^0 represents the increase in total energy when a single quasiparticle is added to an otherwise undisturbed system.

As the basis for his derivation of a generalized Boltzmann equation, Landau assumed that the energy $\epsilon_{p\sigma}(\mathbf{r},t)$ could be considered a quasiparticle Hamiltonian, with the quasiparticle velocity $\mathbf{v}_{\mathbf{p}\sigma}(\mathbf{r},t)$ given by

$$\dot{\mathbf{r}} = \mathbf{v}_{\mathbf{p}\sigma}(\mathbf{r},t) = \frac{\partial \epsilon_{\mathbf{p}\sigma}}{\partial \mathbf{p}}, \tag{69}$$

while the time rate of change of the momentum is

$$\dot{\mathbf{p}} = -\frac{\partial \epsilon_{\mathbf{p}\sigma}}{\partial \mathbf{r}}. \tag{70}$$

Because of the Hamiltonian form of these equations of motion, the Boltzmann equation becomes

$$\frac{\partial f_{\mathbf{p}\sigma}}{\partial t} + \frac{\partial \epsilon_{\mathbf{p}\sigma}}{\partial \mathbf{p}} . \frac{\partial f_{\mathbf{p}\sigma}}{\partial \mathbf{r}} - \frac{\partial \epsilon_{\mathbf{p}\sigma}}{\partial \mathbf{r}} . \frac{\partial f_{\mathbf{p}\sigma}}{\partial \mathbf{p}} = \left(\frac{\partial f_{\mathbf{p}\sigma}}{\partial t}\right)_{\text{coll}}. \tag{71}$$

Although this has the appearance of a conventional Boltzmann equation, it should be recalled that $\epsilon_{\mathbf{p}\sigma}$ is a functional of the distribution function and that $-\partial\epsilon_{\mathbf{p}\sigma}/\partial\mathbf{r}$ therefore includes interaction terms, once (68) is inserted. Such interaction terms are responsible for the unusual collective modes that may arise in a Fermi liquid such as *zero sound*. When (71) is linearized in the deviation from local equilibrium (the equilibrium Fermi function with $\epsilon_{\mathbf{p}\sigma}$ inserted), one obtains a transport equation with very different properties from the usual Boltzmann equation. For instance, one finds a soundlike mode in the collisionless regime, where the frequency ω is large compared to a typical collision rate $1/\tau$. The velocity of this mode differs from that of ordinary sound, which propagates in the opposite limit $\omega \ll 1/\tau$. The transition between ordinary (first) sound and zero sound is observed experimentally by studying sound propagation at a fixed frequency and cooling the liquid to lower temperatures, since a typical collision time varies as the inverse temperature squared, $1/\tau \propto T^2$. At the temperature corresponding to $\omega\tau \simeq 1$, the velocity of sound is found to increase (by a few percent), while the temperature dependence of the attenuation coefficient changes from that characteristic of hydrodynamic behavior (proportional to T^{-2}) to that characterizing the collisionless regime (proportional to T^2).

The $T = 0$ ground state of the Fermi liquid is a filled Fermi sea with all states with momentum $\mathbf{p}$ of magnitude less than p_F occupied. The Fermi momentum p_F is given by the same relation as in the noninteracting system, $p_F = \hbar(3\pi^2 n)^{1/3}$, where n is the number density of ^{3}He atoms. The fact that the typical collision rate is proportional to T^2 is a general property of a Fermi liquid. As a result the characteristic times entering the transport coefficients are all inversely proportional to T^2, albeit of different magnitude. As an example we quote expressions for the thermal conductivity κ and the viscosity η, which may be written as $\kappa = C_V v_F^2 \tau_\kappa/3$ and $\eta = m^* n v_F^2 \tau_\eta/5$, respectively. Here v_F is the Fermi velocity, defined by the expansion $\epsilon^0 = \mu + p_F(p - p_F)/m^*$, where μ is the chemical potential. The quantity C_V is the specific heat per unit volume, equal to m^*/m times its value in the interacting system. The times τ_η and τ_κ can be measured, since m^* is known from measurements of the specific heat. One finds at melting-curve pressure, $p = 34 \times 10^5$ Pa, that $\tau_\kappa T^2 = 2.2 \times 10^{-13}$ s K^2 and $\tau_\eta T^2 = 6.6 \times 10^{-13}$ s K^2. The calculated values, obtained from solutions to the Boltzmann equation and scattering amplitudes based on known values of the Fermi-liquid parameters, differ by less than 15% from such experimental results.

7. THE VALIDITY OF THE BOLTZMANN EQUATION

Although the Boltzmann equation was originally introduced for the purpose of describing transport phenomena in dilute classical gases, it has proved a successful approach to the description of the transport properties of both degenerate and strongly interacting systems. The limit of validity of the Boltzmann equation has been a subject of debate for many decades. The fact that agreement with experiment may be lacking for a particular system may be due to a fundamental limitation of the approach, but it may also reflect a lack of detailed knowledge of the system and the important collision processes that limit the transport. There exists no simple universal answer to the question: how good is the Boltzmann equation? Its validity depends on the particular physical system under consideration, including the nature of the different scattering processes that particles may undergo, and on external conditions such as the presence of electric or magnetic fields.

It is generally agreed that the Boltzmann description is valid for classical gases, in which the range of interaction R is much less than the average interparticle separation $n^{-1/3}$, where n is the particle density. The need for including quantum mechanics in the calculation of scattering cross sections entering the collision probability depends on whether the thermal de Broglie wavelength λ_{th} is so large that it is comparable to R. If this is not the case, classical mechanics will suffice. The validity of the Boltzmann equation for the description of transport in metals has been a much debated question. As regards impurity scattering, for electrons moving in three dimensions, the *Landau* criterion must be satisfied, $\hbar/\tau \ll \epsilon_F$. It is not, however, necessary that $\hbar/\tau$ is small compared to kT. In two dimensions, weak localization occurs, and the Boltzmann description is invalid at zero temperature no matter how weak the impurity scattering is. If only electron–phonon scattering is present in a metal, mass renormalization effects such as those entering the electronic specific heat are absent from transport coefficients such as electrical and thermal conductivity, but *not* from the thermoelectric coefficients. The additional presence of electron–impurity and electron–electron scattering complicates the issue, which must be addressed through microscopic calculations based on diagrammatic perturbation theory. Mesoscopic effects, in which the wave nature of the electron states plays an essential role, lie generally outside the scope of the Boltzmann equation.

There exist a variety of methods for deriving a Boltzmann equation starting from a Hamiltonian. Such methods have been used extensively for superconductors, in which the presence of an energy gap puts stronger limits of validity on the use of a Boltzmann equation. These more general methods supplement the approach we have described above in the sense that they may be more general but also more difficult to use. The Boltzmann approach to transport should be viewed as a useful tool—but not the only one—allowing a unified description of transport phenomena in gases, liquids, and solids.

GLOSSARY

Distribution Function: A measure of the mean number of particles in a volume element of the six-dimensional phase space of a single particle. For a classical gas in equilibrium the distribution function is given by the Maxwell distribution, and is thus proportional to $\exp(-mv^2/2kT)$, where v is the magnitude of the particle velocity and m the particle mass.

Phase Space: A six-dimensional space, which may be defined by the position vector $\mathbf{r}$ of a particle and its canonical momentum $\mathbf{p}$. In the case of an electron moving in the periodic potential of a solid, the phase space is defined by its position vector $\mathbf{r}$ and the Bloch vector $\mathbf{k}$.

Relaxation Time: A measure of the mean time between collisions. It may depend on energy and temperature and, in solids, on the direction of the Bloch vector $\mathbf{k}$. The transport time entering the transport coefficient is a related concept, but may differ in magnitude and temperature dependence from (typical) relaxation times.

Transport Coefficient: The coefficient relating the driving force to the current density. In the case of electric conduction the current density $\mathbf{j}$ equals $\sigma\mathbf{E}$, where $\mathbf{E}$ is the electric field strength and σ the transport coefficient, which is independent of the electric field under conditions of linear response.

INTRODUCTION

Tribology is defined as "the science and technology of interacting surfaces in relative motion and of related subjects and practices." This word was coined by a British committee in 1966 from the word "tribos," which means "rubbing" in classical Greek.

A typical example of relative motion is sliding. The lateral force due to sliding is friction; the process of a surface being worn down by friction is wear; and the action of applying oil or some other substance in order to decrease friction and wear is lubrication. Decreasing the friction enables a machine to run more easily and reduces its energy consumption. Decreasing wear extends a machine's working life. On the other hand, brakes and friction-drive mechanisms, such as traction-drive transmissions and ultrasonic motors, make use of frictional forces. Tribology is a key technology for mechanical systems, because almost all machines have sliding mechanisms.

Sliding mechanisms have a very long history. Wheels having bearings were invented about 5000 years ago. The ancient Egyptians used liquid lubricants to slide sledges loaded with huge stones or statues. However, scientific studies of friction began much more recently than these ancient empirical applications.

In the 17th century, Amonton discovered the two basic laws of friction: The frictional force is proportional to the load and independent of the area of the sliding surfaces. These laws were verified in the 18th century by Coulomb and are now known as the Amonton–Coulomb laws. However, Leonardo da Vinci had already foreseen these laws through his scientific experiments in the 15th century. There were two different theo-

ries about the origin of friction. Coulomb concluded that friction was due to the interlocking of surface asperities. On the other hand, at about the same time, Desaguliers proposed that friction was due to molecular adhesion between the surfaces. It took about 200 years to establish the scientific theory of friction. The interlocking theory cannot explain the energy dissipation calculated from the friction force. From the end of the 19th century to the beginning of the 20th century, researchers including Hardy and Tomlinson systematized the adhesion theory. However, this theory requires a friction force proportional to the contact area, which conflicts with experimental results that the friction force is independent of the contact area. In about 1940, several researchers including Holm, Bowden, and Tabor found that the real contact area is very small compared with the geometrical contact area, and Bowden and Tabor explained the empirical Amonton–Coulomb laws using deformations of contacting asperities and adhesion of the real contact areas. This theory is now generally accepted. On the other hand, molecular dynamics studies in the 1990s have led to a new interlocking theory of friction being evaluated as an atomistic friction mechanism without wear.

In the 19th century, Tower showed that a rotating journal bearing generates high pressure in the oil film between the bearing and the spindle. This hydrodynamic pressure sustains the bearing load. Reynolds formulated an equation expressing the pressure in 1886. This lubrication equation is called the Reynolds equation. Around the turn of the 20th century, Stribeck experimentally studied the influence of variables such as load and velocity on friction. A curve of friction versus a combination of such variables is known as a Stribeck curve (see Sec. 1.5).

When lubricated sliding surfaces are so close to each other that surface asperities and the average gap are of the same order, some parts of the surfaces may be covered by very thin lubricant films (a monolayer or a few layers of lubricant molecules). In the 1920s, Hardy studied this regime, called boundary lubrication. He pointed out that the chemical constitution of the lubricant is important rather than its viscosity. Since then, chemically active lubricant additives have been developed for boundary lubrication.

The scientific study of wear started in the 1930s. In 1953, Archard found the empirical rule that the wear volume is proportional to the load and the sliding distance, and inversely proportional to the hardness. At about the same time, Burwell classified the physical mechanisms of wear. However, there are many kinds of interactions between sliding surfaces, such as mechanical, chemical, thermal, and fluidic interactions. The effects of these interactions depend on the sliding conditions and materials, and they affect each other. Furthermore, wear is made more difficult to understand by wear processes being irreversible. Although a lot of engineering data on wear has been accumulated, scientific explanations are still insufficient.

In 1938, Siebel suggested that joint research was needed by physicists, chemists, metallurgists, theorists, designers, and engineers because of the complexity of wear processes. This suggestion is still important for tribology today. In many cases, metals have been used for sliding surfaces, but new materials, such as ceramics and hard coatings, are beginning to be used widely. For progress in materials, we need much more scientific knowledge to understand friction, lubrication, and wear processes and to develop materials and machines having higher tribological performance. Not only engineering data but also scientific understanding of phenomena are needed for tribology. Thus, tribology ranges from basic physics and chemistry to machine development—it is an interdisciplinary research area.

1. TRIBOPHYSICS

1.1 General Aspects

Tribophysics depends on the dynamics of continuum bodies, and several important mechanisms have been clarified, such as deformation, friction, lubrication, and wear. Another approach is from physics at atomic and molecular scales. This approach is to reveal fundamental physical information that is important for understanding the origin of friction and wear and learning the limits of continuum-body dynamics.

1.2 Contact Mechanism

Practical surfaces are not flat but have asperities. The real contact area is small. Even with lightly loaded surfaces, the pressure at the points of contact is high, and these contact regions are responsible for the friction, wear, and interaction between the solid surfaces.

Hertz analyzed the contact of elastic bodies at the end of the 19th century. The process and results of this analysis can be found in many books on the deformation theory of materials (for instance, Timochenko and Goodier, 1951). When two spheres having radii R_1 and R_2 make contact with each other as shown in Fig. 1 under a load W, then if W is not too large, the deformation is elastic. The contact circle of radius a, the indentation distance δ, and the maximum pressure p_0 are shown in Table 1, where E is the elastic modulus, ν is Poisson's ratio, and W is the load.

Concerning the stresses in the contact region, we find the following:

Table 1. Results of Hertz contact equation between two spheres. $\Theta_1 = (1 - \nu_i^2)/E_i$, $\gamma_i = 1/R_i$, $p_0 = 1.5p_{\text{mean}}$; $i = 1, 2$.

a	$\left(\frac{3W}{4}\frac{\Theta_1 + \Theta_2}{\gamma_1 + \gamma_2}\right)^{1/3}$
δ	$\left[\frac{9W^2}{16}(\Theta_1 + \Theta_2)^2(\gamma_1 + \gamma_2)\right]^{1/3}$
p_0	$\frac{3}{2\pi}\left[W\left(\frac{3}{4}\frac{\Theta_1 + \Theta_2}{\gamma_1 + \gamma_2}\right)^{-2}\right]^{1/3}$

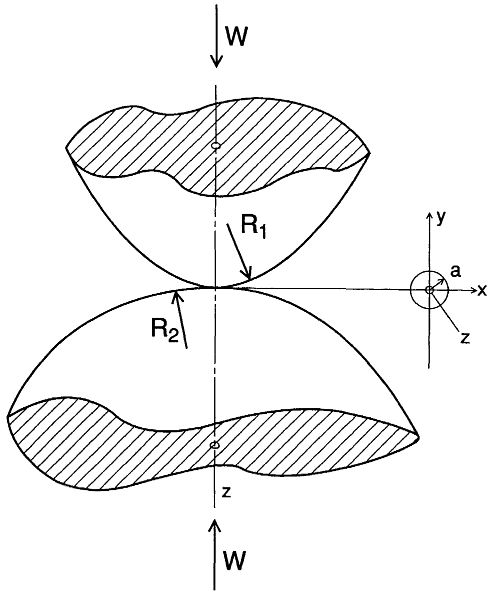

FIG. 1. Contact between two spheres.

1. Maximum compression pressure occurs at the center of the contact and is equal to the maximum pressure.
2. A brittle material is broken by the maximum tensile stress. In this case, the maximum tensile stress $(\sigma_r)_{\max}$ occurs around the contact circle and is expressed by

$$(\sigma_r)_{\max} = \tfrac{1}{3}(1 - 2\nu)p_0. \tag{1}$$

3. A plastic material tends to deform plastically at the maximum shear stress. In this case, the maximum shear stress occurs inside the material, a short distance from the contact surface. If Poisson's ratio ν is 0.3, the main shear stress is equal to $0.31P_0$ at $z = 0.47a$.
4. When friction acts on the contact area, it affects the values of the deformation and the stresses.

As the load increases, the pressure increases and exceeds the elastic limit. At this stage, plastic deformation occurs at the point of maximum shear stress in a plastic material. However, the other points still remain in a state of elastic deformation. When the load is increased further, the region of plasticity grows rapidly, and a stage is reached in which all the material around the contact region flows plastically.

Contact between practical surfaces occurs at many points. The real contact area is very small compared with the nominal contact area, and it varies with the deformation state—plastic or elastic. Greenwood and Williamson (1966) proposed the following equation for a plasticity index ψ involving the properties of the geometries of the surfaces in contact:

$$\psi = (E'/H)(\delta_a/r_m)^{1/2}$$
$$\frac{1}{E'} = \frac{1 - \nu_1^2}{E_1} + \frac{1 - \nu_2^2}{E_2}, \tag{2}$$

where H is the hardness, δ_a is the standard deviation of the distribution of asperity summits, and r_m is the average radius of the contact points. Considering the ratio of the areas of plastic contact and elastic contact, the state of deformation is estimated (Whitehouse and Archard, 1970) as follows:

1. Almost all contact points are elastic at $\psi < 0.6$.
2. Almost all contact points are plastic at $\psi > 3$.

Although the Hertz equations indicate that a zero load produces zero deformation, some surface interaction force still remains. Johnson *et al.* (1971) expressed this effect with the derivatives of the surface energy, showing a finite contact area even at zero load.

A convenient way to determine the real contact area is to measure the electrical resistance between the touching surfaces. Furthermore, electrical contacts are often used in practice in electrical relays and sliding brushes. A large electric current produces heat at the contact point and sometimes causes the contact point material to melt (Holm, 1967).

1.3 Friction

A primary factor in dry friction is the shear force needed to break the adhering points created by contact between two solid surfaces. The shear force (friction force) F and the friction coefficient μ are expressed by the following equation:

$$\mu = F/W = A_r\tau/W = \tau/p_m. \tag{3}$$

Here, A_r is the sum of the real contact areas, τ is the shear strength of adhering points, W is the load, and p_m is the yield stress.

When plastic deformation occurs at a contact area of clean metallic surfaces and adhesive junctions are formed, the contact area increases because of the combined action of tangential force and normal force. This phenomenon is called junction growth. When dry friction occurs between clean metal surfaces, the friction coefficient is very high (up to 100 in extreme cases). Buckley (1981) measured friction coefficients of several transition metals in vacuum conditions and showed that with an increase in the *d*-bond character defined by Pauling's resonating-valence-bond theory of metals (Pauling, 1949), there is a decrease in the friction coefficient; that is, the greater the degree of self-bonding (of a metal), the less the bonding across the interface.

Because the adhesive force is reduced by adsorption of gases on surfaces, the friction coefficients in air are lower than those in vacuum. Sliding surfaces covered with a low–shear-strength material or an inactive material exhibit low frictional coefficients. A lubricant layer decreases friction considerably (see Sec. 1.5).

Most of the work of friction is converted into heat. Even with moderate speeds and loads, the surface temperature often becomes very high, which changes the surface conditions.

1.4 Wear

Wear processes are classified into four types:

1. adhesive wear,
2. abrasive wear,
3. chemical wear, and
4. fatigue wear.

Adhesive wear is the result of breaking the adhering points between surfaces. Abrasive wear is a kind of cutting of a sliding surface by sharp hard points. In many cases, the wear rate depends on this type of wear. Chemical wear results from removal of the corrosion layer by environmental gases and/or liquids adsorbed on the solid surface. The most common type of corrosion is oxidation. Corrosion is accelerated by the repeated mechanical interactions of sliding. Fatigue wear is surface destruction caused by cyclic stress changes during sliding. The delamination theory explains that cracks are nucleated and propagated below the surface with repeated loading, and these cracks finally shear to the surface (Suh, 1977).

In general, wear is driven by the load, and the wear rate is proportional to the load in light-load conditions. Sometimes, there is a critical load and critical sliding speed, which indicates the transition load from a small wear rate (mild wear) to a heavy wear rate (severe wear). Figure 2 shows a wear map (Ashby and Lim, 1990). This map shows that wear processes contain many physical and chemical factors. The temperature increase

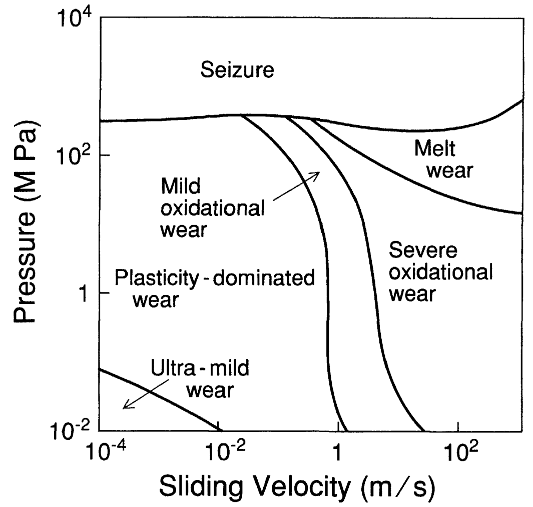

FIG. 2. Example of a wear-mechanism map. Pin-on-disk wear tests for a steel surface (Ashby and Lim, 1990).

and temperature gradients influence the material properties and activate chemical reactions. There are two temperature rises: a rise in bulk temperature and a rise in local temperature or "flash temperature." When the bulk temperature exceeds the melting point, the surface wears down rapidly by melt wear. Severe oxidational wear occurs in conditions that are not severe enough to cause melting; a high flash temperature still appears at conditions insufficient to make the bulk temperature high, and the real contact areas are hot enough to oxidize. With a low sliding velocity and low pressure, there is no significant temperature rise of any sort. In that case, plasticity-dominated wear occurs. With a very low sliding velocity and very low pressure, the plastic deformation no longer dominates. This region is still unclear. It corresponds to the range from molecular or atomic level wear to "zero wear." The wear process on a practical surface is complicated, because many factors such as adhesion between materials, chemical interactions, heat effects, and long-term changes in the surfaces affect wear processes. Our understanding of wear mechanisms is still empirical and unclear.

1.5 Lubrication

Lubrication is a process that reduces friction and wear of sliding surfaces with a low-shear material film or a fluid film. Solids with a lamellar structure, such as graphite and molybdenum disulfide, have low friction. Surfaces having low surface energy, such as a fluorinated surface, also have low friction. Solid-film lubrication is essentially a state of dry friction. Solid lubricants are introduced in Sec. 3.3.

The different types of fluid-film lubrication with oil are explained by the Stribeck curve shown in Fig. 3. This curve shows the change in the coefficient of friction as a function of the nondimensional parameter $\eta V/p$, where η is the viscosity of the lubricant, V is the sliding velocity, and p is the nominal pressure on the sliding surface. There are three modes: hydrodynamic lubrication, mixed lubrication, and boundary lubrication.

When a thick liquid or gas film exists between solid surfaces and the fluid pressure of the film sustains the load, friction force is generated by the shear force.

A fluid film in a converging wedge between sliding surfaces develops hydrodynamic pressures. These pressures can be expressed with the Reynolds equation. A generalized Reynolds equation was derived by Dowson (1962) from the Navier–Stokes

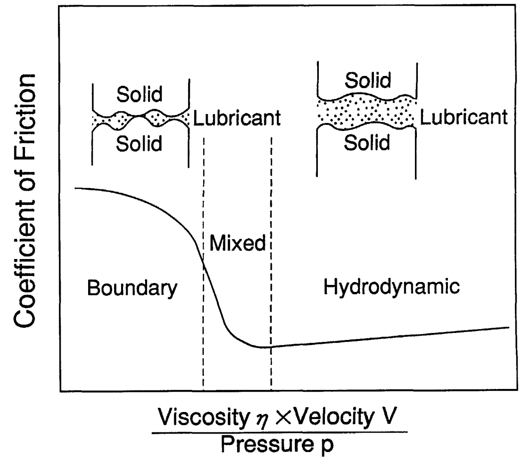

FIG. 3. Stribeck curve. Under purely hydrodynamic lubrication, the coefficient of friction is low and proportional to $\eta V/p$. Under boundary lubrication, the coefficient of friction depends mainly on the properties of lubricant molecules adsorbed on solid surfaces. When the lubricant film is broken, solid-to-solid contact occurs and the coefficient of friction becomes large. Mixed lubrication is the transitional region from hydrodynamic lubrication to boundary lubrication.

equation expressing the dynamics of continuum flow, using the following assumptions:

1. The thickness of the fluid film is very small compared with the dimension of the sliding surface.
2. There is no variation in pressure across the fluid film.
3. The flow is laminar.
4. No external forces act on the film.
5. Fluid inertia is small compared with the viscous shear.
6. There is no slip at the sliding surfaces.
7. The velocity gradient across the fluid film is dominant.

Adding the assumptions that there are no variations in the fluid density ρ or coefficient of viscosity η across the fluid film and that the surfaces slide in the x direction with speeds of V_1 and V_2, the Reynolds equation is expressed as follows, referring to Fig. 4:

$$\frac{\partial}{\partial x}\left(\frac{\rho h^3}{\eta}\frac{\partial p}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{\rho h^3}{\eta}\frac{\partial p}{\partial y}\right) = 12\frac{\partial(\rho h)}{\partial t} + 6\frac{\partial}{\partial x}[\rho h(V_1 + V_2)]. \quad (4)$$

In hydrodynamic lubrication mode, the sliding surfaces are completely separated, and there is no wear. The friction coefficient is proportional to the parameter $\eta V/p$.

When very high hydrodynamic pressure is generated locally across a small gap, the surface is elastically deformed, and this affects the hydrodynamic behavior. Lubricant properties are sometimes changed by high pressure. This condition is called elastohydrodynamic lubrication (EHL).

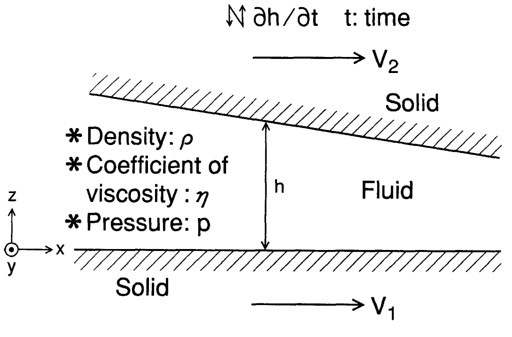

FIG. 4. Fluid film between solid surfaces. Here, p is the pressure in the film and V_1 and V_2 are sliding speeds.

When sliding surfaces are so close to each other that surface asperities are dominant, hydrodynamic effects are not sufficient to support a load. However, very thin lubricant films (a monolayer or a few layers of lubricant molecules) on asperities still sustain part of the load. This is mixed lubrication. When the sliding speed is slow, the load is supported by very thin lubricant films instead of by the hydrodynamic pressure. In many cases, several areas of the very thin lubricant films are broken by the high pressures, and solid-to-solid contact and wear occur. The friction coefficient becomes higher and independent of the viscosity of the lubricant and the sliding velocity. This is boundary lubrication. In boundary lubrication, the physical and chemical properties of a lubricant molecule are more important than the coefficient of viscosity in continuum flow.

1.6 Tribology at Atomic and Molecular Scales

The ultimate goal will be to understand tribological phenomena with physics at atomic and molecular scales. Sliding parts with very light loads are beginning to be used in magnetic recording and micromechanical systems, which require wear rates that are almost zero. This field is called "microtribology," and it needs more engineering data from atomic and molecular level studies. Thus tribology at atomic and molecular scales is important for both science and technology.

Computer simulation based on molecular dynamics can be used to trace the movement of each atom in contacting or sliding surfaces. Landman *et al.* (1990) showed atomistic mechanisms of adhesion and indentation. Hirano and Shinjo (1990) studied the origin of friction, and they found the existence of a sliding condition that generates no frictional force. This state of vanishing friction is called "superlubricity."

Scanning probe methods, such as a scanning tunneling microscope (STM) and an atomic force microscope (AFM), are used for atomic-level observation of surfaces. An AFM can also be used as a nano-hardness tester and nano-wear tester. Kaneko and Hamada (1993) reported the microwear process of polymers. For example, a polycarbonate surface first formed a plateaulike upheaval several nanometers high, then formed projections, and finally was worn down. The wear marks of the first and second stages reflect the plastic deformation that led to destruction.

Using an AFM, Mayer *et al.* (1992) observed wearless friction on surfaces covered with a Langmuir–Blodgett film. The initial stages of wear were also observed as a displacement of groups of molecules. A surface force apparatus (SFA) (Israelachvili, 1992) is used to observe the behavior of a molecularly thin film between smooth solid surfaces. One of the main achievements of the SFA has been to measure oscillatory solvation or structural forces. An ultrathin film of simple spherical molecules such as cyclohexane shows high friction with stick-slip motion, where, in the sticking state, the film becomes essentially solidlike. On the other hand, longer-chained and branched molecules give low friction and smoother sliding (Israelachvili *et al.*, 1990).

Surfactant molecules, tightly bound to the smooth surfaces, show stick-slip motion not only between a "static" and a "kinetic" state but also between a static or kinetic state and some "superkinetic" state that exhibits ultralow friction (Yoshizawa *et al.*, 1993). In the superkinetic regime, the surfactant chains become shear-aligned or combed into a configuration that results in very low friction.

One of the most important parameters in molecular gas dynamics is the Knudsen number, which is defined as $\mathrm{Kn} = \lambda/h$, where λ is the molecular mean free path and h is the characteristic length of the flow. When the value of Kn is larger than 0.1, flows in the gas film cannot be described by a continuum flow model. Fukui and Kaneko (1988) introduced a Reynolds-type equation for an arbitrary Knudsen number. This equation is called the molecular gas-film lubrication (MGL) equation. The MGL equation was derived from a linearized Boltzmann equation and contains a term expressing pressure flow for arbitrary Knudsen number. The conventional Reynolds equation based on a continuum flow model underestimates the pressure flow rate for a high Knudsen number. In fact, the molecular gas effects decrease the pressure of a gas film. These effects cannot be ignored for gas-film lubrication mechanisms having a very small spacing, such as a flying-head slider for magnetic recording that flies with a spacing of 100 nm or less.

2. TRIBOCHEMISTRY

2.1 General Aspects

Liquid lubricants are a mixture of a base oil and additives, which are mainly composed of organic compounds. Under boundary lubricating conditions, the lubricating performance of liquid lubricants is closely related to their chemical behavior. Details of lubricant components are shown in Sec. 3.2.

Tribochemistry includes chemical reactions and chemical phenomena such as chemisorption under tribological processes. Tribological behavior is strongly affected by tribochemical reactions—for example, the formation of lubricating surface films from lubricant additives, chemical or corrosive wear, and degradation of lubricants as shown in Fig. 5.

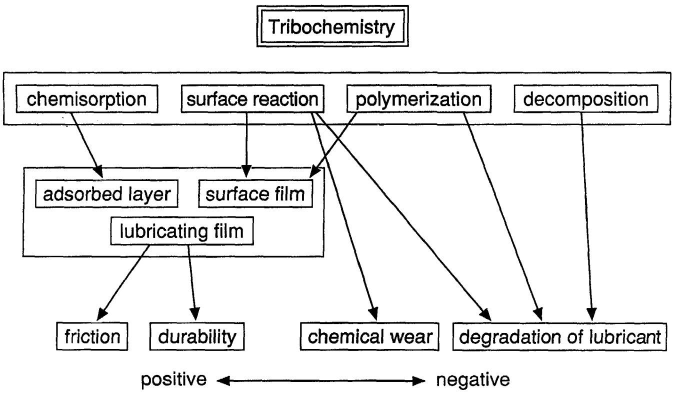

FIG. 5. Relationship between tribological performance and tribochemistry.

Tribochemical phenomena occur under the effect of mechanical contacts. Chemical reactions are enhanced by the mechanical effect at sliding contacts. There are two main causes for tribochemical reactions:

1. temperature and pressure rise at sliding contacts and
2. enhanced activity of mechanically contacting surfaces as shown in Fig. 6.

In general, surfaces are stabilized chemically by oxides, hydroxides, adsorbed water, and organic contaminants on the surfaces. When the surface layers are removed by mechanical contact, active sites such as surface defects are introduced on the surface.

2.2 Chemical Interaction with Surfaces

Adsorbed layers and reaction products from lubricant additives act as a lubricating film. Frictional properties in boundary lubrication are controlled by the surface coverage of the lubricant film to prevent direct solid–solid contact. The lubricity of the surface films depends on the chemical interaction between lubricant molecules and surfaces. The interaction is estimated from the chemisorption energy.

2.2.1 Chemisorption on Oxide-Covered Surfaces Lubricant components chemisorb on oxide or hydroxide layers on metals that are formed at atmospheric pressure. The chemisorption energy can be estimated from the heat of adsorption as well as from the heat of immersion. Compounds having a polar functional group, such as a carboxyl or amine group, chemisorb more easily than nonpolar compounds by a polar–polar interaction between the functional group and the oxidized surface. For example, the heat of immersion of water on silica or alumina is more than five times that of *n*-hexane (Wade and Hackerman, 1964). The heat of adsorption on iron oxide powder is ranked as follows: mineral oil (hydrocarbon) < cetyl alcohol < stearic acid = stearyl amine (Groszek, 1962). Fatty acids interact strongly with metal oxides on surfaces, resulting in the formation of stable surface films, sometimes a soap, and the surface films show good lubricity. Polar compounds, such as fatty acids having a higher heat of adsorption on iron oxide surface, exhibit a lower wear rate for steel (Groszek, 1962).

FIG. 6. Causes of tribochemical activation.

2.2.2 Chemisorption on Nascent Surfaces The surface layers on metals are removed by mechanical contact, resulting in the formation of nascent metal surfaces. Lubrication behavior under severe conditions is affected by chemical reactions on the nascent surfaces, which are chemically active because of dangling bonds on the surface. Evaporated metal films have been used as a model of the nascent surface. Since α-olefins chemisorb on evaporated aluminum films, they have been used as a metal-working fluid for aluminum (Owens *et al.*, 1966). Decomposition of carboxylic acid was also reported using evaporated iron film (Morecroft, 1971).

The nascent metal surface formed by scratching proved to be more active than evaporated films. On the other hand, the chemisorption behavior of model lubricant compounds on the nascent steel surfaces is different from that on metal oxide surfaces and closely depends on their molecular structure (Mori and Imaizumi, 1988). Nonpolar compounds such as aromatic compounds, olefins, and organic sulfides chemisorb on transition metals more easily than polar compounds such as carboxylic acids and amines that chemisorb easily on metal oxide surfaces. Saturated hydrocarbons do not chemisorb on nascent metal surfaces.

2.2.3 Tribochemical Reactions Under severe sliding conditions, the temperature at a real contact may exceed several hundred degrees centigrade (Bowden and Thomas, 1954). This high temperature at the contact is called a flash temperature or hot spot. Under such conditions, lubrication films are formed by tribochemical reaction between lubricant additives and materials. Chemical or corrosive wear is accelerated by tribochemical reaction between materials and surrounding gases and liquid chemicals such as oxygen, sulfur dioxide, and lubricant additives. Lubricant degradation is also accelerated by tribochemical activation.

Mechanical action alters the surface structure and composition, resulting in a change in chemical activity of surfaces (Buckley, 1974). The enhanced chemical activity originates from nascent surfaces of metals and ceramics and radical sites at ruptured covalent bonds of polymers and ceramics. For example, lubricant degradation and polymerization of aromatic compounds have been reported under the chemical effect of metallic surfaces (Goldblatt, 1971). The radical sites initiate some reactions such as oxidation, decomposition, and polymerization of organic compounds (Kurokawa *et al.*, 1978; Schrader *et al.*, 1969).

Electrons, known as exoelectrons, are emitted from the mechanically activated surfaces (Kramer, 1957). The emission intensity increases with stimulation by both thermal and optical energy. Since the emitted electrons have an energy of more than 1 eV, they have been identified as one of the active sources for tribochemical reactions—for example, the formation of soap from carboxylic acid (Smith and Fort, 1958) and the reaction of lubricant additives (Kajdas, 1987).

2.3 Lubrication Behavior

Under boundary lubrication conditions, lubricating behavior is controlled by surface films such as adsorbed layers and reacted layers. Chemisorbed organic layers prevent adhesion between two solid surfaces, which reduces the friction force and wear. Reacted layers are often composed of soft substances such as metal sulfides and phosphates that prevent adhesive wear.

2.3.1 Lubrication with Adsorbed Layers Adatoms such as oxygen, sulfur, and chlorine on metal surfaces reduce adhesion and friction between two metal surfaces (Ferrante, 1987; Wheeler, 1976). Organic monomolecular films of fatty acids, amines, or alcohols are also lubricating (Cottington *et al.*, 1958). Such lubricating layers of these compounds can also be formed by adsorption from their solution in a base oil. These compounds chemisorb by chemical interaction between their functional groups (COOH, NH_2, or OH) and metal oxide surfaces. The higher the carbon number of the alkyl chain in the organic compound, the lower the friction and the longer the durability (Cottington *et al.*, 1958). Multilayers give greater durability to the lubricant film than monolayers. The lubricity disappears at elevated temperatures (100–300 °C depending on the compounds), because of desorption of the organic compound. When surfaces are covered with solid organic layers, friction increases sharply above the melting point of the surface compounds (Rabinowicz and Tabor, 1951).

2.3.2 Lubrication with Reacted Layers Organic deposits, known as friction polymers, are formed at sliding contacts from lubricant components and organic vapors in the surrounding gas. The polymerized matter acts as a lubricant film (Fein and Kreuz, 1965). At elevated temperature, organic compounds decompose and carbonaceous matter is formed on the surface; this acts as a solid lubricant. Oxide layers on metal surfaces reduce the wear rate and prevent metal–metal contact. Such layers are reformed by the oxidation of nascent surfaces by atmospheric oxygen and water. Lubrication with reacted layers from additives is shown in Sec. 2.3.5.

2.3.3 Chemomechanical Effect The mechanical properties of materials are altered by the surface effects of chemicals. The mechanical strength of metals such as tin and ionic crystals is reduced by chemisorption of polar compounds (known as the Rehbinder effect). The ductility of alkali halides such as potassium chloride is reduced by the presence of water on the solid surface (Joffe effect). On the other hand, the surface hardness of metals such as cadmium is increased by the presence of an oxide layer on the surface (Roscoe effect). Since tribological behavior depends on the mechanical properties of the materials, these effects directly affect the tribological behavior. For example, friction and wear of magnesia and alumina are affected by the adsorption of *n*-alcohols (Westwood *et al.*, 1981).

2.3.4 Degradation of Lubricants Lubricating oils degrade mainly through thermal oxidation. The reaction is accelerated at elevated temperature under sliding conditions and is catalyzed by metal surfaces and metal ions formed by the oxidation of metals. Degraded oil contains metal ions, alcohols, fatty acids, soaps, and esters as oxidation products. The viscosity of oils decreases after decomposition. On the other hand, some of a lubricant oil is polymerized during the oxidation, resulting in an increase in its viscosity. Since the oxidation occurs through a radical transfer mechanism, radical scavengers such as amines are used as antioxidation agents. The role of nascent surfaces and exoelectrons in the initiation of degradation has also been pointed out (see Sec. 2.2.3).

2.3.5 Effects of Additives Adsorption and reaction layers on materials play an important role in reducing friction and wear as discussed above. Several types of additives are added to mineral or synthetic base oils. Oiliness agents having a polar group such as a carboxyl group chemisorb on the oxide surface on metals. Extreme-pressure additives containing such elements as sulfur, phosphorus, and chlorine react with material surfaces under severe conditions, resulting in the formation of a soft layer that acts as a lubricating solid film to prevent metal–metal contact (Sakurai and Sato, 1966). In general, these additives have a long-chain alkyl group in order to dissolve in base oils. Lubricating performance is affected by the surface coverage of additives that increases with the concentrations of additives. Chemical or corrosive wear occurs at higher concentrations of additives that attack materials chemically. When additives react with materials readily, wear is also accelerated chemically. Therefore, there is an optimum concentration or reactivity of additives for a lubricant mixture as shown in Fig. 7.

3. TRIBOMATERIALS

3.1 General Aspects

"Tribomaterials" include sliding materials facing each other and coatings of solid or liquid films between the sliding materials. They are required to reduce, or in some cases to control, adhesion, friction, and wear of mechanical components. During sliding, they are subjected to mechanical, thermal, and chemical attack depending on the operational conditions and environments. Friction and wear of tribomaterials are therefore very complicated phenomena involving various mechanisms and factors. Suitable selection of tribomaterials depending on the operating conditions plays an important role in controlling the life of mechanical components.

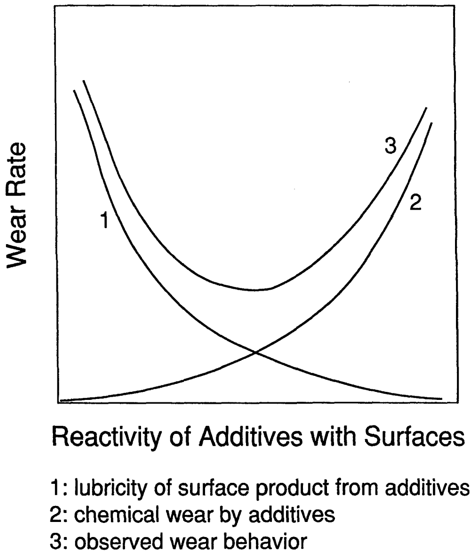

FIG. 7. Relationship between wear rate and additive reactivity with surfaces.

3.2 Liquid Lubricants

Liquid lubricants reduce or control friction and wear by separating sliding solids with a liquid layer. They also act as heat carriers to remove heat generated by sliding. Liquid lubricants are composed of a base oil and additives.

Base oils are classified as mineral or synthetic oils. Mineral oils, a mixture of paraffinic, naphthenic, and aromatic hydrocarbons, are produced from petroleum by distilling and refining. Several types of synthetic oils can be used to improve tribological performance such as viscosity index, thermal and oxidative stability, and volatility. Typical synthetic oils are hydrocarbons (olefin oligomers and arylalkanes), esters (diesters and polyol ester), halogenated organic compounds (perfluorinated ethers and chlorinated compounds), phosphonates, polyglycols, polyethers (polyphenyl ethers), and silicon derivatives. The tribological performance of synthetic oils closely depends on their molecular structure.

Lubricant additives are mainly composed of organic compounds having different functional groups. Oiliness agents having a polar functional group such as a carboxylic group chemisorb on material surfaces and reduce friction and wear. Carboxylic acids such as stearic acid, esters, and soaps are used as oiliness agents. Extreme-pressure (e.p.) additives having such elements as phosphorus, sulfur, and chlorine react with materials to form lubricating films. Organic sulfides, phosphates, and chlorides—for example, dibenzyl disulfide, tricresyl phosphate (TCP), and chlorinated paraffine—are used as e.p. additives. A typical e.p. additive is zinc dialkyl dithiophosphate. Viscosity-index improvers, high-molecular-weight polymers such as polymethacrylate (PMA), improve viscosity at elevated temperature. Oxidation inhibitors such as hindered phenol inhibit a radical transfer in the oxidation of oils. Sometimes solid lubricants are added to liquid lubricants.

Greases are composed of a base oil and fine solid particles called a thickener. A typical thickener is soap such as lithium stearate that forms a fibrous micelle. Urea compounds, fine polymer powders, and surface-treated clay powders are also used as thickeners. The base oil is held in the three-dimensional structure of the thickener. Since grease has a solidlike structure that is easily softened by mechanical shear, it has several advantages: It is easy to supply without maintenance for a long time, and it protects sliding contacts from water, dust, and corrosion.

3.3 Solid Lubricants

Solid lubricants are inorganic and organic compounds of low shear strength. Typical inorganic lubricants are molybdenum disulfide, tungsten disulfide, graphite, and carbon fluoride, which all have a hexagonal lamellar structure; lead oxide (PbO) and barium fluoride/calcium fluoride eutectic, BaF_2/CaF_2, which are nonlaminar solids; and soft metals, such as lead, silver, and gold. Typical organic lubricants are fats, soaps, waxes, and polymers, such as polytetrafluoroethylene (PTFE) and polyimide. These solid lubricants are utilized, normally in the form of coatings or self-lubricating composites, at elevated temperatures, say above 300 °C, where liquid lubricants thermally degrade (Sliney, 1982).

Graphite and molybdenum disulfide, which are the most widely used solid lubricants, have different tribological responses to the environment. Contaminants in air—water and hydrocarbons—adsorb well on molybdenum disulfide and increase the bonding strength between two adjacent lattice layers. Thus molybdenum disulfide lubricates better in the absence of these contaminants, such as in a vacuum or in dry inert gases. Conversely, graphite has better lubricative properties in ambient air than in vacuum or in dry air.

Transition-metal dichalcogenides, such as niobium disulfide and tantalum disulfide, are not themselves lubricative, even though they have a layered lattice crystal structure, but they show better lubricity after intercalation of guest elements, such as silver atoms, between adjacent lattices (Hironaka, 1992).

PTFE appears in the "Guiness Book of Records" as the solid with the lowest friction coefficient (0.04).

The temperature dependences of the friction of typical solid lubricants are shown in Fig. 8. Molybdenum disulfide, graphite, and PTFE lose their lubricative properties through decomposition or oxidation degradation. On the other hand CaF_2/BaF_2 and boron oxide (B_2O_3) acquire lubricative properties at elevated temperatures as a result of softening or melting.

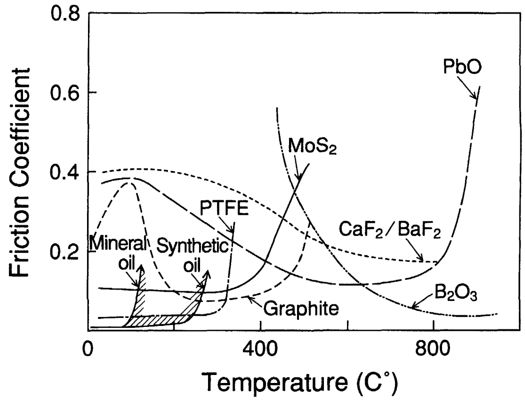

FIG. 8. Friction coefficient of lubricants as a function of temperature in air.

3.4 Wear-Resistant Sliding Materials

Wear generally occurs at real contacts between the sliding surfaces, where the stress is concentrated. Since plastic contact promotes wear, a tribological design is required to ensure that surfaces in contact are elastic. This requirement is achieved by reducing the plasticity index ψ in Eq. (2). The E'/H in the quantity ψ for pure metals is about 200, whereas for inorganic solids having covalent bonds, it is about 10; conventional materials have values between 10 and 200. Generally, the harder the material, the lower the value of E/H. Harder materials, however, are generally brittle, which leads to destructive wear. Wear-resistant tribomaterials are thus designed as multiphase solids or composites, combining hard solid phases in a ductile solid matrix of metals or polymers.

One example is a high-speed tool steel having a heat-treated martensite phase in which hard carbide phases such as $M_{23}C_6$, M_6C, or MC (M is W, Cr, or V) are precipitated. Nonferrous superalloys have been developed for wear resistance at high temperatures: for example, Triboloy® is essentially a nickel-based superalloy containing very hard intermetallic compounds (Laves phase). Stellite® is a Co–Cr based superalloy containing chromium and tungsten carbides.

Many polymers are used for mechanical components: polyamide (PA; Nylon®), polyoxymethylene (POM), polycarbonate (PC), modified polyphenylene oxide (PPO), polybutylene terephthalate (PBT), and polytetrafluoroethylene (PTFE, Teflon®). These are known as engineering plastics, whereas polyimide (PI), polyether ether ketone (PEEK), polyphenylene sulfide (PPS), and liquid crystalline polymer are known as super engineering plastics. They are superior to engineering plastics in heat resistance and other mechanical properties. PA, POM, and PBT are self-lubricative and wear resistant. PTFE is self-lubricative, but has high wear. The wear resistance can be improved by using PTFE composites, containing various fillers such as bronze mesh or carbon fiber.

Ceramics, such as silicon nitride, silicon carbide, alumina, and zirconia, are hard, low–thermal-expansion, noncorrosive, and heat-resistant materials. They therefore have potential as tribomaterials for use in extreme conditions and hostile environments, where components made of metals and polymers cannot operate. Some species in the environment form films on sliding surfaces of these ceramics as a result of tribochemical reactions, as described in Sec. 2. For instance, the friction and wear of silicon nitride were reduced by additives such as phosphorus-containing compounds, sulfonates, and glycol compounds in a paraffin-based oil but were increased by chlorinated compound additives (Gates and Hsu, 1991). The former additives are thought to form a lubricative film in the contact region. Silicon nitride also reacts with water, methanol, and ethanol to form tribochemical films of SiO_2 and $Si(OH)_x$ in water (Tomizawa and Fischer, 1986), SiO_2, amines, and polymeric compounds in n-alcohols (Hibi and Enomoto, 1989). In these fluids, hydrodynamic lubrication sets in above a certain sliding velocity.

Diamond, the hardest material, and diamond coating have a low coefficient of friction of between 0.05 and 0.15 in air. Water is effective for lubricating diamond on diamond, but oil is not (Feng and Field, 1991).

3.5 Coating and Surface Modifications

Coating and surface modifications have been widely used in tribological applications. There are two ways to reduce sliding wear. One is to reduce the stress concentration in the contact region. This can be achieved by using soft, more or less lubricative solids for coating materials. Another way is to enhance the resistance against deformation and fracture in the contact region, which can be done by using hard materials as an overlayer (Ura *et al.*, 1989).

Typical hardnesses of conventional coating materials and surfaces modified for tribological use are shown in Fig. 9. The processing temperatures fall into three main groups: at around 1000 °C, thermodynamic chemical reactions proceed on the substrate, and adhesion between film or modified layer and substrate is high. At around 400–500 °C are ion plating and plasma sputtering. Adhesion strength can be enhanced by ion cleaning a substrate by sputtering prior to coating. For other coatings at process temperatures below about 500 °C, substrates are usually sand-blasted for cleaning and roughening to enhance the adhesion of overlayers.

Optimum coating thicknesses of triboma-

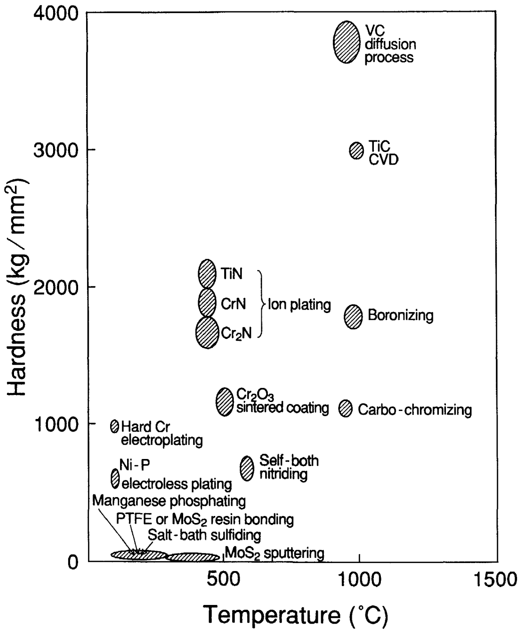

FIG. 9. Hardness of coatings as a function of substrate temperature for coatings.

terials will vary depending on whether the material is soft or hard. For soft layers, the basic tribological concept is that vertical loads are supported by the hardness of the substrate materials and soft layers lower the shear resistance. Therefore, the thinner the soft layers, the better the tribological response should be. An initial thickness of 3–15 μm is common. On the other hand, a hard coating or overlayer is designed to support the load. In the first approximation, the thickness of the hard layer is selected to be greater than the depth of the maximum shear stress, which depends on the operational conditions.

4. SUMMARY

Tribology is a key technology for mechanical systems and also an important area of surface science and material science, because science is important for understanding the origin of friction and wear. Thus, tribology ranges from basic physics and chemistry to mechanical engineering.

In this article, fundamentals of tribology were overviewed in three areas: tribophysics, tribochemistry, and tribomaterials. Tribophysics involves deformation, adhesion, friction, and wear mechanisms, which are described by the dynamics of continuum bodies. Tribochemistry involves chemical reactions on sliding surfaces. And many kinds of tribomaterials for sliding surfaces have been developed. These tribological knowledge have been applied to design many kinds of machine elements.

However, tribological phenomena are very complicated. All these areas (i.e., tribophysics, tribochemistry, and tribomaterials) should be understood by analyzing sliding mechanisms of surfaces. Not only engineering data but also scientific understanding are needed for further advance in tribology.

GLOSSARY

Boundary Lubrication: Lubrication without a liquid layer generating hydrodynamic pressure to sustain the load. The friction is affected by the physicochemical interaction at the solid-lubricant-solid interface.

Chemisorption: Adsorption that occurs through a chemical interaction between molecules (adsorbates) and surfaces. The heat of chemisorption is more than 100 kJ/mole.

***d*-Bond Character:** The amount of *d*-electrons that contribute to metal bonding in the *dsp* hybrid orbital. The greater the *d*-bond character of a structure, the more stable it is (see Pauling, 1949).

Exoelectrons: Electrons emitted from activated surfaces by mechanical treatments, irradiation of high-energy particles, and so on. One of the active sources for tribochemical reactions.

Extreme-Pressure Additives: Lubricant additives containing phosphorus, sulfur, and/or chlorine, and some metals such as zinc and molybdenum, to form surface-lubricating films by reaction with materials.

Flash Temperature: High temperature generated at mechanical contact exceeding several hundred degrees centigrade.

Nascent Surface: Chemically active surfaces formed by the removal of surface films of oxides and organic contaminants at mechanical contact.

Oiliness Agent: Surface-active agents that have long alkyl chains and polar groups, such as a carboxyl group, and that adsorb on the material surface and reduce friction and wear.

Poisson's Ratio: The ratio of the relative lateral contraction to the relative longitudinal extension. For most substances, this value lies between 0.2 and 0.4.

Viscosity Index: Viscosity decreases with increasing temperature. The viscosity index is a parameter for expressing the temperature dependence of viscosity. The higher the index, the lower the dependence.

INTRODUCTION

Dye lasers are among the most widely used tunable coherent sources of light from the near UV to the near IR. Although at certain specific wavelength ranges other sources have eclipsed their use, they continue to play an important role because of their availability in many possible configurations at any wavelength and at various pulse durations and output power levels. In addition, the relative simplicity and affordability (of most of the available configurations) and, most importantly, true tunability assures their continuing importance for some time to come. In this article the physical and theoretical principles of dye lasers are given and some of the most important types of systems in use today are described. It is not a comprehensive theory or a complete survey; the aim is to give an understanding of the basics and some knowledge of the practical aspects of the most important types of tunable dye laser systems. Additional, related topics can be found in the Further Reading.

1. BASIC DYE-LASER PRINCIPLES

The active materials in dye lasers are various organic dyes, which can have widely different chemical compositions. However, the basic photophysical principles are essentially the same for all of them. A description based on rate equations and stimulated absorption and emission cross sections is commonly used, and the relevant parameters have somewhat similar values. The radiative properties of laser dye solutions depend on both the dye molecular structure and the properties of the solvent. There is extensive literature (Shank, 1975; Maeda, 1984; Duarte and Hillman, 1990; Schäfer, 1990) on dye lasers and on the spectroscopic and chemical properties of dyes. No detailed description of these is required for a basic understanding of the dye laser, and only a brief summary of the relevant properties is given here.

Dye molecules are large, with many internal degrees of freedom. There are also very frequent collisions with the solvent molecules. Figure 1(a) shows the basic energy-level scheme of a typical laser dye in liquid

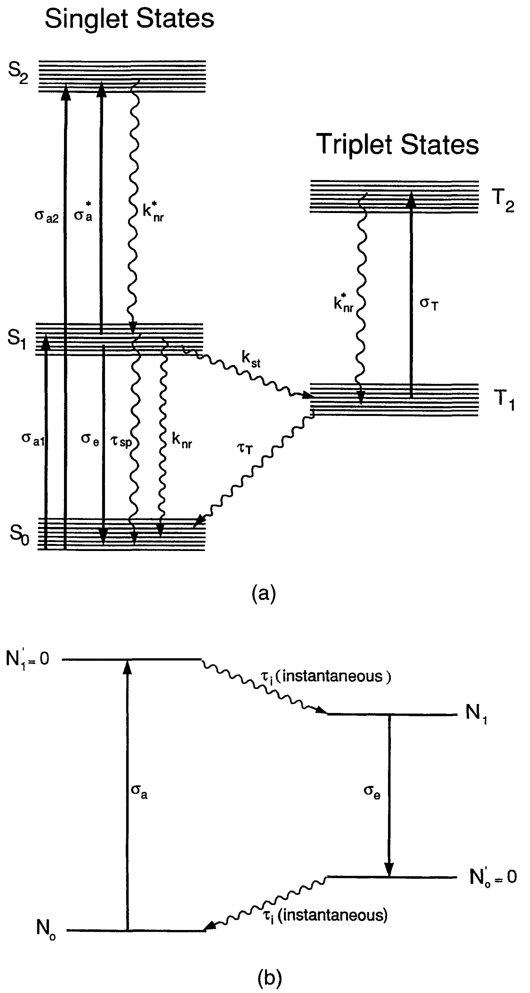

FIG. 1. (a) Schematic of the energy levels of a typical laser dye showing singlet and triplet manifolds, spontaneous rates (lifetimes), and stimulated cross sections. The nonradiative rates shown as k_{nr}^* are so fast as to quench radiative emission from those levels. (b) An equivalent four-level model of the two lowest singlet states (S_0,S_1) in (a). The primed levels have zero population.

solution form. There are two main energy manifolds: singlets and triplets. Within each electronic state there is a broad-band quasi-continuum of vibrational–rotational energy levels. The main absorption band is that corresponding to the ground-state singlet (S_0) to first excited singlet (S_1); there is also a shorter-wavelength and somewhat weaker band from S_0 to S_2. Laser action takes place between the first excited singlet (S_1) and the ground-state singlet (S_0) bands. Only the S_1 band is radiative, because a molecule in any of the higher singlet levels undergoes rapid nonradiative decay to S_1 completely quenching any emission. Nonradiative decay from S_1 to S_0 and intersystem crossing between singlet and triplet states also take place, but for laser dyes the radiative process is dominant. In the triplet energy manifold, the lowest state (T_1) is metastable while the higher-energy states are also nonradiative. As a result of the nonradiative quenching of all except the S_0, S_1, and T_1 states, only these three bands have non-negligible populations in a dye laser. Another important process is the essentially instantaneous intraband thermalization that takes place within the vibrational–rotational continuum bands. As a consequence, the total population within any band is always in quasi thermal equilibrium. The strengths of the various spontaneous (radiative and nonradiative) processes are given as lifetimes (τ_{sp}, τ_T, τ_i, etc.) or rates (k_{ST}, k_{nr}, etc.) as shown on the diagram. The total lifetime of state S_1 is τ_1, where $1/\tau_1 = 1/\tau_{sp} + k_{nr} + k_{ST}$, and is typically of the order of a few nanoseconds. Optical pumping, to achieve an effective population inversion, is usually in the main singlet absorption band. However, since the S_2 state decays very rapidly (and nonradiatively) to S_1, the secondary (S_0 to S_2) absorption band can also be used to populate the S_1 state.

The singlet manifold may be modeled as an effective four-level homogeneously broadened system, as shown in Fig. 1(b). Homogeneous means that the entire population of a given band (level) participates in the stimulated transitions from that level. The broad emission and absorption line shapes are always determined experimentally. The probability of a stimulated process is $I\sigma$, where I is photon intensity (in s^{-1} cm^{-2}) and σ is process cross section. Figure 2 shows the cross sections (σ_e, σ_a, σ_T) vs wavelength for one of the best laser dyes, rhodamine 6G (R6G), and the inset gives approximate values of some of the lifetimes and rates under conditions found in a typical laser. The main absorption-band and the emission-band curves are approximately mirror images of each other. This arises from a superposition, with Boltzmann probability distribution, of Lorentzian-shaped transitions of various oscillator strengths. The peak of the emission is energy downshifted from that of the ab-

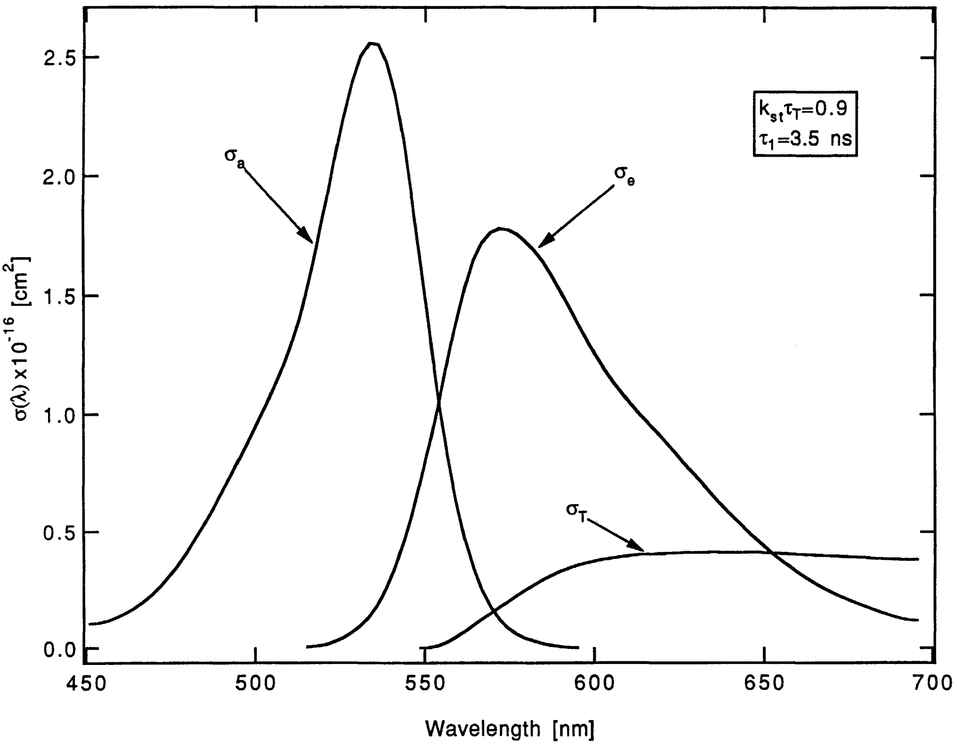

FIG. 2. Singlet absorption and emission and triplet absorption cross sections [defined by Eqs. (1) and (4)] vs wavelength for the dye R6G. The inset box shows values of the other parameters used in the calculations of Fig. 8.

sorption on account of the Franck-Condon principle. In some dyes this shift may be so large that the emission and absorption curves have only a very small overlap. The emission cross section can be obtained from the spontaneous fluorescence line shape $E(\lambda)$ (given vs the wavelength λ) by

$$\sigma_e = \lambda^4 E(\lambda)/8\pi\tau_1 c n^2, \tag{1}$$

where

$$\int_0^\infty E(\lambda)d\lambda = \phi, \tag{2}$$

n is the index of refraction, and c is the speed of light. The quantity $\phi = \tau_1/\tau_{sp}$ is the quantum efficiency of the fluorescence, and also equals the ratio of the areas under the emission and absorption curves. This parameter must obviously be as close to unity as possible for a laser dye. The nonradiative processes, i.e., k_{nr}, k_{ST}, and τ_T, are dependent on the molecular structure of the dye, on the dye concentration, and on impurities (or deliberate additives) present in the solution. For example, in R6G for concentrations larger than ~0.5×10^{-3} mol/L, τ_1 gradually decreases from the low-concentration limit because of increasing nonradiative decay (concentration quenching). It should also be noted that a value of ϕ close to unity is necessary for, but does not always guarantee, lasing. This is because the excited-state (S_1 to S_2) absorption (σ_a^* in Fig. 1) can overlap the emission and can prevent lasing. In dyes suitable for lasing, this absorption lies outside the emission band. On the other hand, the triplet absorption always at least partially overlaps the emission and is therefore an important loss factor that is discussed later. It is obvious from Figs. 1 and 2 that even if only a rather small fraction of the total molecules is in the first singlet level, a dye has an effective population inversion and therefore optical gain in the long-wavelength region of the emission. Additionally, because the emission spectrum is very broad, the gain bandwidth is wide. The resulting tunability, however, comes at a price. The high stimulated-emission probability (large σ_e) over a wide band also means that the lifetime of the lasing level is very short, of the order of a few nanoseconds. The consequence of this is that high pumping intensities are required to obtain and maintain a population in level S_1.

A very large number of dyes have been made to lase by various optical pumping schemes. However, for the purposes of practical applications, a much smaller number are used. Dye lasers may be divided into two broad categories by the method of pumping: cw and pulse pumped. The first is always pumped by a laser, while the second may be either flashlight or laser pumped. The pumping and lasing configurations are very different for these two groups. Nevertheless, the same simple basic gain equation applies to all of them. In what follows, the subscripts 0, 1, and T refer to the corresponding levels in Fig. 1(a), and the subscript l on a cross section indicates its value at the lasing wavelength, while the subscript p refers to the pump and its wavelength. The differential gain for a forward-traveling laser beam I_l^+ is

$$g = \frac{1}{I_l^+}\frac{dI_l^+}{dz} = \sigma_e N_1 - \sigma_T N_T - \sigma_{al} N_0, \qquad (3)$$

where N_i are population densities (in cm^{-3}). The total dye molecular density is $N = N_0 + N_1 + N_T$. Figure 3 shows the gain vs wavelength for R6G, assuming $N = 3 \times 10^{17}$ cm^{-3}, and various fractions in the three different levels. The most important point to observe is that, because of the displacement of the singlet absorption and emission spectra (Franck-Condon shift), gain exists in a broad spectral region even when the population of the first excited singlet state is much smaller than that of the ground state. The characteristic sharp dropoff of the gain (to loss) on the short-wavelength side is due to the singlet absorption, which partially overlaps the emission spectrum. In some dyes this gain cutoff may be considerably less sharp than seen in this example, in consequence of a larger Franck-Condon shift and a more gradual decrease of the emission. The second important characteristic of these curves is that, because the triplet absorption overlaps the singlet emission, the gain depends very strongly on the population of the lowest triplet state. The gain is drastically reduced and lasing will be prevented if the triplet state population is of the same order as that of the excited singlet. Unfortunately, the lowest triplet state is metastable, i.e., its decay rate τ_T is slow, and with time the triplet-state population tends to accumulate. In the descriptions of the various types of dye lasers, it is shown how this triplet absorption problem is partially solved.

The design and operation of all dye lasers can be best understood by studying the dynamics of the gain through standard rate

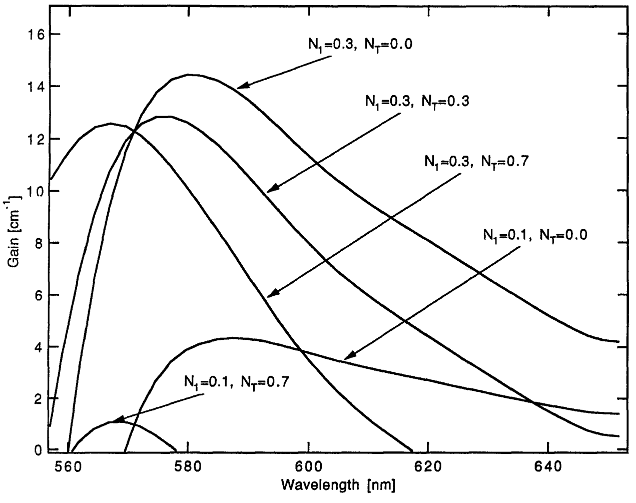

FIG. 3. Differential gain vs wavelength for the dye R6G, with various fractions of the total population in the excited singlet and in the triplet states.

equations for the population densities N_i. The two basic geometrical configurations used are collinear (or nearly collinear) pumping and transverse pumping, corresponding to the pump light being nearly in line with or perpendicular to the laser beam in the cavity, respectively. For either of these configurations, at some arbitrary point inside the laser medium (within the cavity) the population-rate equations may be written as

$$\frac{dN_1}{dt} = N_0\sigma_{ap}I_p - \frac{N_1}{\tau_1} - N_1\sigma_e I_l + N_0\sigma_{al}I_l, \quad (4)$$

$$\frac{dN_T}{dt} = k_{ST}N_1 - \frac{N_T}{\tau_T}. \quad (5)$$

Here, I_l is the *total* laser photon intensity (in a linear cavity, $I_l = I_l^+ + I_l^-$, two opposite traveling waves, while $I_l = I_l^+$ in a unidirectional ring cavity), and I_p is the pump photon intensity, each defined according to their respective directions of propagation in the dye medium. The dye-laser photon density also obeys time-dependent rate equations. However, for many dye lasers the cavity decay rate is considerably shorter than the pulse duration and the buildup time of the oscillations can be neglected. In any case, the main characteristics of most dye lasers can be understood without considering cavity dynamics. (An exception is discussed briefly in Sec. 3.2). Equation (4) is valid for laser pumping, but it is also approximately correct for a broad-band pump source (such as a flashlamp), provided that the absorption cross section used is a weighted average over the bandwidth of the pump light. Exact analytical solutions of Eqs. (3)–(5) are only possible for cw dye lasers, which are axially pumped. However, much can be learned for all dye lasers from examination of these rate equations. For the case of cw or long-pulse pumping, the solution of Eq. (5) is

$$N_T = k_{ST}\tau_T N_1, \quad (6)$$

which when substituted into (3) gives

$$g = \sigma_e f_T N_1 - \sigma_{al}N_0, \quad (7a)$$

where

$$f_T = 1 - k_{ST}\tau_T\sigma_T/\sigma_e. \quad (7b)$$

Even for wavelengths for which σ_{al} is zero, cw lasing is prevented if $f_T < 0$. The only remedy is triplet quenching, i.e., decreasing the triplet population by whatever means possible. Since it is very difficult to reduce the intersystem rate (k_{ST}), to minimize N_T the lifetime of the triplet (τ_T) must be decreased. Molecular oxygen, O_2, is a well-known triplet quencher. However, O_2 tends also to increase k_{ST}, and its concentration needs to be optimized. It has been found that for several good laser dyes, including R6G, atmospheric air has a nearly optimum O_2 concentration. Another method of triplet quenching is by the addition of certain organic additives to the dye solution. By contrast, it has also been shown that lasing is completely prevented if the dye solution is deoxygenated by bubbling pure nitrogen through it: τ_T increased to the order of milliseconds, resulting in a negative value of f_T for all wavelengths. For the case of pulsed dye lasers, accumulation of molecules in the triplet state depends on the pump pulse duration. For pump pulses of the order of or somewhat longer than the characteristic lifetimes ($1/k_{ST}$ and τ_T), the triplet population builds up in time, and therefore the factor f_T becomes a time-dependent quantity. Obviously, its value is always smaller than the cw steady-state value given by Eq. (7b). In other words, another solution for the triplet problem is to pump with short pulses. Pumping with light pulses of duration $\Delta\tau_p \ll 1/k_{ST}$ prevents significant accumulation in the triplet state. Another important point that can be learned from the above rate equations is that dye lasers require high pump intensities. From (4), just below threshold (i.e., no lasing), at wavelengths where singlet absorption is negligible, for the cw (or quasi cw) case,

$$N_1 = N_0 I_p \sigma_{ap}\tau_1. \quad (8)$$

At the other extreme, for very short pump pulses, the maximum value of N_1 is still given by (8), but with τ_1 replaced by $\Delta\tau_p$. In either case, as a result of the short lifetime of the lasing level, the required pump intensity is high. For example, to maintain $N_1/N_0 = 0.1$ in a R6G dye solution, pumping at $\lambda = 514$ nm requires $I_p = 1.8 \times 10^{23}$ photons s^{-1} cm^{-2}, or 6.9×10^4 W/cm^2.

A laser oscillator is made by placing the gain medium in a resonant cavity and coupling out some of the circulating coherent oscillation through one of the mirrors. The coupled-out fraction acts as a loss and, together with other losses inside the cavity, determines the cavity Q factor. The spectral characteristics of the output are determined by the properties both of the gain medium and of the cavity. A laser cavity has a large number of resonant frequencies that are separated by $\Delta f = c/2L$, where $2L$ is the total effective round-trip distance in the cavity. There are typically of the order of 10^6 or more resonant modes within the gain bandwidth. An important issue for any type of dye laser is control and tuning of the frequency of the laser oscillation. This is examined in separate sections for cw and pulsed lasers.

2. cw DYE LASERS

Probably the most important and most widely used dye lasers today are cw dye lasers. Although they require expensive high-power cw sources for pumping, and although their configuration can be very complicated, no other optical sources provide a comparable combination of tunability, resolution, and power. They cover a spectral range from ~365 to ~1000 nm, with more than 100 mW of power output possible through this range (more in the yellow–red region). This is adequate for most spectroscopic and other research applications. The available resolution, while not easy to obtain, is also very impressive. A true single-mode cw dye laser has a line width of ~0.5–1 MHz. A typical tuning range of $\sim 0.5 \times 10^{14}$ Hz available from a *single* dye thus can contain up to $\sim 10^8$ spectral resolution elements (linewidths), and a multiple-dye cw laser tuning range can contain more than ten times that. By use of standard frequency doubling and mixing techniques in nonlinear crystals, the tuning range has been extended down to 260 nm. Additionally, the broad gain bandwidth of a single dye makes possible ultrashort pulse generation by mode locking (see ULTRASHORT PULSE PHENOMENA), resulting in the shortest optical pulses available today (Fork *et al.*, 1987).

The high pump intensity required to achieve lasing necessitates tight focusing of the pump light into a very small active volume that in turn dictates a special cavity design and a flowing-dye cell. Although they may appear quite different, the physical configurations of nearly all the cw dye lasers used today are derived from the same basic folded-cavity design (Kohn *et al.*, 1971; Dienes *et al.*, 1972). Two commonly used versions, a three-mirror standing-wave cavity and a ring laser, are shown in Figs. 4 and 5. Both configurations include various frequency-tuning and bandwidth-control elements, which are discussed in Sec. 2.2.5. There are good reasons for the folded-cavity design. A brief simplified theoretical description greatly aids in the understanding of the basic operating principles and of the issues important for the design and operation of this device. With minor modifications, this simple theory can also be used to describe semiquantitatively the operation of most flashlamp pumped dye lasers (Sec. 3).

2.1 Theory

In what follows, it is assumed that the dye is pumped by a cw laser beam that is collinear with the lasing radiation as shown in a simplified schematic in Fig. 6. Since the transitions are homogeneous, the laser radiation can be considered to be monochromatic at some arbitrary wavelength within the emission band. It is assumed here that the pump and laser beams are plane waves

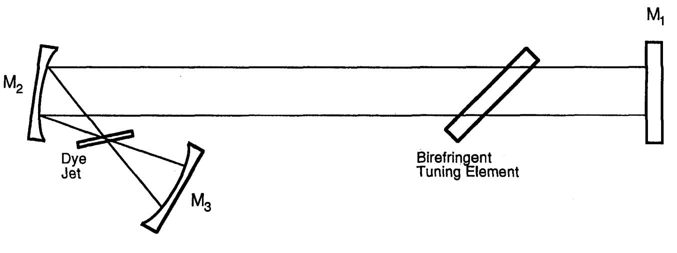

FIG. 4. A standing-wave–type folded three-mirror cavity for cw dye lasers. The various elements and their functions are described in the text.

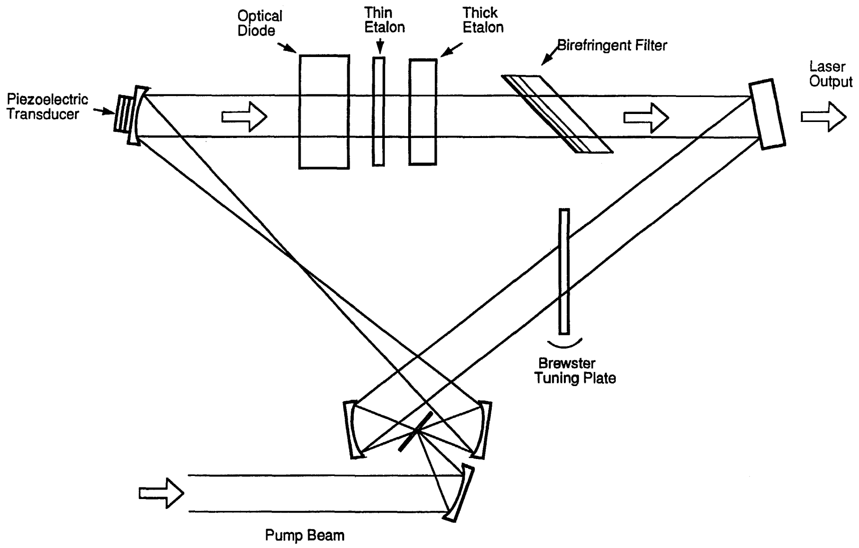

FIG. 5. A unidirectional traveling-wave ring cavity for cw dye laser, showing several frequency-control elements, which are described in the text.

with finite and equal areas. Thus in the rate equations (3)–(5) all the intensities and population densities are functions only of the longitudinal variable (z) in the medium. Solving (4) and (5) in the steady state, integrating over the length of the path (L) in the dye medium, and using the approximation that the total laser intensity I_l is constant with z, one obtains the total single-pass saturated gain $G = I_l^+(z = L)/I_l^+(z = 0)$,

$$\ln G = \sigma_e f_T \tau_1 \frac{1}{1 + I_l/I_s} I_{p0} a. \tag{9}$$

Here $I_s = 1/\sigma_e \tau_1$; the parameter a is the fraction of the pump beam absorbed in the dye cell, $I_{p0} = P_{p0}/A$, where P_{p0} is the input pump power and A is the cross-sectional area of the pump beam in the dye. Since the cavity Q is high, the required gain is small. Thus, N_1 is a small fraction of the total population, and therefore N_0 can be approximated as constant and equal to N. Then,

$$a = 1 - \exp(-\sigma_{ap} N L). \tag{10}$$

Equation (9) shows that the shorter the lifetime, the more pump intensity is required. The dye concentration (N), the pump absorption coefficient (σ_{ap}), and the cell thickness (L) only enter through the parameter a. In cw dye lasers, these quantities are adjusted so as to give $a \cong 0.9$ in a cell length that is determined by other factors, as is seen later.

Threshold is reached when the small-signal ($I_l \to 0$) gain equals the cavity loss. The gain is inversely proportional to the cross-sectional area of the excitation. Using parameters for R6G and $a = 0.9$, for a typical 15% round-trip gain ($G_0 = \sqrt{1.15} = 1.072$) at $\lambda_1 = 600$ nm, one finds a required pump intensity $I_p = 0.87 \times 10^5$ W/cm^2 at $\lambda_p = 514.5$ nm. This requirement dictates tight focusing of the pump beam and restricts possible pump sources. High gains cannot

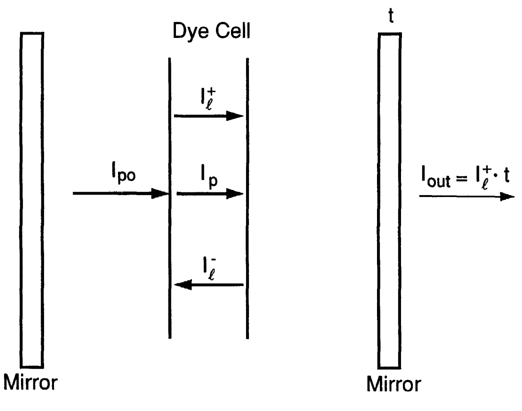

FIG. 6. Simplified schematic of the pumping and lasing geometry for the cw dye-laser theory.

be achieved, and thus the typical coupling loss is in the range of 5–20%. The first pump sources used, and still widely used, are cw ion lasers, argon and krypton. (Another, recently developed pump source is discussed in Sec. 2.2.4.) For a circular beam waist of radius ~20 μm, the above threshold corresponds to a pump power $P_p = 280$ mW. Since the confocal length corresponding to such a beam waist is ~1 mm, the dye cell must be shorter than that. Although early research used cells made of fused silica or glass, today practical cells are flowing dye jets with typical thickness of around 100–200 μm. For the above example, the dye molecular density N for 90% absorption in a 150-μm-thick cell is $1 \times 10^{18}/\text{cm}^3$, a concentration of 1.6×10^{-3} mol/L. At this concentration, increased nonradiative quenching begins to reduce both τ_1 and σ_e somewhat. Additional problems, such as solubility and aggregation of the dye molecules, also pose problems, requiring corrective measures in the form of special additives, such as surfactants to help disperse the molecules.

When pumping is done above threshold, the dye laser intensity builds up inside the cavity. The steady-state population N_1 is decreased by the stimulated emissions so that the gain saturates to the cavity loss (i.e., to the threshold gain). The population of the ground state (N_0) is thus clamped at its threshold value, and regardless of how strong the pumping is, the absorption of the pump does not decrease by depletion of the ground state but remains the *same* value as at threshold (Teschke *et al.*, 1976a; Chan, 1979). The output intensity is obtained by equating the round-trip gain to the round-trip loss and using $I_{\text{out}} = tI_l^+ \approx tI_l/2$ (where t is the transmission of the output mirror). The result, for the main part of the gain region where $\sigma_{al} = 0$, is

$$P_{\text{out}} = \eta[P_{p0} - P_{\text{th}}], \tag{11}$$

where the slope efficiency and threshold power are

$$\eta = \frac{\nu_l}{\nu_p} f_T a \frac{t}{t + l}, \tag{12a}$$

$$P_{\text{th}} = Ah\nu_p \frac{t + l}{af_T\sigma_e\tau_1}. \tag{12b}$$

Here, $1 - t - l = 1/G_0$ is the total round-trip cavity loss (l being the fractional residual loss other than the coupling-out loss). Typically, $t + l$ in actual systems is less than ~0.1. This equation shows a simple linear dependence of the output power on the pump. The threshold pump power depends linearly on the cavity losses and on the area, and inversely on the fraction of the pump power absorbed by the dye (a), on the emission cross section, and on the triplet loss factor (f_T). The slope efficiency, on the other hand, only depends on a, f_T, and the cavity losses, and of course on the energy ratio of the pump and laser photons.

This theory can be made more rigorous by including the effects of the singlet absorption losses (which are nonzero at the short-wavelength end of the emission band) and by considering the pump and laser beams to be fundamental Gaussian beams of generally different radii. Following the methods of Pike (1971) and others (Chan, 1979), it can be shown that Eq. (11) remains valid with

$$\eta = \frac{m}{\sqrt{1 + m^2}} \frac{\nu_l}{\nu_p} f_T a \frac{t}{t + l + 2s(1 - f_T)}, \tag{13a}$$

$$P_{\text{th}} = \frac{m + 1}{2} \pi w_p^2 h\nu_p \frac{t + l + 2s}{af_T\sigma_e\tau_1}. \tag{13b}$$

Here, s is the singlet absorption loss given by $s = -\ln(1 - a)[\sigma_{al}/\sigma_{ap}]$, w_p is the pump-beam radius, and $m = w_l^2/w_p^2$, the ratio of the areas. Singlet absorption adds to the losses in the cavity; the threshold pump power rapidly increases where σ_{al} is significant and lasing cuts off. As for the effects of unequal Gaussian pump and lasing beam sizes, we see that decreasing the pump-beam area relative to the lasing area increases the threshold but also increases the slope efficiency. For strongly pumped lasers a value of m between 1.5 and 2 is best, i.e., pump-beam area slightly smaller than the dye-laser-beam area. For the R6G example, pumped by the 514.5-nm Ar laser line, with $t = 0.057$, $l = 0.02$, $w_p = 20$ μm, and $m = 1.5$, at $\lambda_1 = 590$ nm we have $P_{\text{th}} = 1.3$ W and $\eta = 0.36$. Experimentally, similar values were achieved early in the history of the cw dye laser (Dienes *et al.*, 1972). A multiple-wavelength pump laser is often used in practice, since this gives more available pump power. This does not substantially alter the above theory. Although this theory was derived for a linear cavity, it is also valid for ring dye lasers, provided that the factor of 2 multiplying the singlet loss s is omitted (since the laser beam traverses the dye only once).

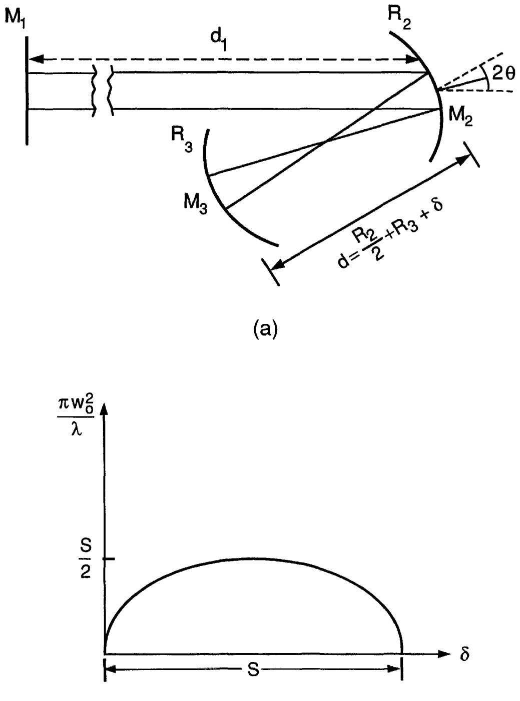
2.2 Practical cw Dye Lasers

The above theory gives a good description of cw dye lasers. In actual lasers there are some additional effects, which result in somewhat lower efficiencies than predicted by this theory. They are discussed briefly in Sec. 2.2.4. In practice, the parameters of most dyes are not known with sufficient accuracy to apply the theory quantitatively, and design procedures are usually carried out in a trial-and-error fashion (Yarborough, 1974; Johnston *et al.*, 1982). In this article the theory is used for a kind of "reverse engineering," through which the principles underlying the design and operation of currently used systems are explained. There are three types of cw dye lasers in general use today:

1. linear-cavity, moderately wide-bandwidth laser;
2. narrow-linewidth unidirectional ring laser (with single-mode operation possible); and
3. colliding-pulse mode-locked dye laser.

The design of these systems is now examined, beginning with consideration of the laser resonator.

2.2.1 The Laser Resonator The required very small mode area can be achieved by using a small cavity with concentric radii of curvature (R_i). This is how the first cw dye laser was made (Peterson *et al.*, 1970). However, for practical lasers a longer resonator (Kohn *et al.*, 1971; Dienes *et al.*, 1972) is desirable, with a well-collimated beam that either allows placement of elements for frequency tuning and control or allows an additional focal spot for passive mode locking (Ippen *et al.*, 1972) etc. The folded cavities shown in Figs. 4 and 5 fulfill these requirements. The three types of cw dye lasers listed above all use these, or variants of such cavities. The critical properties of this type of cavity can be understood by simple ray tracing in a three-mirror cavity as shown in Fig. 7(a). The parallel rays from mirror M_1 are focused to the focal point of mirror M_2. This is where the dye cell is placed (at Brewster's angle to minimize the internal losses). If this point is also the center of curvature of mirror M_3, then the diverging rays are returned upon themselves. Thus, for $R_3 = R_2/2 = f$, the folded arm has total length $d = R_2/2 + R_3 + \delta \cong R_2$, where δ is a small adjustment parameter of the order of a few microns. The cell is located in the middle of this folded arm. The length of the long arm d_1 is not critical but should be much longer than d, and $R_1 = \infty$ (flat mirror) or a large value. For a ring cavity R_2 and R_3 must be made equal when the cell is located in the middle (see Fig. 5) as is also obvious from ray tracing. Additional folded focusing arms



(a)

(b)

FIG. 7. (a) Simplified schematic of the three-mirror folded cavity showing mirror distances, and geometrical-optics ray tracing for the laser beam in the focusing fold and in the long collimation arm. (b) Minimum beam radius w_0 (in units of the confocal distance) vs the adjustment distance δ for the three-mirror laser cavity shown in (a).

can also be easily added (Ippen *et al.*, 1972) if needed. To find the actual mode parameters and the stability range of the resonator, standard Gaussian beam analysis is used (Kogelnik, 1966; Kogelnik and Li, 1966). The main results for the basic three-mirror version are given below.

The Gaussian "waist" size vs the position of the mirror M_3 (δ) is shown in Fig. 7(b). The stability range is $S = f^2/d_1$, and in the middle of this range the beam waist area is given by $\pi w_0^2/\lambda = S/2 = f^2/2d_1$. For example, letting $R_1 = \infty$, $R_2 = 10$ cm ($f = 5$ cm), $R_3 = 5$ cm, and $d_1 = 100$ cm yields $w_0 = 15$ μm, which is a typical value needed for lasing. In contrast, the beam in the long arm has a minimum beam radius of $w_0 \sim 0.6$ mm (on the flat mirror), a well-collimated beam. The above calculated beam waist radii are in free space. Inside the dye cell, after refraction into the Brewster-angle cell, the beam becomes elliptical and the area πw_p^2 is larger by a factor n (index of refraction of the cell). Increasing R_2 increases the waist area and will increase the threshold pump power since the pump beam must approximately overlap this waist. Consequently, on account of threshold requirements, R_2 cannot be much larger than 10 cm. On the other hand, practical geometrical considerations, as well as beam aberrations (coma and astigmatism), restrict R_2 to values larger than ~5 cm. All practical cw dye lasers use R_2 (and R_3) between 5 and 10 cm in the folded arm around the dye cell. Exact collinearity of the pump and laser beams is not essential since the very thin dye cell allows excellent overlap even with a substantial angle between the two beams. Independent focusing with a lens or a mirror is most commonly used, with the focal length about the same as or slightly smaller than that of the folding mirror, as shown in Fig. 4.

An additional feature of the folded, tightly focused cavity is that the tilting of the folding mirror introduces an astigmatism between the tangential (in the plane of the diagram) and sagittal (perpendicular) planes, due to the different effective focal lengths of the folding mirror M_3 in these two planes (Kogelnik *et al.*, 1972). This may greatly reduce the stability of the resonator by displacing the stability regions of the two planes with respect to each other, and it also results in elliptical-shaped beams. Interestingly, the Brewster-angle cell in the focal region also causes an astigmatism due to the different effective cell lengths in the two planes. These two astigmatisms are of opposite signs, allowing compensation by adjusting the cell thickness or the folding angle. Detailed analysis has been given in the literature (Kogelnik *et al.*, 1972). Because all practical cw dye lasers use thin free-flowing dye cells, full compensation is not feasible (e.g., for $L = 150$ μm and $R = 10$ cm, the theory shows that $2\theta = 4.5^0$ is needed). Thus, current systems either have some residual astigmatism or use added compensation such as an extra Brewster plate near the dye cell or inside an additional fold (Johnston *et al.*, 1982). Astigmatism may also be present in the pump beam if a tilted focusing mirror is used instead of a lens. For all of the above reasons, in an actual dye laser the beam areas and the parameter m are only approximately known.

2.2.2 The Flowing-Dye Cell and Triplet Quenching Continuous-wave operation of the laser causes continuous power dissipation. Much of this takes place in the active dye volume through internal nonradiative processes, resulting in watts of heat dissipated in the active volume of $\sim 1 \times 10^{-7}$ cm^3. To carry this heat away, a flowing-dye cell is needed, together with a small heat exchanger in the flow system. Although early designs used cells with glass windows (Kohn *et al.*, 1971; Dienes *et al.*, 1972), all modern systems use free-flowing dye jets (Runge and Rosenberg, 1972; Shank *et al.*, 1973) whose advantages of simplicity, high-speed flow, and long lifetime outweigh the disadvantage of some low-frequency noise introduced by the physical motions and local ripples of the jet. A jet nozzle simply consists of a flattened stainless steel tubing. Since the nozzle opening is very narrow, filtration of the flowing dye is needed in order to avoid clogging. Ethylene glycol has a high enough viscosity to produce a smooth-surfaced ribbon and is usually used as the solvent, sometimes mixed with water or other organic solvents and certain additives (to improve solubility and reduce aggregation). Using a centrifugal pump to produce a pressure of ~241 kN/m^2 (35 psi), an approximately rectangular ribbon of ~3-mm width and ~100–200-μm thickness is typically produced with a flow speed of up to

10 m/s. Even at this high flow speed, at high pump-laser powers beam-profile distortions (thermal blooming) (Teschke *et al.*, 1976b; Johnston *et al.*, 1982) will occur, limiting both the beam quality and the dye-laser efficiency. The dye concentration is adjusted to give around 90% absorption of the pump. For multiple-line pumping, some pump wavelengths may be weakly absorbed, and the net pump absorption may be somewhat lower.

The high-speed flow and circulation of the dye partially solve one of the other important requirements for cw lasing: quenching (i.e., shortening) the lifetime of the metastable T_1 state (Shank *et al.*, 1973; Yarborough, 1974; Schäfer, 1990). This is accomplished mostly by the aeration of the solution in the flow–circulation system but also by actually moving the molecules in the T_1 state out of the active volume. The combination of these two effects shortens the effective triplet lifetime and gives a triplet loss factor f_T sufficiently close to unity for cw operation in some dyes. In spite of this, the triplet absorption remains a limiting effect, and only certain dyes can be cw lased. The additive cyclo-octatraene (COT) can further decrease the triplet lifetime and improve laser efficiency (Yarborough, 1974; Johnston *et al.*, 1982). However, since this chemical is unstable and smells bad, its use is avoided whenever possible. For R6G, with aeration but without using COT, typically $k_{ST}\tau_T = 0.9$. This results in an f_T that is positive over a large range, decreasing from a value of 0.65 at 560 nm to zero at 650 nm.

2.2.3 Mirror Transmission The output mirror transmission (t) must be carefully designed for optimum lasing efficiency for each laser dye. For a given pump power there is an optimum value of transmission (t_{opt}) at each wavelength. This is found from Eqs. (11) and (13) as

$$t_{\text{opt}} = \sqrt{[l + s(1 - f_T)][g_0 - sf_T]} - [l + s(1 - f_T)], \tag{14}$$

where $g_0 = \ln G_0$ is the small-signal gain. For $\sigma_{al} = 0$, this reduces to $t_{\text{opt}} = \sqrt{lg_0} - l$, in agreement with the well-known general theory of homogeneously broadened lasers (Rigrod, 1963) and with experiments (Shank *et al.*, 1973). In practice, while a certain amount of tailoring of the mirror transmission is possible, compromises must be made. In Fig. 8 the calculated power output of a R6G dye laser vs wavelength is shown, with a mirror transmission that is constant at 5.7% and with mirror transmission optimized at each wavelength, together with the t_{opt} used. With the optimized mirror, improved output is seen on the long-wavelength side. The transmission is largest at 580 nm where the linear gain is the largest and decreases at both shorter and longer wavelengths. However, on the short-wavelength

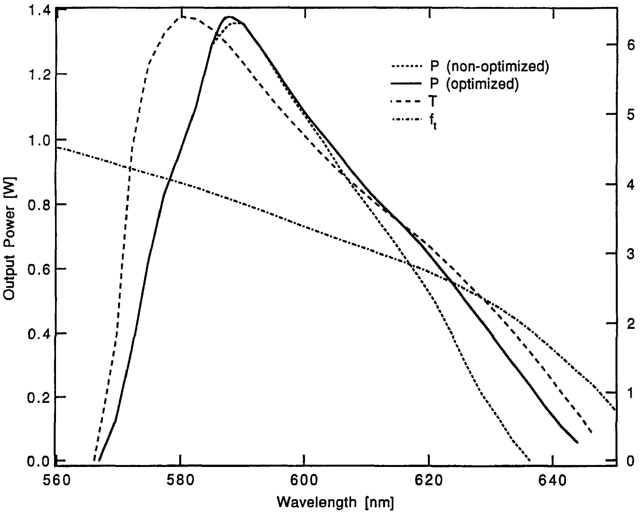


FIG. 8. Power (in watts) vs wavelength calculated for a R6G cw dye laser in a linear cavity, using the data shown in Fig. 2. The triplet reduction factor f_T (unitless) is also shown. Additional parameters: pump-beam area = 1.25×10^{-5} cm^2 (w_p = 20 μm), pump to laser beam area ratio μ = 1.5, residual loss l = 2%. The output mirror transmission t is optimized at each wavelength for one output power curve and is constant for the other. The optimized mirror transmittance vs wavelength is also shown (in %, scale on right).

side the absorption dominates the total loss, and optimizing the mirror transmission does not result in improvement. The important point for output mirror design is to optimize the transmission *on the long-wavelength side* of the peak gain. In these calculations the function f_T was calculated using $k_{ST}\tau_T = 0.9$, and is also shown on the graph. According to the theory given above, at any wavelength the output is a linear function of the input power. In reality, however, this is only true up to some value of pump intensity where thermal effects begin to be significant.

2.2.4 Performance Limitations There are factors that limit the performance of cw dye lasers but were not included in the simple theory.

1. As already mentioned, at high pumping powers, a thermal lens is created in the pumped region. As discussed in the literature (Johnston and Sasnett, 1992), this lens is astigmatic as a result of the flow and cannot be compensated. For relatively low-power systems this problem is not serious and results in only minor degradation of performance. For high powers, however, the thermal defocusing lens also becomes highly irregular and unstable, resulting in severe deterioration of the lasing beam. The laser must always be operated below this limit. For example, typically under normal laboratory conditions, 1–2 W of output can be obtained from R6G. The record powers reported in the literature can only be obtained with special solvent mixtures and additives (Johnston *et al.*, 1982) and are not easily accomplished.
2. Aggregation of the dye molecules occurs for many dyes at the concentrations needed to absorb a high fraction of the pump in the thin dye jet. This problem can be partially solved by the addition of a small amount of a surfactant such as Ammonyx LO (Peterson *et al.*, 1970; Johnston *et al.*, 1982), which, however, introduces some problems such as foaming.
3. Residual aberrations (astigmatism and coma) in both the pump and laser beams increase the effective areas and reduce the beam overlap, thus increasing threshold and decreasing slope efficiency. These effects also prevent the use of focusing mirrors (for both pump and cavity) with $R < 5$ cm.
4. Transverse modes may be partially present in the pump and may also appear in the dye laser beam.

On account of the combination of the above effects, actual threshold powers and slope efficiencies are somewhat lower than calculated by the theory, although with careful optimization nearly ideal performance *can* be approached.

2.2.5 Dyes and Pump Sources Only a small number of all the dyes that have been made to lase are suitable for cw operation. Both the UV and the IR ranges are limited by the availability of pump sources. Infrared-emitting dyes suffer from instability problems, whereas the blue- and UV-emitting dyes have much smaller emission cross sections [note the λ^4 dependence in Eq. (1)] and also tend to have large triplet absorption together with difficulty of quenching the triplet population. In the previous sections the R6G dye laser was used as an example, since the parameters of this dye are quite well known. This was the first cw dye laser and is still one of the best. Pumped with a powerful 24-W multiple-line argon laser, and with special solvent mix to alleviate thermal problems, a record high multimode power output of 6.5 W and single-mode power of 5.6 W has been obtained (Johnston *et al.*, 1982). Today, many cw laser dyes are available from the near UV to the near IR, and the performance of the best ones approaches, and in some respect surpasses, that of R6G. A comprehensive listing of dyes is not given here, but the tuning range of some of the best performers with their common abbreviations are shown in Fig. 9. These dyes, made especially for laser applications, are commercially available from various chemical companies. The overlapping lasing ranges cover the wavelength range from ~360 to ~1000 nm. Optimized systems using these dyes have been reported (Yarborough, 1974; Jarret and Young, 1979; Johnston *et al.*, 1982; Johnston, 1988). The output power depends on the power of the pump source, as well as on many details of the specific design. In Fig. 9, the pump source and specific line (or group of lines) needed is indicated for each dye. The commonly available pump lasers and their useful strong lines are listed in

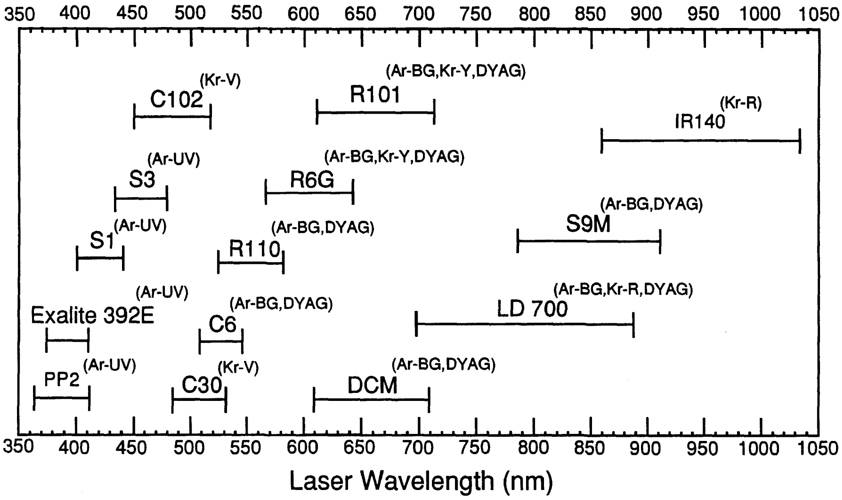

FIG. 9. The tuning ranges of some of the best cw laser dyes. For each dye the possible pump laser and pumping lines are also shown with the codes from Table 1. (C = coumarine, R = rhodamine; other abbreviations for the dye names are the standard ones used by the commercial catalogs).

Table 1. The obvious requirement is that the absorption band must overlap with one or more of these lines. A regular Ar^+ laser has the two familiar strong blue and green lines. For blue- and ultraviolet-emitting dye lasers, an UV-capable argon-ion laser is needed (which can also provide the blue-green lines with a change of mirrors). The longest-wavelength dyes can only be pumped with the red lines of the krypton laser. This laser also has a group of violet lines useful for pumping some blue-green laser dyes, and yellow-green lines of reasonable power that can be used as the excitation source for some red-lasing dyes. Thus, while a single ion laser obviously is not capable of pumping the entire range of laser dyes, a large fraction can be covered. Recent developments in all-solid-state laser sources made available a useful and practical new pump source: the diode-laser–pumped Nd:vanadate ($Nd{:}YVO_4$) laser whose output is efficiently doubled in a nonlinear crystal to provide several watts of power at $\lambda = 0.532$ μm wavelength. This system is an excellent pump source for several dyes emitting in the range 550–800 nm. Its biggest advantage is that it has much smaller electrical power and cooling requirements than ion lasers. It also has less random noise and superior beam characteristics.

Table 1. Lasers and laser lines for pumping cw dye lasers.

Laser type	Wavelength of line	Notes	Code for Fig. 11
Argon or UV-capable argon	476.5		
	488.0	a	
	496.5		Ar-BG
	501.7		
	514.5	a	
UV-capable argon	300.3–335.8	b	
	333.6–363.8		Ar-UV
	363.8–385.8	b	
Krypton	647.1–799.3	c	Kr-R
	520.8–568.2	c	Kr-Y
	337.5–422.6	c	Kr-V
Doubled $Nd{:}YVO_4$	532		DY

[a] These two lines are much stronger than the others and contribute most of the pump power.

[b] These groups of lines can be obtained only at very high tube current (e.g., 65 A in a Coherent Innova Model 100UVE). Change of mirrors is also needed.

[c] Change of mirrors is needed for each of these groups of lines.

Dye lasers between 530 and 930 nm provide the highest output powers, and they are the easiest to design, set up, and operate. This is due in part to the high emission cross section and low triplet absorption of these dyes (high σ_e, and f_T close to unity) and also to the use of the two blue-green (480 and 514.5 nm), high-power argon-ion laser lines as pump. An example is given in Fig. 10. The

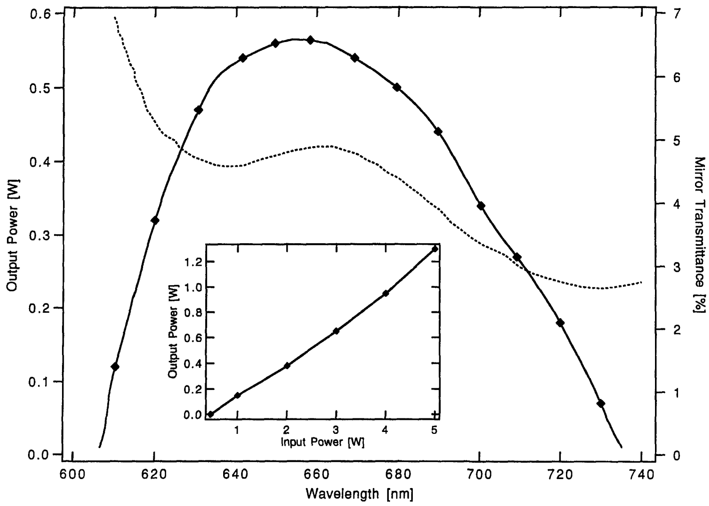

FIG. 10. Experimentally measured output power (solid line) and output mirror transmittance (dotted line) vs wavelength for the dye DCM in a ring cavity. The mirror transmission is approximately optimized. Inset: Input vs output power at the peak output wavelength. Data provided by T. Johnston, Coherent Inc.

output power and approximately optimized mirror transmission vs wavelength, as well as output vs input power at the peak emission wavelength, are shown. The dye is DCM, lasing in a single longitudinal mode, ring configuration (Johnston, 1988), similar to the one shown schematically in Fig. 5. The behavior is similar to that described earlier by the theory. The threshold pump power of 400 mW at the peak lasing wavelength is smaller than that calculated for the R6G example. This indicates a higher effective emission cross section, or a longer singlet lifetime, or a combination of both of these effects. The peak-wavelength slope efficiency is 0.78 times the value calculated for R6G. Some of this difference is due to the 1.1 times longer wavelength of the DCM emission and some to the smaller output-mirror transmission. The output-mirror transmission increases toward the peak on the long-wavelength side, as required by the theory, but unlike the calculated optimum mirror, the transmission continues to increase on the short-wavelength side because of design practicalities. This departure from the theoretical optimum makes no practical difference, as was noted in Sec. 2.2.3.

The blue- and UV-emitting dyes have lower values of the effective emission cross section ($f_T\sigma_e$), and the available pump power in the UV is also much less. As an example, the results reported for the shortest-wavelength dye PP2 (Johnston, 1988) are examined briefly. This dye was pumped with a large Ar^+ laser (Coherent Innova 100 UVE) operated at a high discharge current of 65 A. A total of 3.4 W was obtained in 6 UV lines, 300.3–335.8 nm, and was focused with a mirror to $w_p \sim 25$ μm in the dye jet, where 84% of this pump power was absorbed. The ring cavity had a folding-mirror radius R = 7.5 cm. With an output mirror transmission of 1.9%, the lasing range was 364–408 nm with a maximum output of 255 mW at 383 nm. At this wavelength the slope efficiency was ~11% and can be semiquantitatively explained by the theory as follows. The given values of $a = 0.84$, $t = 0.019$, and estimated values of $m = 1.5$, $\nu_l/\nu_p = 0.84$, $l = 0.025$, $s = 0$ give a slope efficiency of 11% if the value of the triplet factor $f_T = 0.44$, which is within the known range for blue-emitting dyes.

2.2.6 Bandwidth Control and Tuning

One of the most important characteristics of dye lasers is their very wide gain bandwidth. To utilize this large bandwidth properly, one must be able to tune the wavelength of oscillations and also to control the bandwidth of the output. For many applications, a bandwidth of ≈0.5 nm (≈500 GHz), or even larger, is quite sufficient, while some spectroscopic experiments require a bandwidth as low as ~1 MHz. To achieve this bandwidth, oscillation must be restricted to a single cavity mode (since cavity-mode spacing is typically ~150 MHz). Frequency stabilization may also be required. In this article we discuss tuning and bandwidth, but not frequency stabilization.

Dyes are spectrally homogeneous, which means that all the lasing frequencies compete for the same excited singlet population, i.e., for the same gain. This would imply, according to well-known fundamental laser theories, that the strongest lasing mode suppresses the others, and single-mode operation results. However, in practice this is not the case. Without any wavelength control, a standing-wave (linear cavity) cw dye laser operates at the peak of the gain with a bandwidth that is typically as broad as ~1–2 nm (1–2 THz). This is due to an effect known as spatial hole burning. For each of the cavity resonance modes, the two oppositely traveling beams form a standing-wave pattern inside the cavity, with the adjacent patterns having numbers of nodes differing by one. As a result, the different laser modes do not interact with the same molecules but saturate (or "burn down") different spatial locations. Mode competition is thus greatly diminished, and many laser modes oscillate. Another way to describe this effect is that oscillation at one mode is able to extract the available energy only at the antinodes, and the laser will oscillate in so many modes that an overall uniform intensity is established with maximum energy extraction. This assumption was built into the theory, since standing-wave patterns of the laser intensity were ignored. It is possible to force a linear-cavity cw dye laser into single-mode operation by placing a hierarchy of ever narrower-bandwidth filters inside the cavity. However, the output power of the laser is considerably diminished because only about half of the actual inverted medium is utilized. In practice, the single-mode output of such a laser is typically about 40% of that obtained in broad-band operation (Johnston *et al.*, 1982). This problem can be overcome by using a ring configuration (Jarret and Young, 1979; Johnston *et al.*, 1982) and forcing the laser radiation to travel unidirectionally. In such a laser the resonant modes are pure traveling waves, all modes compete for the same populations, and single-mode operation results. An element commonly called an optical diode is used to force a ring dye laser into unidirectional operation. This element is lossless for a laser beam propagating in one direction but provides a loss in the other direction. A differential loss of about 0.5% is achieved by rotating the polarization of the laser beam a few degrees for one direction of travel only. For this beam, a small loss is experienced at the various Brewster-angle surfaces of the other cavity elements that follow the "diode." Polarization rotation for only one direction of propagation is accomplished by a series combination of two well-known elements: a birefringent quartz half-wave plate rotator and a Faraday-effect rotator. The rotations due to the above two elements cancel for one direction of propagation and add for the other. Details of the design of an optical diode can be found in the literature (Johnston and Proffit, 1980). On account of mechanical instabilities, the output of a ring-type laser will still be broad band because the frequency of lasing will rapidly change among many modes. But it is possible to narrow this bandwidth by the addition of tunable-frequency selective filters to a much narrower bandwidth and even to a single mode without significant loss of output. The selectivity of these elements inside the dye-laser cavity is much stronger than would be in normal extracavity use because the spectrally homogeneous dye laser is very sensitive to small variations of the net gain (Klein *et al.*, 1973). A net gain reduction as low as 0.5–1% on a propagation direction or on a group of modes is sufficient to suppress the lasing.

One of the most obvious frequency-selective element is a diffraction grating. But its insertion loss is far too high to be used inside a cw dye-laser cavity. Diffraction gratings *are* important for the tuning of pulsed-laser–pumped dye lasers, which have high gain. While many different types of tunable wavelength-selective filters have been successfully used in cw dye lasers, the simplest, cheapest, and most reliable are the birefringent (Lyot) filter and the Fabry-Pérot etalon. A birefringent filter consists of several quartz plates, with thicknesses related by integral multiples, cut with the optic axis parallel to the surface, and tilted at the Brewster angle relative to the direction of propagation. The frequency selectivity results from the birefringence of the plates combined with the polarization-dependent loss from the Brewster-angle surfaces. Each of the plates acts as a wavelength-dependent wave plate that changes the polarization of the light passing through it. The filter is tuned by rotating it about the normal (while maintaining the Brewster-angle orientation) and thereby changing the amount of birefringence (Bloom, 1974; Teschke and Holtom, 1974). In general the polarization exiting each plate is elliptical, and loss is experienced at the Brewster surfaces. At one wavelength, however, the light exiting each plate is linearly (p) polarized and thus experiences no loss. This is the center of the main pass band. Typical birefringent elements for a dye laser have one to three plates. The main pass band is about 1.5 THz wide for a three-plate Lyot filter.

A single glass plate, placed at near-normal incidence and coated on each side for a desired reflectivity, is a suitable Fabry-Pérot etalon for the cw dye laser. The transmittance of such a parallel-plate interferometer is

$$T(\delta) = \left[1 + \frac{4R}{(1-R)^2}\sin^2(\tfrac{1}{2}\delta)\right]^{-1}, \qquad (15)$$

where $\delta = (4\pi nL/\lambda)\cos\theta$. Here, R is the power reflectance of the etalon's surfaces, L is its thickness, n is its index of refraction, and θ is the angle between the etalon normal and the inside direction of propagation. This angle is kept small to minimize "walkoff" losses. The finesse F, which is the ratio of the free spectral range (mode spacing) to the half-power bandwidth, is given by $F = \pi\sqrt{R}(1-R)^{-1}$. The center frequency of an etalon can be tuned by changing either the length L or the angle θ. A length change of one-half wavelength tunes the frequency through one free spectral range.

A hierarchy of three frequency-selective elements is typically needed to achieve single-mode operation of a cw dye laser. The resolving powers must be chosen so that one (coarser) element is able to select a single resolution element of the next (finer) component, as shown in the diagrams of Fig. 11. The element with the coarsest resolution is usually a birefringent filter with half-power bandwidth of about 1.5 THz. This is usually followed by two etalons. The first of these is a single glass plate with a free spectral range of around 200 GHz, tunable by rotation. The second is a thicker, air-spaced etalon made of two parallel glass surfaces between Brewster-cut glass prisms, with free spectral range of about 10 GHz and tunable by changing the spacing. The etalons are coated for a low finesse of about 3. By virtue of the sensitivity of the laser to small variations of the net gain, the last element is able to select a single one of the cavity modes (typically spaced about 150 MHz). The bandwidth of this single-mode laser is now determined by the mechanical stability of the optical elements and of the gain. Unless specially engineered and stabilized for true single-mode operation, some mode hopping will take place, resulting in a bandwidth that may be of the order of 1 GHz. Feedback-stabilized, true single-mode cw dye lasers have bandwidth (determined by the jitter of the single-mode frequency) typically of the order of ~1 MHz, but stability and bandwidth down to the kilohertz range has also been achieved.

It is easy to understand from the above

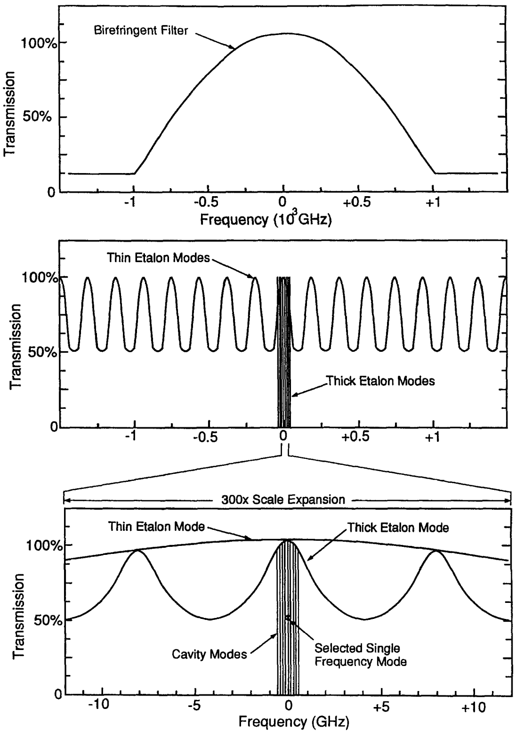

FIG. 11. Schematic of a hierarchic three-element frequency-selection and tuning scheme for a cw ring dye laser (after Duarte, 1990). The passband of each finer selective element is tuned to the center of the next coarser element. The sensitivity of the dye laser to small gain variations results in lasing in only one passband of each element. The final thick etalon selects a single cavity mode.

discussion why two designs are most often used for tunable cw dye lasers. One is a relatively simple, compact three-mirror standing-wave cavity laser with a single wide-band, mechanically controlled tuning element. The width of the broad-band output depends on the tuning element. A single-plate birefringent filter results in ~400 GHz bandwidth, but ~40 GHz can be achieved with a three-plate filter. The second common design is a unidirectional ring laser with a hierarchy of frequency-selective elements, resulting in narrow bandwidth and capable even of single-mode operation. For either of these designs one must be able both to tune and to track the operating frequency. This is a relatively easy task for the broad-band, linear-geometry laser, since the reproducibility needs to be only as accurate as the bandwidth. Tuning is accomplished by mechanically rotating the birefringent filter. The wavelength of lasing is approximately calibrated and can be externally measured. For the much narrower-bandwidth ring laser, sophisticated electromechanical design is required. The coarsest adjustment is made with the birefringent filter, usually purely mechanically. The next stage of tuning is by rotation of the thin etalon using a galvo-motor. The next coarser adjustment is made by piezoelectric tuning of the length of the thick etalon. The finest tuning adjustment, within a portion of the thick-etalon bandwidth, is made by changing the effective cavity length. This is usually done in two stages: by piezoelectric translation of one cavity mirror and by slight rotation of a thick Brewster-angle plate (or double Brewster plates). Tracking the oscillating frequency requires simultaneous and precise control of several elements. Description of a tracking system design is beyond the scope of this article. Typically, the continuous scanning range is limited to about 30 GHz. Computer-controlled tuning and tracking over the entire tuning range of a given dye has been developed, and such systems are commercially available.

Finally, it should be mentioned that injection locking has also been used to achieve bandwidth-limited performance. In this method a precise, narrow-band but very weak signal (from another source) is injected into the cavity of a more powerful oscillator. Because of the sensitivity of the oscillator to small perturbations, its output locks to the injected signal with narrow bandwidth. This method is useful and straightforward but is limited by the availability of the injection signal.

2.3 Mode-Locked cw Dye Lasers

The two commonly used tunable cw dye-laser systems described in the previous sections both aim for narrow bandwidth and wide tunability. Another very important utilization of the very wide gain bandwidth of dye lasers is for ultrashort pulse generation. In this case, lasing takes place over as wide a bandwidth as possible, with all frequencies brought into perfect coherence, to give a train of ultrashort pulses. Very little tunability is therefore possible for a given dye. Full description of these lasers properly belongs to a separate article (see ULTRASHORT PULSE PHENOMENA). However, no discussion of dye lasers would be complete without at least a brief description of these systems, which played such an important role in the development of femtosecond pulse generation.

The gain bandwidth of a typical dye would support pulses as short as 5–10 fs, but pulse-broadening mechanisms, such as dispersion, limit durations to typically an order of magnitude longer. A train of 50-fs pulses at 10-ns repetition rate (the round-trip time of the laser cavity) is composed of 2×10^5 individual modes, all having identical phase. To achieve this coherence, a strong pulse-shortening mechanism is necessary. Although the first reported mode-locked cw dye laser (Dienes *et al.*, 1971) used active modulation, and synchronous pumping has also been successfully used, passive mode locking with saturable dyes is the only method that results in pulses less than 300 fs in duration. The pumping and laser cavity configurations are simple variations of the two used for narrow-band cw dye lasers (Figs. 4 and 5). Another folded arm is added for tight focusing into the saturable absorber, and, in place of the frequency tuning and restricting elements, dispersion compensation elements are added. The shortest pulses were obtained in the ring configuration shown in Fig. 12, where two sets of pulses circulating in opposite direction "collide" in the saturable absorber, increasing the pulse-shortening action. Pulses as short as 27 fs have been reported (Valdmanis and

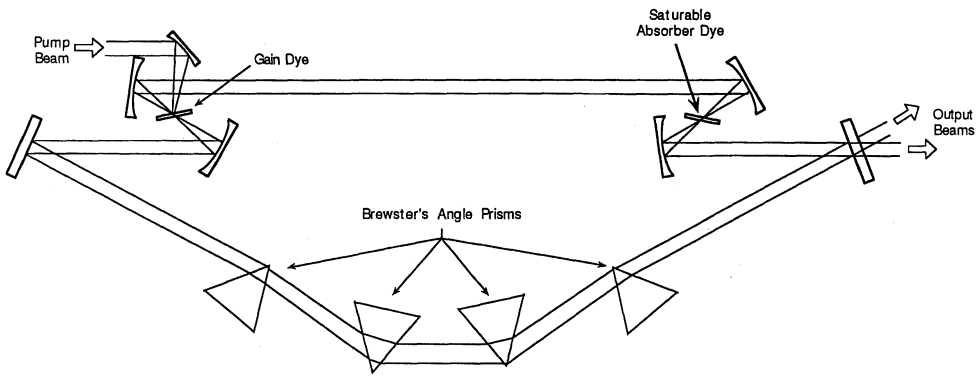

FIG. 12. Schematic diagram of a colliding-pulse mode-locked cw dye laser with a dispersion-compensating four-prism sequence included in the cavity.

Fork, 1986) from such a setup, but more commonly pulses around 50 fs long are obtained. The dynamics of pulse shortening in this laser are now examined briefly.

One can distinguish three stages in the evolution of the mode-locked pulses. In the first stage, a noise burst in each direction of circulation, around some picoseconds long, is selected by the gating action of the saturable absorber acting alone. The duration of the noise burst is limited by the recovery time of the absorber. In the second stage, two coherent single pulses (one in each direction) are formed by the combined pulse-shortening action of saturation in both (absorber and gain) dyes, together with the dispersion-compensating effect of the four-prism sequence. Figure 13(a) shows semiquantitatively the dynamics of the pulse shortening in this, most critical, stage. The center of the pulse has gain while both leading and trailing edges experience loss. This is the result of a rather delicate interplay of the two saturations, of their recovery, and of the linear loss. At the leading edge, the loss is higher than the initial gain because the gain has not fully recovered to the small-signal value after one round trip. On the other hand, the loss experienced by the trailing edge is due to the linear loss that remains after the absorber is fully saturated, while at the central portion of the pulse there is net gain due to the faster saturation of the absorption. It can be deduced from this diagram that for effective pulse shortening

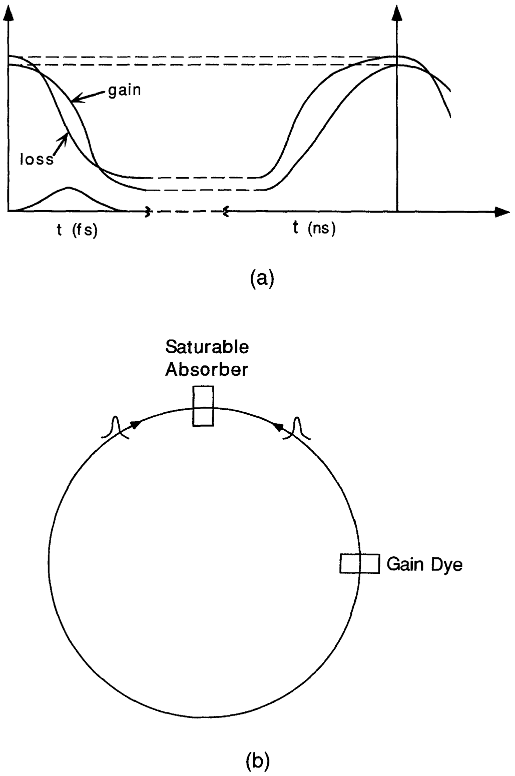

FIG. 13. (a) Pulse-shortening dynamics in passively mode-locked cw dye lasers. The loss includes that of the saturable dye, as well as the fixed losses. The saturation of the gain and of the absorption takes place on a femtosecond time scale during the passage of the pulse. The recovery is on a nanosecond time scale. (b) Schematic of the optimum placement of the gain dye and of the saturable absorber in the colliding-pulse ring configuration.

1. absorber saturation must be stronger than gain saturation; and
2. the absorber must fully recover by the time the next pulse arrives, but the gain must not fully recover.

These conditions *can* be met in a linear configuration but are easier in the ring configuration where the oppositely traveling pulses arrive simultaneously ("collide") in the absorber. Additionally, the oppositely traveling pulses should experience the same initial (not fully recovered) gain. For these reasons the pulses not only must collide in the absorber but also must anticollide (i.e., arrive with maximum separation) in the gain medium. This condition determines the location of the dyes and the corresponding focal points in the ring cavity to be as is schematically shown in Fig. 13(b). These multiple-folded ring cavities have rather complicated stability regions, depending on the dimensions of the various arms and radii of curvature of the mirrors. Detailed Gaussian-beam analysis has been done to optimize thedesign (Li *et al.,* 1981; Magni *et al.,* 1992).

The pulse shortening described above is opposed by pulse broadening due to second- and higher-order dispersion. Dispersion results in the addition of a spectral-domain phase $\Phi(\omega)$ to the oscillation spectrum (Siegman, 1986). This phase is nonlinear in the frequency ω. In a dye cavity this is the result of the reflections from the broad-band multilayer mirrors as well as of propagation through glass or fused-silica elements. Second-order or group-velocity dispersion is the most important and results in a symmetric broadening of a pulse. While pulses as short as or even shorter than ~100 fs have been achieved without dispersion compensation, the shortest pulse durations are achieved only with a prism compensator in the cavity. The four-prism sequence introduces adjustable second-order dispersion and allows optimization of the net dispersion experienced by the pulse in a round-trip. This optimum is not exactly zero value because in the third stage of pulse formation—which is reached only for pulses shorter than ~100 fs—new nonlinear effects become significant, and optimal pulse shortening requires a small amount of negative group-velocity dispersion to be present. In this third stage of pulse formation, self phase modulation by the nonlinear index n_2 in the absorber (and to a lesser extent in the gain dye) in combination with negative second-order dispersion results in a discrete soliton formation mechanism (Valdmanis and Fork, 1986). Positive frequency sweep (chirp) on the carrier due to the self phase modulation is canceled by a negative chirp due to dispersion. The pulse shortens until a balance is reached, corresponding to a fundamental soliton (a pulse of fixed shape and intensity) circulating in the cavity. This last stage is necessary if the shortest possible pulses (less than ~50 fs) are to be reached but requires very critical adjustment of cavity and other parameters.

In principle, the center wavelength of the mode-locked femtosecond pulses should be tunable within the available gain bandwidth because even the shortest pulses achieved have a spectral width that is only a fraction of that of the gain. However, in reality all mode-locked dye lasers operate only at one fixed wavelength. This is due to the small range allowed on a variety of parameters. The required combination for achieving good mode locking and femtosecond pulses can usually only be obtained near one wavelength with a limited tuning range. For the same reason, not all cw laser dyes have been successfully mode locked for femtosecond pulse operation. The best results have been achieved with R6G as the gain dye and DODCI as the saturable absorber, at the central wavelength of ~630 nm. This was the dye combination in the first passively mode-locked cw dye laser (Ippen *et al.,* 1972) which used a nonoptimum linear configuration and resulted in 1.5-ps pulses without any dispersion compensation. The invention of the colliding-pulse mode-locked ring configuration, together with dispersion compensation, gradually shortened the pulse duration to eventually 27-fs pulses (Valdmanis and Fork, 1986). Until the recent development of the Kerr-lens mode-locked Ti:sapphire laser, this was the shortest laser pulse from any system directly without external compression. Other dye combinations have resulted in cw mode-locked pulses in the femtosecond range at several additional wavelengths, but pulse durations are somewhat longer and mode locking is more difficult. A list of cw mode-locked dye lasers with lasing wavelength ranges and best reported pulse lengths is given in Table 2. Additional gain–absorber dye combinations have been mode locked using pumping by mode-locked lasers (hybrid mode locking). A description of this technique and a table of results are given in the literature (Duarte and Hillman, 1990).

3. PULSED DYE LASERS

Because dye-laser excitation requires high photon flux, cw pump sources are both limited in number and expensive. Additionally, on account of limitations of the pump sources, difficulties in quenching the accumulation of molecules in the triplet state, and thermal problems, relatively few dyes can lase in cw mode. On the other hand, pulse excitation allows excitation of a larger number of dyes using a variety of sources. To pulse-excite dye lasers, two different photon sources have been utilized: either a pulsed laser at a wavelength within one of the singlet absorption bands of the dye or a flashlamp. Historically, the first dye lasers were demonstrated (Schäfer *et al.*, 1967; Sorokin and Lankard, 1967) using pulsed pumping with giant-pulse ruby lasers and with flashlamps. Today a wide variety of pulsed dye lasers exist, either sold commercially or constructed in the laboratory. In this section both methods of excitation are discussed, and various pulsed dye-laser configurations are described. Methods of tuning and reduction of the dye-laser bandwidth are also presented.

3.1 Flashlamp-Pumped Dye Lasers

A simple, practical, and relatively inexpensive method of dye-laser pumping involves the use of the broad-band visible and UV emission that results after an electrical discharge takes place in xenon, i.e., flashlamp pumping. Flashlamp pumping allows a highly symmetric excitation of a dye solution and can yield large output laser energies. The active volume of flashlamp-pumped dye lasers is relatively large. The dye-cell length ranges from ~15 cm to over 50 cm, and the diameter from a few millimeters up to ~2 cm. In all flashlamp excitation schemes the absorption of the pump is, by necessity, transverse to the lasing direction. The dye concentration is adjusted so as to absorb in a distance about the diameter of the dye cuvette, resulting in the absorption of a fairly high fraction (~0.8–0.9) of that spectral portion of the flashlamp output that has wavelengths overlapping the singlet absorption band. The two main types of excitation use linear and coaxial flash lamps. As shown in Fig. 14(a), linear excitation usually utilizes two or more flashlamps symmetrically arranged around the active region (the dye cuvette) and a reflective surface around the perimeter. Single or double elliptical reflectors may be used to improve the dye excitation. Coaxial excitation, shown in Fig. 14(b), yields a concentric dye illumination and very uniform pump intensity distribution resulting in large output energies (Baltakov *et al.*, 1972). A third configuration involves the use of a single helical flashlamp, with the dye cuvette placed at the axis and a cylindrical re-

Table 2. Passive mode-locking dye combinations and results (after Duarte and Hillman, 1990).

Gain dye	Saturable absorber[a]	Wavelength range (nm)	Shortest pulse width (fs)	Notes
Coumarin 102	DOCI	493–502	93	Ring cavity
Coumarin 6H	DOCI	492–507	110	Ring cavity

---

[a] The acronyms for the dyes are the standard ones used in the literature and in the commercial dye catalogs. Full chemical names are rarely if ever used but can be found in the literature (e.g., DODCI = diethyl-oxa-dicarbocyanine-iodide).

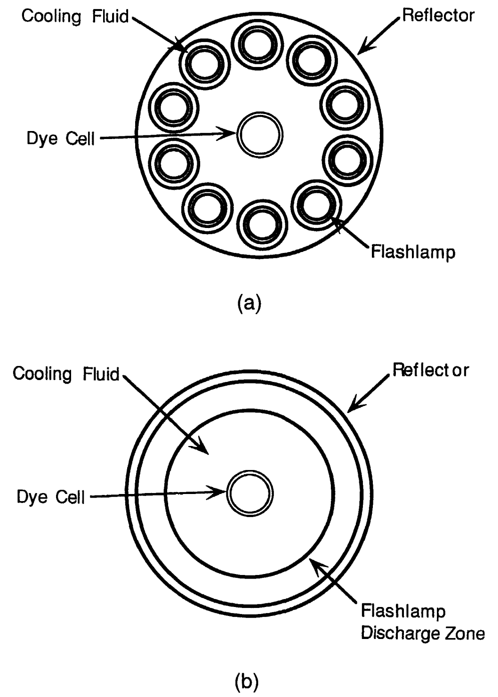

FIG. 14. (a) Cross-sectional diagram of a linear flashlamp excitation scheme using multiple flashlamps. (b) Cross-sectional diagram of a coaxial flashlamp excitation scheme. The discharge takes place longitudinally in the hollow-cylinder flashlamp.

flector outside. Flashlamps are fairly efficient in transforming electrical to light energy, and both peak output power and total output energy are high. The detailed spectral characteristics of the light output depend on the excitation current. The output is always very broad band, and only a fraction (typically ~10% or less) of this output falls in the right wavelength region to be absorbed by the main singlet absorption band of the dye. This greatly limits overall efficiency, and it also poses problems of dissipating the heat that results from the energy in the unused wavelength ranges. In spite of these problems flashlamp pumping is simple and inexpensive to implement. It is also one of the schemes that can be "home built" in almost any laboratory. Although today the use of flashlamp pumping is no longer extensive, its study, besides the obvious historical importance, greatly helps with the general understanding of all dye lasers.

3.1.1 Theoretical Description and Discussion With flashlamp excitation, no exact analytical theory can be given. However, by making a few simple approximations, useful expressions *can* be derived. In fact, with some minor but important modifications, much of the theory given in Sec. 2.1 can be used to understand the operational principles, as well as the limitations, of these devices. The duration of the flashlamp pulse is a very important parameter, and its effects are discussed below. Figure 15 shows a schematic of the excitation electronics, based on the simple principle of discharging the energy stored in a large capacitor through the ionized gas of the tube. The discharge is triggered by a spark gap. The pulse length depends on the size of the capacitor and on the impedance of the discharge (and therefore on the size of the flashlamp). Several small flashlamps together can give the same energy as a single large one, but in a much shorter pulse. Dye-laser flashlamps have durations ranging from less than 100 ns to tens and sometimes even hundreds of microseconds.

Although the pumping geometry is very different from the cw-excitation case, with absorption of the pump taking place transversely to the propagation of the laser pulse, the rate equations (for an arbitrary point in

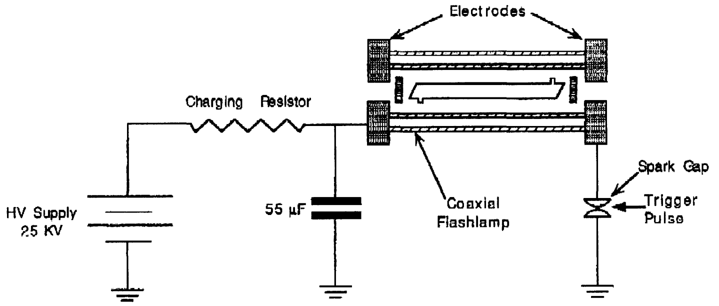

FIG. 15. Schematic of the overall configuration and of the electrical excitation of flashlamps for pumping dye lasers.

the dye medium) presented in Sec. 2 are still valid for any flashlamp-pumped dye laser. One modification is that the pump absorption coefficient σ_{ap} must be a weighted average over the entire singlet absorption band of the particular dye, because the flashlamp is a broad-band source, covering wavelengths from the infrared to the ultraviolet. Since the lifetime of the singlet (τ_1) is much shorter than the pump-pulse duration, quasi steady-state conditions can be assumed to exist for the singlet absorption pumping; i.e., the population N_1 essentially follows the pump pulse, as per Eq. (8). This is not the case, however, for the triplet-state population N_T. Just as in cw systems, triplet absorption is also a severe problem in flashlamp-pumped dye lasers, since pump-pulse durations tend to be longer than $1/k_{ST}$, while τ_T is also on the same order or longer. Because of the time-dependent pump intensity, the exact nature of the resultant triplet absorption is more complicated than for the cw case. This problem has been investigated in considerable detail (Maeda, 1984; Schäfer, 1990), and it is well known that the values of k_{ST} and τ_T to a large extent determine the duration of an optimum pump pulse and that of the resulting dye-laser pulse.

If long pulses (microseconds or longer) are desired, quasi-cw conditions apply in the triplet rate equation as well, and consequently one is restricted to using those dyes in which $k_{ST}\tau_T$ can be quenched to a small enough value to give f_T close to unity (i.e., those that are capable of cw operation). However, dyes in which the large value of $k_{ST}\tau_T$ cannot be quenched still can be made to lase if pumped with sufficiently short pulses. It is easy to show that for these dyes the rise time of the pump pulse (τ_{pr}) must be short (equal to or shorter than $1/k_{ST}$). Then, lasing can start before triplet accumulation has taken place. But lasing will be cut off by the buildup of the triplet population, which is governed by the crossover rate k_{ST} and the triplet decay rate τ_T. These effects together determine the optimum pump-pulse duration. Detailed modeling of the power output can be made by numerically solving the rate equations. Here, some simple but useful results that aid a basic understanding are given. First, below–lasing-threshold conditions are considered, assuming that for the given dye the value of the triplet factor f_T [given by Eq. (7b)] is negative, i.e., no cw or quasi-cw lasing can take place. For N_1, quasi-cw conditions can still be assumed, giving

$$N_1 = N_0\sigma_{ap}\tau_1 I_p(t). \tag{16}$$

For a fast-rise-time flashlamp ($\tau_{pr} \ll 1/k_{ST}$ and τ_T) a time-dependent triplet factor $f_T(t)$ takes the place of f_T. During the buildup of the intense pump pulse, assuming $\tau_T \gg 1/k_{ST}$,

$$N_T = k_{ST}\int_0^t N_1 dt, \tag{17}$$

and thus the triplet reduction factor becomes during this rise time

$$\begin{aligned} f_T(t) &= 1 - \frac{N_T}{N_1}\frac{\sigma_T}{\sigma_e} = 1 - \frac{k_{ST}\int_0^t N_1 dt}{N_1}\frac{\sigma_T}{\sigma_e} \\ &= 1 - \frac{k_{ST}\int_0^t I_p dt}{I_p}\frac{\sigma_T}{\sigma_e}. \end{aligned} \tag{18}$$

For $\tau_{pr} \ll \tau_T$ this is much smaller than f_T, the cw triplet reduction factor. Thus even with $f_T < 0$, the value of $f_T(t)$ can remain positive, and lasing can be achieved if the rise time is fast. However, the triplet population continues to build up and limits the lasing. If the pump intensity is approximately constant after the fast rise, then the value of $f_T(t)$ will decay toward the cw value exponentially, with time constant τ_T, and lasing will be terminated when $f_T(t) = 0$. It is evident that an optimum pump pulse should also terminate around this time. On the other hand, if the steady-state value of the triplet factor f_T is larger than zero, fast pump-pulse rise time is not needed to reach lasing threshold, and the lasing will follow the pump pulse. These points are further illustrated graphically in Fig. 16, which shows an *exact* solution for the factor $f_T(t)$ and for the gain $g(t)$ for a long pump pulse with an exponential rise time τ_{pr}, for $f_T = -0.3$, and for various ratios of τ_{pr}/τ_T. It can be clearly seen from these curves that it is wasteful and even detrimental (because of the resultant heat generated) to use too long a pump pulse. A partial list of dyes that do not lase when cw long-pulse pumped but can be lased by fast excitation is given in Sec. 3.2.

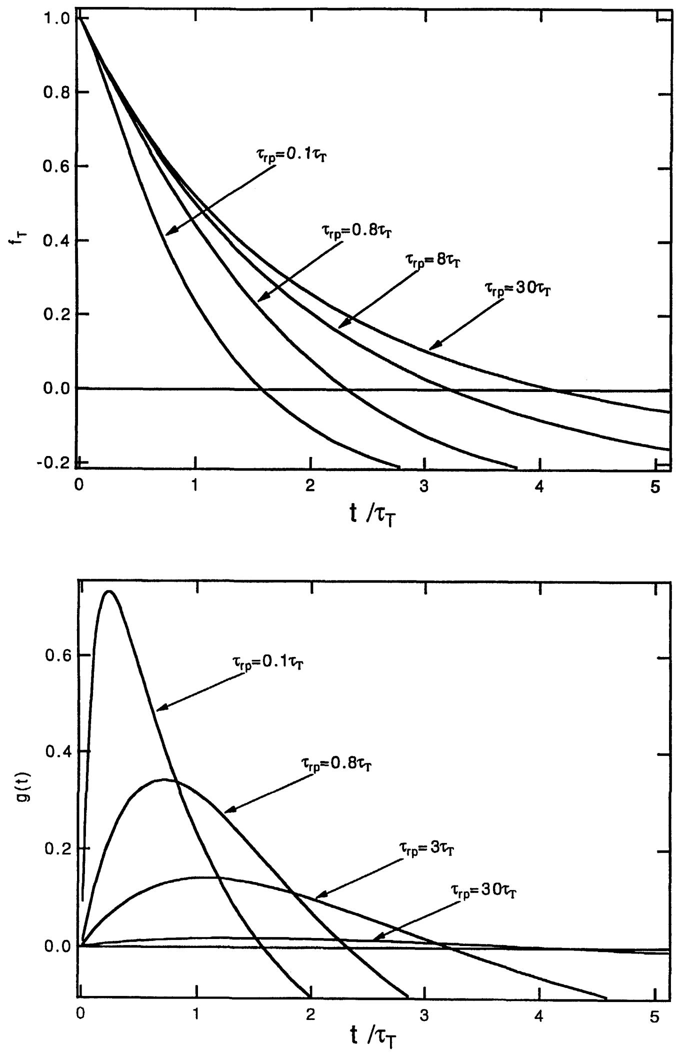

FIG. 16. Calculated time dependence of the triplet reduction factor $f_T(t)$ and of the incremental gain $g(t)$ for a long pump pulse with shape given by $I_p(t) = 1 - e^{-t/\tau_{pr}}$.

The above equations are valid at an arbitrary point in the dye-laser medium. To describe fully the behavior of a flashlamp-pumped dye laser and to find its power (or energy) output, the full rate equations, under lasing conditions, must be integrated over the entire active volume. It is not possible to do this as accurately as was the case for cw excitation. Nevertheless, a useful approximate description *can* be given. In this approximation it is assumed that the laser is well above threshold and that the cavity decay rate is much shorter than the pulse duration, and thus cavity dynamics can be ignored. In spite of the fact that both the pumping and cavity configurations look very different from the cw dye laser, and the excitation is time dependent, a great deal of similarity exists in the descriptions. This is because quasi steady-state conditions exist with regard to the singlet absorption excitation. The necessary modifications of the theoretical expressions derived in Sec. 2.1 are due to the different pumping geometry, to the broad-band nature of the flashlamp photon output, and to the possible lack of a steady-state triplet population.

The method described in Sec. 2.3 is used, with the new assumption that the excitation is uniform in the longitudinal direction (along the lasing axis) and that all quantities are averaged in the transverse cross section of the active volume. It is also assumed that the absorption length is approximately equal to the diameter of the dye cell. This, combined with a reasonably uniform transverse distribution of the photon flux around the surface of the dye cuvette, results in an approximately uniform excitation over the cross section. For a simplified derivation, a dye cuvette of length L with a square cross section D is assumed with a uniform photon flux input on one rectangular ($L \times D$) side of the cuvette. This incident photon flux is subject to an average absorption cross section σ_{ap} with an approximately constant ground-state population (N). The fraction of the incident flux absorbed is $a = 1 - \exp(-\sigma_{ap}ND)$. In the same manner as in Sec. 2.1, we integrate the population densities in the transverse dimension and then solve for the gain and the power output. It is found that the gain is proportional to the absorbed pump power divided by the cross-sectional area of the active medium (perpendicular to the lasing direction). For the flashlamp-pumped dye laser this area is simply the cross section of the dye cuvette. The resulting expression for the output power is identical to that given in Eq. (11) for the cw dye laser, with only the following slight modifications for slope efficiency and threshold:

$$\eta = \frac{\nu_l}{\nu_p} f_V f_T a \frac{t}{t+l}, \tag{19}$$

$$P_{\text{th}} = Ah\nu_p \frac{t+l}{f_T \sigma_e \tau_1 a}. \tag{20}$$

Here, the extra factor f_V represents the fraction of the dye cuvette volume that is filled by the dye-laser mode. The area A is the cross section of the dye cuvette, and the pump frequency ν_p is now value-averaged over the dye singlet absorption band. For pump pulses longer than the triplet decay rate (τ_T), the triplet factor f_T is the same as the cw value [Eq. (7b)], which must be positive. For those cases when this factor is negative, no lasing occurs with long-pulse pumping. For lasing with short-pulse pumping, the equations remain approximately valid provided that f_T is replaced by the time-dependent factor $f_T(t)$ (which can be estimated; see Fig. 16). Such results for the power output, while approximate, correctly describe the behavior of flashlamp-pumped dye lasers. They are useful not so much to calculate the output of the laser but to help understand and discuss their most important characteristics not yet examined in the preceeding paragraphs. Some of the particular points that can be made are these:

1. In order to input most of the incoherent pump light into the dye cell and to insure good uniformity of the absorbed power over the transverse cross section, the dye cuvette must typically have diameter from a few millimeters up to ~1 cm. It also follows that the required dye concentration must be rather low, of the order of 10^{-4} to 10^{-5} mol/L, in contrast with the cw dye laser where the absorption depth is around 100 μm using typical concentrations of ~10^{-3} mol/L. If the concentration is too high, absorption will take place in a thin layer near the dye-cell walls resulting in an unsuitable annular gain region. Because of the relatively low concentration, there are no dye aggregation or concentration quenching problems.
2. The pump powers required are high because the dye transverse cross section is of the order of millimeters or even a few centimeters. By comparison, in cw dye lasers the active region (defined by the focused pump beam) is ~10–30 μm diameter. In Sec. 2.1 it was calculated that, for R6G with the pump beam focused to a diameter of 20 μm, a pump power of ~280 mW is needed to obtain a threshold round-trip gain of 15%. For a flashlamp-pumped system, assuming a dye cuvette diameter of 6 mm, and assuming that the triplet decay is quenched to the same value as in a cw dye laser, the threshold pump power to achieve the same gain is ~10^5 × higher, or ~25 kW of power absorbed in the dye.
3. The power (or energy) output does not directly depend on the dye volume and concentration. Instead, for dye lasers the power output increases linearly with the pump power and is limited in practice by the power of the pump lamp itself and by the practical problem of getting rid of the excess heat. A larger flashlamp will, of course, mean larger pump power and necessitates a proportionally larger dye cuvette as well as larger reflector and housing with cooling system.

In addition to the obvious photon-frequency conversion loss (ν_l/ν_p), the fraction of pump light absorbed (a), and the reduction factor by triplet absorption [$f_T(t)$], the efficiency of the dye laser is determined by the ratio of the output-coupling loss to the total cavity losses, $t/(l + t)$, in similarity with cw systems. Typically, this last factor is smaller than in a cw dye laser, on account of the somewhat higher cavity losses. The overall electrical power to laser light efficiency is also given by Eqs. (11) and (12) if the factor a is modified to include the fraction of the electrical power input that is converted into light with wavelengths within the absorption band of the particular dye. This fraction is typically around a few percent. Thus, if the flashlamp-pumped dye laser is properly designed to have an output with duration approximately the same as that of the pump (either by strong triplet quenching or by using a fast-rising and short pump pulse), then one can estimate an overall energy efficiency as follows. Assuming the typical values $a = 0.04$, $\langle\langle f_T\rangle\rangle = 0.4$ (average value), $f_V = 0.8$, $\nu_p/\nu_l = 0.7$, and $t/(l + t) = 0.6$ gives a slope efficiency of about 0.5%. The threshold electrical energy for a 2-μs pulse is around 30 J. These estimated values are representative of the best (cw and long-pulse lasing) dyes with triplet quenching. For low–repetition-rate excitation (typically in the tens of hertz), actual laboratory or commercial systems indeed provide performance in this range for the best dyes (such as R6G and others; see Sec. 2.2.4) and also show nearly linear dependence of the output on input energy. For example, a commercially available high-energy system (by Cynoshure Inc.) provides output pulses in the 1–30-J range for electrical input energies of 250–8000 J and pulse durations of 0.5–4 μs for the most efficient (cw) dyes. For those dyes that can be made to lase only by fast pulses, the output efficiency is considerably lower. Fast flashlamps are also much smaller, providing considerably lower output energies. Today, pulsed-laser pumping is used exclusively for fast excitation. This is described in Sec. 3.2.

3.1.2 Practical Performance Limitations of Flashlamp Systems There are some additional performance-limiting effects that are not covered by the theory. It is well known that increasing the repetition rate greatly degrades performance. Both linear and coaxial flashlamps radiate large amounts of thermal (infrared) energy. Most of the unabsorbed visible and UV light is also eventually converted to heat. All this excess energy must be dissipated by liquid cooling. There are various designs for practical cooling systems, but they all rely on circulating, water-based heat exchangers. In addition, the dye itself is circulated by a separate system to provide both cooling and easy replacement of dye molecules lost to long-term deterioration. Up to a certain maximum repetition rate, the cooling system is very effective in carrying away the excess heat, and the output power increases linearly with the repetition rate. However, above a certain repetition rate, first some gradual decrease of the slope efficiency begins, followed by degradation of performance for still higher rates. As an example, while average powers ~30 W have been reported (Jethwa and Schäfer, 1974) at a repetition rate of 30 Hz, the average output power does not increase linearly for higher repetition rates. Thermal blooming as well as actual deterioration of the dye is one of the most important practical limiting effects in high-power, high-energy, flashlamp-pumped dye lasers, and it is difficult to obtain efficient operation at high (>100 Hz) repetition rates. Another important point in practical designs has to do with dye deterioration due to UV light absorption. Spectral studies of the emission produced by flashlamps indicate that a substantial portion of the photon flux peaks around 200 nm. Such emission gives rise to excitation to higher singlet states and can result in the photodegradation of the visible-emitting dyes. For this reason UV filters (Calkins *et al.*, 1982) (Pyrex or glass) have been used in the dye cell, or UV absorbers (Knyazev *et al.*, 1983) have been incorporated into the liquid refrigerant.

3.2 Pulse-Laser–Pumped Dye Lasers

While flashlamp-pumped lasers were historically very important and are still in use, today pulse-laser–pumped dye lasers are much more important. To select an appropriate pump for a particular dye (or group of dyes), the main consideration is the same as it was for the cw systems: the location of the singlet absorption bands. For best efficiency, the pumping should take place in the main (lowest) singlet absorption band (S_0–S_1 transition). Copper-vapor and pulsed xenon lasers emit blue-green lines and are suitable for pumping dyes that lase in the yellow to red spectral region. The frequency-doubled Nd:YAG laser is another suitable pump source. Dyes emitting in the infrared spectral region and wavelength longer than 1.2 μm can be pumped with the fundamental of Nd:YAG lasers. For UV and blue-green emitting dyes, excimer or nitrogen lasers with their intense UV output are excellent pump sources. These last two lasers can also be used to pump yellow-red emitting dyes. This is because the UV output of these two lasers falls into a higher-order singlet absorption band (usually S_0–S_2 transition; see Fig. 1) of these dyes. While the efficiency is obviously reduced by the considerably larger photon energy downshift, and there may also arise some problems with UV-induced photodegradation, such pumping has proven to be both easy and practical. Most of the mentioned pump sources will yield dye-laser pulses a few nanoseconds in duration and provide highly energetic pulses in the 100–500-kW range. It is obvious then from the discussion presented in Sec. 3.1.1 that, because of their short-pulse durations, these types of short-duration pump sources allow the lasing of a number of dyes that cannot be made to lase in cw or long-pulse mode.

For some of the pulsed pump sources (e.g., Xe, YAG, copper-vapor lasers) longitudinal excitation of the dye is possible. The Xe laser can operate with microsecond-long pulses, and most of the discussion on cw dye lasers applies. Pumping with a Xe laser has been used to construct an inexpensive long-pulsed and mode-locked femtosecond dye-laser system (Ansari *et al.*, 1985). Copper-vapor pumping also has been used for long-pulse operation, and the characteristics of such dye lasers have been investigated (Singh *et al.*, 1993). Longitudinal excitation is the preferred method of pumping for making dye-laser amplifiers. Until the advent of the mode-locked Ti:sapphire laser, the mode-locked cw dye laser was the only source of sub-100-fs pulses. Because these pulses are rather low in energy, amplification is necessary. Both Nd:YAG and copper-vapor lasers have been used to pump pulsed dye-laser amplifiers for femtosecond pulses (Fork *et al.*, 1987; Knox, 1988). In spite of its temperamental behavior, the copper-vapor laser has for many years been the workhorse pump for amplifying mode-locked dye-laser pulses. By dye-laser–based amplification of such pulses, fiber-based chirping and compression, and further dye-laser–based amplification, ~10 fs pulses with energies in the 100 mJ range have been achieved (Boyer *et al.*, 1991). Today, Ti:sapphire-laser–based all solid-state femtosecond oscillator amplifiers are replacing most of these femtosecond dye-laser systems. A similar, dye-laser–based amplifier has been recently demonstrated for the amplification of sub-100-fs pulses from a mode-locked cw Ti:sapphire laser, for the purpose of producing UV ultrashort pulses (Lucia and Reilly, 1995). The output of one dye laser can also be used to pump another longer-wavelength dye laser, usually (but not exclusively) in longitudinal configuration.

An alternative, and very often used, method of pumping for dye-laser oscillators is the transverse pumping configuration. This method has the advantage of being easy to implement and circumvents the sometimes problematic interaction of the pump beam with the optical elements of the dye-laser oscillator cavity in longitudinal excitation geometry. Additionally, output pulse energies can be high. One disadvantage of the transverse pumping geometry is the uneven spatial excitation of the active volume. Because this pumping scheme is very widely used, the pump sources are described in more detail. Most commonly used pump sources are various excimer lasers, and (historically earlier, but less often today) the N_2 laser. These are gaseous lasers, typically excited by a long transverse electrical discharge. Their gains are very high, and instead of a cavity, they usually have only one end mirror. Thus, the output is essentially a two-pass–amplified (and gain-narrowed) spontaneous emission. The output spectrum is rather broad and incoherent, but narrow enough to allow all the emitted light to be efficiently absorbed by a dye. As a result, much less of the light energy is converted into heat than in flashlamp pumping. N_2 lasers emit a number of closely spaced lines near 337 nm, corresponding to transitions between the C and B bands of the triplet manifold of the molecule. They typically provide peak powers of ~100 kW with pulse lengths ~10 ns (i.e., ~1 mJ energy) at repetition rates around 100 Hz. Excimers are molecules that exist only in the excited state (the upper level of the laser transition). Those used for dye pumping are excimers of rare-gas halides, which are formed in a pulsed electrical discharge. Depending on the gas mixture employed, these lasers emit with high intensity in the ultraviolet at several wavelengths from 193 to 353 nm. Specific examples of halides used in excimer lasers, and the wavelengths emitted, are KrF, 248 nm; XeCl, 308 nm; XeF, 351 nm. Typically, excimer lasers provide pulse lengths in the 10–30-ns range with repetition rates from less than 1 Hz to ~100 Hz. The pulse output energy of commercially available systems is in the 10- to 1000-mJ range, with the KrF being the most energetic. Thus the peak power is even higher than that of the N_2 laser. As a consequence of the transverse discharge geometry, the output beams of both N_2 and excimer lasers are of rectangular cross section. While this characteristic may be inconvenient for many uses, it is very well suited for transverse pumping a dye cell of the same length as the longer dimension of the output-beam rectangle. The basic configuration is shown in Fig. 17. The rectangular pump beam is focused by either a cylindrical or a spherical lens, resulting in a narrow and intense strip of light, which propagates through the dye cell in a direction orthogonal to the dye-laser beam. It is absorbed by the dye, resulting in a transversely nonuniform inverted region. UV light from the second or third harmonic of a pulsed solid-state (usually Nd:YAG) laser can also be utilized for transverse pumping. The basic configuration is the same, with some minor differences in the setup due to the circular output beam of these pump lasers. The less reliable copper-vapor laser has also been used for transverse pumping (Dixit *et al.*, 1997). Good beam quality and low divergence were achieved by using a special diffraction-filtered resonator. Today, however, the use of this pump would only be justified if no other pump source is available.

Early work with transversely laser-pumped dye lasers mainly utilized the N_2 laser (Meyer *et al.*, 1970; Shank *et al.*, 1970) and made only crude attempts at tuning, using a grating in place of one of the mirrors, as shown in the schematic of the basic setup (Fig. 17). A cylindrical lens of focal length 10–20 cm was used to focus the pump light into the dye cell. This resulted in a long pumped region with a small transverse cross section, which allowed easy lasing of many dyes. However, the beam quality was very poor. A more sophisticated N_2-laser–pumped, transverse excitation scheme was implemented by Hänsch (1972) and is described in Sec. 3.3, where tuning and bandwidth narrowing for pulse-pumped dye lasers are discussed. The transverse pumping approach is also readily applicable to excimer lasers (Duarte and Piper, 1980). Furthermore, this simple method of pumping has also been used for the excitation of amplifier stages where improved excitation has been demonstrated using two counterpropagating collinear pump beams (Klick *et al.*, 1985).

To understand in more detail the characteristics of transverse laser-pumped systems, one can still use the rate equations given in Sec. 1. However, the quasi-cw approximation used for the dynamics of the excited singlet population is no longer valid because the pump-pulse rise time and duration approach the singlet decay rate τ_1. The complete rate

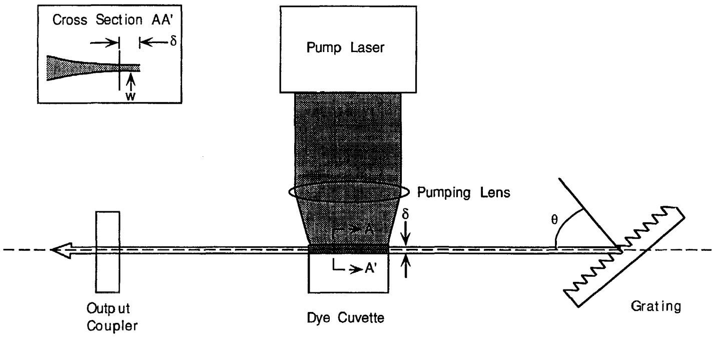

FIG. 17. Schematic of transverse pumping by N_2 or excimer lasers. The pump laser output is rectangular with the longer dimension shown. The focusing lens can be either cylindrical or spherical. The dye active region has length L and a cross-sectional area (A-A′) defined by the focused thickness of the pump beam (w) and the absorption depth in the dye (δ). The simple tuning arrangement of a diffraction grating (in the Littrow configuration) replacing one mirror is also shown.

equations must be solved *with* cavity risetime dynamics also included. Nevertheless, some important qualitative conclusions can still be reached by examination of the previously derived results. In particular, although for these systems Eqs. (8) and (9) are no longer valid, the gain is still inversely proportional to the cross-sectional area (A) of the active volume (perpendicular to the lasing axis). As shown in Fig. 17, this cross section is defined in one dimension by the focusing of the pump beam (to a width w) and in the other dimension by the absorption depth (δ) in the dye. The dye concentration is adjusted to give a short absorption depth, typically on the order of ~ 100 μm. The focused width of the pump beam (w) typically ranges from 0.1 to 1 mm. Thus, the cross-sectional area A is very small, only about one order of magnitude larger than in cw dye lasers, but the pump power is many orders of magnitude larger. The resulting gain is very high, 10–50 dB, with the higher values typical for good visible-wavelength dyes and the lower ones for the harder to lase blue and UV dyes. As a result, strong amplified spontaneous emission (ASE) is often observed without any mirrors. This ASE is normally undesirable because it is rather incoherent with a very wide bandwidth, and it will saturate the gain of the desired cavity oscillations. However, the ASE can be used to measure the gain (Dienes, 1975) and offers a convenient means of comparing various laser dyes whose parameters are not well known. Because of the high gain, cavity oscillation readily occurs even from the uncoated end surfaces of the dye cell, which must be tilted well away from the normal to avoid this occurring. The very high gain also allows placement of highly lossy elements (such as, for example, a diffraction grating) within the cavity, which is not possible with cw or flashlamp-pumped dye lasers. The use of gratings for frequency control is discussed in more detail in Sec. 3.3.

A phenomenon that occurs only in these short-pulse–pumped lasers is partial or full relaxation oscillations (also called self-Q-switching). This phenomenon is normally observed in solid-state lasers that have very long lifetimes (τ_1) that preclude equilibration of the population inversion. Dyes have very *short* lifetimes, and in all the dye lasers discussed so far, cw or quasi-cw conditions exist for the excited singlet population. Consequently, time-dependent cavity rate equations were not needed to describe their behavior. Here, however, the rise times of excimer (or nitrogen) laser pulses are *shorter* than τ_1; the pumping intensity is very high as discussed above; and the cavity Q is typically very low, i.e., the cavity lifetime is also short. As a result, relaxation oscillations can occur, whereby the population in the excited singlet level (N_1) rapidly builds up, resulting in very high gain. Intense stimulated emission rapidly depletes the population to near or below threshold, and lasing diminishes or stops (the lasing intensity can change rapidly when the cavity lifetime is fast). The process will repeat as long as the strong pump light is on. To describe this behavior quantitatively, time-dependent rate equations for the laser emission in the cavity need to be added to the dye rate equations (4) and (5). Detailed solutions of the complete rate equations have been made (Schäfer, 1990) for simulation of these lasers and yield the type of behavior qualitatively described above. Experimentally, both partial and complete relaxation oscillations have been observed (Lin and Shank, 1974) corresponding to the pulse shapes shown in Fig. 18. Subpicosecond pulses have also been produced by quenching all but the first burst (Lin and Shank, 1974). The same type of dynamics is responsible for the generation of ultrashort (picosecond duration) pulses in short-cavity dye lasers (Bor, 1980) (usually axially pumped). In these lasers, the cavity decay time is very fast because of the short cavity and the resulting short round-trip time. When pumped with nanosecond- or subnanosecond-dura-

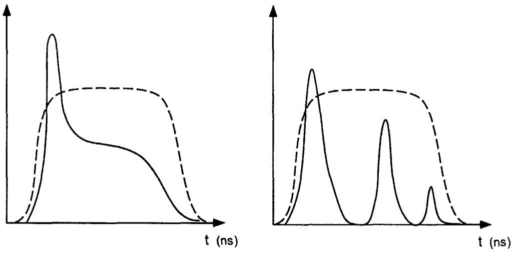

FIG. 18. Typical output pulse shapes that can be seen in N_2-laser–pumped dye lasers at high pump powers, showing partial and complete relaxation oscillations. Dashed line is pump pulse.

tion laser pulses, their output pulses can be as short ~15 ps as a result of the above described self-Q-switching mechanism.

An interesting and unique use of excimer laser pumping was for the generation of high-power tunable ultrashort pulses (Szatmári, 1992). This was accomplished by successive pulse shortening in a multistage cascaded dye-laser oscillator-amplifier system, also containing saturable absorbers. The pump light for all the active media was derived from one XeCl excimer laser in successively split-off beams. Through several stages of cascaded lasers combined with saturable absorption, highly effective pulse shortening takes place. The first three stages consisted of a transversely excimer-pumped, quenched (see paragraph above) dye laser (wavelength 340 nm, pulse length 0.2 ns), which axially pumped a short-cavity dye laser (365 nm, 15 ps). The output was passed through a gated saturable absorber. The resultant (9 ps) pulses transversely pumped the master oscillator, which was another short-cavity dye laser of the distributed-feedback type (see end of Sec. 3.3) producing tunable 0.5-ps pulses. These were then further amplified by a two-stage amplifier (both transversely excimer pumped) with still another saturable absorber for reducing the ASE. The resulting pulses were of 500-fs duration with 0.1-mJ energy; these were then frequency doubled and further amplified in an excimer laser amplifier to result in terawatt-power UV ultrashort pulses. The overall setup is rather complicated, and the reader should consult the reference. Although this system has now been superseded by even more powerful and shorter pulse Ti:sapphire-laser–based systems, it was an important high-power ultrashort-pulse source and provides a very good illustration of the complex systems possible with laser-pumped dye lasers. Both flashlamp and laser-pulse pumping allows the lasing of a large number of dyes (in addition to the efficient dyes used for cw lasing). In particular, dyes down to wavelengths as short as 310 nm have been made to lase, and the range has also been pushed into the infrared to 1.8 μm (Elsaesser and Kaiser, 1992). Table 3 gives a partial list of those dyes that are available commercially (e.g., Exciton Inc). More complete lists can be found in the Further Reading. Flashlamp excitation can also be used for a number of these dyes, but many require the small, fast-rise-time lamps. Laser excitation is very easy to implement but is more expensive. One of the dyes (4-methylumbelliferone) provides an extraordinarily wide tuning range from a single solution (Dienes *et al.*, 1973). No dyes lasing at wavelengths longer than 1.3 μm are included as these are not readily available, are rather unstable, and are seldom used.

Finally, in this section we should mention dye lasers utilizing for gain media dyes dissolved not in liquids, but in solid matrices. This is a relatively recent development and has obvious advantages of ruggedness and compactness. Silica sol-gel and polymeric matrices have both been employed as hosts, for dyes lasing in the blue and near-UV range (Brouwer *et al.*, 1995; Costella *et al.*, 1996; Chao *et al.*, 1996). These dyes are considerably more stable than those lasing in the longer visible and infrared wavelengths. However, even these shorter-wavelength solid-matrix dye lasers have a limited lifetime, much shorter than lasers based on inorganic crystals. Typically their lifetime ranges from a few thousand to several times ten thousand pulses. The simplicity of preparation and the very low cost compensate for the relatively short lifetime, and these simple lasers may find some useful niche applications.

3.3 Tuning and Bandwidth Reduction

Tuning and linewidth reduction for cw dye lasers have already been described in detail in Sec. 2. The intrinsic emission bandwidth of a pulsed dye laser employing a cavity formed by broad-band mirrors is even broader than under cw conditions and can span tens of nanometers. In general, the same principles for linewidth reduction and tuning apply for the pulsed configuration as for the cw case. An important difference is that in the transverse laser-pumped configurations, the gain is very high because of the small cross section of the active region and the high absorbed pump power. As a result, tuning and frequency-control elements with rather high insertion losses can be placed into transversely laser-pumped dye-laser cavities. A single frequency-selective element can offer tuning with a fairly broad bandwidth. A hierarchy of elements is required

Table 3. Pulsed laser dyes.

Dye	Lasing max.[a] (nm)	Wavelength range (nm)	Best laser pump (nm)

for narrow linewidth and precise frequency control. A simple, single tuning-element configuration that can tune the laser and also considerably reduce the laser linewidth consists of a grating mirror resonator (shown in Fig. 17). Early in the history of dye lasers, the use of this configuration enabled Soffer and MacFarland (1967) to demonstrate a linewidth of 0.06 nm from a frequency-doubled ruby-laser–pumped R6G dye laser. The basic principle can be understood by examining Fig. 17, where it is seen that the mirror reflector used at one end of a typical cavity has been replaced by a diffraction grating in the so-called Littrow configuration. In such a configuration a diffraction grating has the property that (for a given order) an incident beam will be reflected back exactly along the direction of incidence, provided

$$2d \cos q = m\lambda, \tag{21}$$

where d is the ruling distance, q is the angle between the incident ray direction and its projection on the grating surface, λ is the optical wavelength, and m is the order of diffraction. It is evident that the laser will operate at the wavelength that satisfies the above condition. The frequency discrimination of this setup depends on the divergence of the beam incident on the grating, as well as on the number of lines illuminated.

A more sophisticated approach uses the concept of beam expansion in the cavity. By expanding the beam, the divergence is decreased, and the number of grooves being illuminated at the grating is increased. The single-pass resolution $\Delta\lambda$ is given by

$$\Delta\lambda = \Delta\theta\left[M\frac{\partial\phi}{\partial\lambda}\right]^{-1} = \Delta\theta\left[M\frac{2\tan\phi}{\lambda}\right]^{-1}, \tag{22}$$

where $\Delta\theta$ is the beam divergence, $\partial\phi/\partial\lambda = 2 \times \tan\phi/\lambda$ is the total dispersion provided by the grating, and M is the beam magnification factor in the cavity, which improves the resolution by a factor M. Beam magnification is especially necessary in the transverse-pumped configuration. Because only a thin region near the inner wall of the dye cell is excited by the pump light (see Fig. 17), diffraction causes a substantial angular spread of the emerging light. Since the resonant condition depends on the incident angle and wavelength, and because only a small area of the grating would be illuminated by the beam, this would severely limit the resolution obtainable with the grating. Telescopic beam expanders (Hänsch, 1972) and prism beam expanders (Duarte and Piper, 1980) have both been used, but the latter is being used almost exclusively today. Telescopic expanders provide a beam magnification of 20 to 50 times and have a length that depends on the focal length of the lenses utilized. The intracavity lenses must be antireflection coated to minimize Fresnel losses and must add elements that compensate for aberrations. Such a system was first implemented by Hänsch (1972) and resulted in a very narrow output bandwidth. Using an inverted telescope with lenses of focal length 8.5 and 185 mm and a high-order echelle grating in a cavity ~40 cm long, an output linewidth of ~3 pm (or about 2.5 GHz at the R6G wavelengths) was achieved. Further reduction of the bandwidth to about 300 MHz resulted from the addition of a Fabry-Pérot etalon with a finesse of 20, made of coated solid fused silica. The wavelength was coarsely tuned by changing the grating angle and finely tuned by adjusting the etalon angle. An important characteristic of this laser was that, since the cavity was relatively long, only a few cavity round-trip passes could take place during the duration of the pump pulse. Therefore, no discrete axial-mode structure existed in this dye laser. Instead, the output was a continuum of frequencies with bandwidth about the same as that of the narrowest wavelength-selector element. As a result, the wavelength could be tuned smoothly without complicated feedback control of the cavity length as is necessary in cw dye lasers (see Sec. 2.2.5).

Today, transverse laser-pumped dye lasers with prism expanders have replaced the above system for current usage. The basic design considerations are very similar, with the main difference being in the geometric arrangement of the prism expander. A typical setup is shown in Fig. 19 and is essentially the same as first reported by Duarte and Piper (1980), but with pumping by excimer lasers or by the doubled output of Nd:YAG laser now most common. Two right-angled prisms are utilized together with a high-order echelle grating in the Littrow configuration. Although a large expansion factor (*M*) can be obtained even with a single prism, this would necessitate an angle of incidence very close to 90°, resulting in high losses and therefore reduced power output and a high fraction of undesirable broad-band amplified spontaneous emission (ASE). Using two prisms, the same expansion factor is obtained at smaller incidence angles, resulting in better efficiency with equally good resolution. The fraction of the undesirable ASE is also greatly reduced. The dye-laser output is taken from a broad-band coupling mirror (*M*1), which has high transmission (~90%) due to the high laser gain. With only the grating and the prisms in the cavity, a linewidth around 0.8 pm can be achieved (Duarte and Piper, 1980). Further reduction, as noted before, can be obtained by additional hierarchic frequency selectors (e.g., etalons). It should be noted that, for this type of arrangement, the dispersion of the prisms adds to the main contribution from

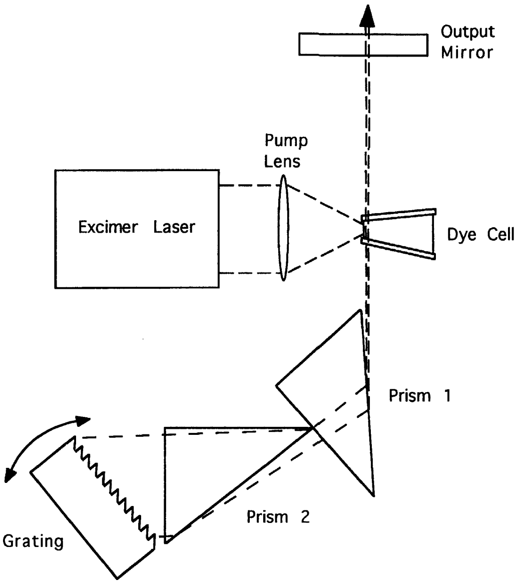

FIG. 19. Typical narrow-band excimer-laser–pumped dye laser showing a two-prism beam expander and a diffraction grating for bandwidth narrowing and wavelength tuning (after Duarte and Piper, 1980).

the grating and must be included as a small correction in the calculation of the linewidth. Detailed theories of prism beam expanders have been reported (Duarte and Piper, 1980, 1983).

Longitudinally laser-pumped configurations are tuned and bandwidth narrowed by similar methods, except that beam expansion is usually not necessary. Recently, a diffraction grating and one intracavity etalon have been used to control precisely the output of a high-power, Nd:YAG-laser–pumped pulsed R6G dye laser (Bhatia and Keto, 1996). An absolute precision of ±0.4 pm has been demonstrated in high-efficiency (40%), high-energy (100-mJ output pulses) operation. Birefringent filters can also be used for tuning of laser-pumped dye lasers. Because of the high gain, up to four plates can be used to achieve very narrow-band output (Zagone and Hetherington, 1996). Because of the broad gain bandwidth of most dyes and because it is possible to mix several dyes in a single solution, multiple-wavelength output can also be readily achieved in laser-pumped pulsed dye lasers. The high gain easily allows the sharing of the dye gain medium by two or more cavities with independent tuning elements (Khare *et al.*, 1995; Ko *et al.*, 1996).

As a result of the much larger cross section of the active volume, flashlamp-pumped dye lasers have much lower gain than transverse laser-pumped systems. Therefore, intracavity gratings cannot be used for tuning and linewidth reduction. However, all the tuning elements suitable for cw dye lasers (described in Sec. 2.2.5) can be used, with similar results. In general, one is satisfied with a moderate linewidth in these systems, and there is normally no attempt to obtain single-mode operation. An alternative linewidth-reduction method used in the early days involved a flashlamp-pumped system that incorporated intracavity isosceles prisms in conjunction with a tuning mirror (Strome and Webb, 1971). (The same principle, with a single prism, was also used in one of the first tunable cw dye lasers; Dienes *et al.*, 1972). The prism method also opens the possibility of ring-type systems. Schäfer and Müller (1971) incorporated six 60° prisms into a ring cavity and obtained a linewidth of less than 0.05 nm with a 40-J electrical-input-energy pumping. An advantage of such a multiple-prism ring cavity is that it obviates the need for mirrors with broad-band dielectric reflective coatings. Aspects of linewidth reduction and tuning using prisms are covered in several references (Marowsky, 1973; Yamagishi and Inaba, 1976). Today, practical flashlamp-pumped lasers use single or multiple prisms as well as Lyot filters and etalons to achieve tuning and output bandwidth control. For long-pulse flashlamp-pumped systems, very narrow-band and even single-mode operation has been achieved (Mandl *et al.*, 1995) by essentially the same methods as are used for cw dye lasers.

Finally, the method of distributed feedback (DFB) should be briefly described. This method, which now is most widely used in semiconductor diode lasers, was first demonstrated in an N_2-laser–pumped dye laser (Kogelnik and Shank, 1971). To achieve distributed feedback, a gain and/or index grating is made along the length of the gain medium to provide frequency-selective feedback, which is governed by the well-known Bragg condition. When implemented in a transverse-pumped dye laser, the grating results either from pumping with two beams at an angle (Kogelnik and Shank, 1971; Bor, 1980), which makes an interference pattern in the total pump intensity, or from imaging a coarse transmission grating in the path of the pump beam onto the dye cell. The laser output can be from moderate to narrow width and can be tuned by changing the grating period. Another advantage of this method is that the mirrorless cavity has a decay rate that is pump-intensity dependent, which favors short-pulse formation (Bor, 1980). This type of tuning arrangement was used in the master oscillator of the terawatt system described in Sec. 3.2. Recently, a system with two independently tunable DFB dye lasers, pumped by the second and third harmonics of a picosecond Nd:YAG laser, has been reported (Mueller, 1996). The ~12-ps output pulses were continuously tunable, with computer control, from 400 to 750 nm.

4. APPLICATIONS OF DYE LASERS

The enormous continuously covered wavelength range, the great range of available powers, and the many different kinds of outputs ranging from cw single mode with a few-megahertz bandwidth to a continuous train of *femtosecond* pulses (cw mode locked), as well as to pulse-pumped with durations from many microseconds to subnanosecond at a variety of repetition rates, allow a countless number of possible applications for dye lasers. Detailed descriptions of the many applications are properly given elsewhere. Here only a few important ones are mentioned with some examples described in more detail. Dye-laser applications include the industrial and the medical and biological areas, where a particular wavelength range and moderate energies may be needed, but there are no narrow-bandwidth or short pulse-duration requirements, to experiments in isotope separation requiring narrow linewidth and precise control, together with high cw power. The most obvious and probably the most important applications, however, are in spectroscopy, in laser manipulation of atoms and molecules, and in measurements of various chemical reaction dynamics. Various pulsed-laser–pumped systems, such as the ones described in Sec. 3.3, are today the cornerstone of molecular reaction-dynamics studies, and they are ubiquitous in chemistry departments of research universities. An important subset of reaction dynamics and spectroscopy is ultrafast spectroscopy (*q.v.*), which involves measurements of processes in liquid and solid-state materials on a femtosecond time scale. The wide bandwidth and tunability of the dye laser is essential in all these applications. It should also be noted that all pulse-laser–pumped as well as mode-locked dye lasers can readily be frequency doubled in nonlinear crystals, further extending into the UV the available wavelengths. Although today solid-state lasers and tunable systems based on them, such as optical parametric oscillators (OPO's), cw, pulsed, and cw mode-locked, are rapidly making inroads into the domain of dye-laser applications, dye lasers remain widely used because no other source has demonstrated the flexibility and the availability of all wavelengths within the very large range from the UV to the infrared.

The following historically important application to high-resolution spectroscopy is a good illustration of the possibilities in this field. The narrow-band N_2-laser–pumped system of Hänsch described briefly in Sec. 3.3 was used to perform a precise measurement of the Rydberg constant (Hänsch *et al.*, 1974) by saturation spectroscopy of the red Balmer line in hydrogen and deuterium. To narrow further the spectral width of the source laser, a scanning Fabry-Pérot interferometer was added externally. This narrowed the bandwidth to 7 MHz, and also allowed precise tuning of the frequency. Saturation spectroscopy (Hänsch *et al.*, 1972) is a powerful cw (or long-pulse) pump-probe technique to find accurately the line center of Doppler-broadened transitions. In the version used for this experiment two counterpropagating laser beams are used to probe the absorption. Moving atoms "see" the two beams Doppler shifted in frequency in opposite directions. Consequently, only atoms with zero velocity along the propagation axis experience interaction with both beams. The strong saturating beam bleaches (saturates) the absorption for the weak probe, and thus a saturation signal is obtained at the true line center. The bandwidth of this signal is the pressure-broadened homogeneous linewidth, which is very narrow in a low-pressure discharge, providing great accuracy in locating the exact resonance. To measure the Rydberg constant, the absolute wavelength of the dye laser for maximum saturation signal was determined by comparison with a separate, stabilized He-Ne laser (locked to a hyperfine component of an $^{129}I_2$ line). The final result was a more precise determination of this fundamental constant to an accuracy of 4 parts in 10^9. Such a resolution attests to the great flexibility and utility of the dye laser as a tunable source. Although now a quarter century old, this *tour de force* experiment still stands as an example of the power of applicability of the dye laser. Similar fundamental measurements by precision spectroscopy are still being performed today using dye lasers. For example, the frequency-doubled output of a modified commercial cw dye laser (Coherent CR 699) at 486 nm was stabilized to a high-finesse Fabry-Pérot cavity, and was used for narrow-linewidth two-photon spectroscopy of the 1*S*–2*S* transition at 243 nm in atomic hydrogen and in deuterium (Leibfried *et al.*, 1995). By directly comparing the frequencies of this transition in the two different isotopes, the isotope shift was deduced and information about the nuclear structure of deuterium was extracted.

Countless experiments on molecular reaction dynamics have been performed using the nanosecond-range pulses from laser-pumped tunable dye lasers, such as the prism-tuned excimer-pumped system described in Sec. 3.3. An interesting subset is the study of excited-state reactions. Atoms or molecules can be prepared in an excited state in sufficient density to allow easy observation of excited-state reactions. As one of many possible examples, the reaction of two-photon–excited Xe and Kr atoms with molecular hydrogen has been investigated using this type of dye laser, which was frequency doubled into the UV (Kawasaki *et al.*, 1992). It is noteworthy that the pulses of this laser are powerful enough that even after frequency doubling sufficient power was available for two-photon excitation.

In contrast to the above-described experiments, ultrashort-pulse spectroscopy uses mode-locked laser pulses for pump-probe exploration of spectrally dependent events on a very short time scale. Tunability is minimal, as a large fraction of the available gain bandwidth is lasing. The shortest optical pulses reported to date (~6 fs) were derived from a mode-locked cw dye laser by external pulse compression (Fork *et al.*, 1987). In the spectral domain, such a pulse corresponds to a coherent (perfectly in phase) superposition of frequencies in a band as wide as the entire (S_0–S_1) absorption band of a typical dye. In a pump-and-probe experiment with such pulses (Fragnito *et al.*, 1989), the entire vibrational band of the S_1 level of the dye malachite green was excited by a pump pulse. The absorption changes were then probed with probe pulses from the same source with ~6-fs resolution. The measured three-dimensional surface of absorption vs wavelength and time showed very distinct oscillations with a time period of 60 fs. These were attributed to vibrational distortions of the ring structure that were coherently excited by the femtosecond pulse. These oscillations persisted for a time longer than 1 ps corresponding to the vibrational dephasing time. It is interesting to note that the continuing presence of these oscillations at the "long" delay time of 1 ps demonstrates that excitation was done on a time scale three orders of magnitude shorter! Other recent ultrashort-pulse spectroscopic applications of mode-locked dye lasers include investigations of fast chemical reactions. Among these are studies of unimolecular dissociation (Rosker *et al.*, 1988), the observation of short-lived intermediate states in bimolecular reactions (Scherer *et al.*, 1987), and investigations of the ultrafast dynamics of isomerization reactions (Banares *et al.*, 1992).

Although the above brief descriptions do no more than give a glimpse into the many applications possible with dye lasers, they do serve to illustrate the tremendous range of possibilities opened up by the family of different dye lasers available to researchers today.

INTRODUCTION

The tunnel diode was first discovered by Leo Esaki in the course of his work on bipolar transistors (Esaki, 1958, 1976). Others about this same time (1957) were on the verge of the same discovery (Pearson, 1957) but fell a measurement short of seeing the distinctive *N*-shaped current–voltage (*I–V*) characteristic of the tunnel diode (see Fig. 1). Since Esaki's original work, which lead to a Nobel prize in physics in 1973, the tunnel diode has been produced in most of the common binary and compound semiconductors, and in numerous heterostructure devices. Interest in the device for electronic applications arose almost immediately upon its discovery because of its remarkable multivalued *I–V* characteristic, which features both negative differential resistance and an ultrahigh-speed transient response. This uniqueness and versatility has retained commercial and academic interest even to the present; however, only discrete devices are commercially available. Device and circuit development is, for the most part, limited to research laboratories.

Current flow in the tunnel diode is governed by the principles of quantum-mechanical particle tunneling, a direct consequence of the fact that matter has both a wave and a particle aspect. (The term *diode* arises from its original discovery in semiconductor *p-n* junctions, but the tunnel diode bears little resemblance to the common *p-n* diode.) In the particular case of a semiconductor device, the particle aspect of electron transport is most often used to describe current flow. To engineer electron transport in a device, potential-energy barriers are commonly formed by the introduction of *p-n* junctions, oxide–semiconductor interfaces, or heterojunctions (junctions formed between dissimilar materials, e.g., AlGaAs/GaAs). An electron can cross over these barriers if it has total energy exceeding the energy barrier height; otherwise, classically, it is constrained to flow alongside the barrier. Ac-

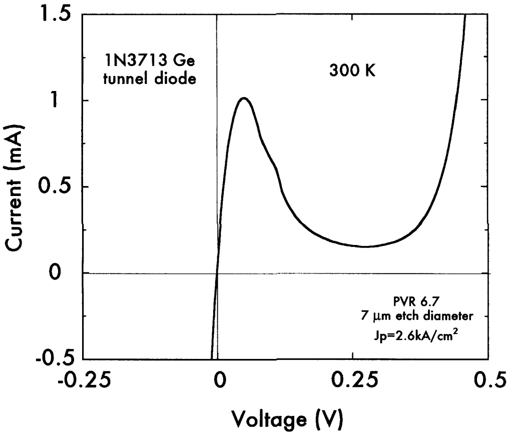

FIG. 1. Measured current–voltage characteristic for a commercial germanium Esaki tunnel diode.

cording to quantum theory, however, a particle such as the electron actually penetrates into any potential barrier for some distance, similar to the way light slightly penetrates an opaque metal surface. As a consequence of this wave penetration property, if a potential barrier is thin relative to the electron's Bloch wavelength, the particle can sometimes slip freely through the barrier without paying the energy costs to surmount it. This ghostlike passage through a barrier is referred to as tunneling.

In the original tunnel diode, also known as the Esaki diode, the barrier through which tunneling occurs is the space-charge depletion region of a *p-n* junction. Potential barriers can also be formed by heterojunctions. These junctions are usually produced by an epitaxial crystal growth process from semiconductors with similar crystallinity, but with different band-gap energies. At the heterojunction, a potential-energy discontinuity results, creating an abrupt potential barrier.

There are many devices that are referred to as tunnel diodes, which can refer to any two-terminal device where the charge transport can be attributed to tunneling; this includes semiconductor p^+n^+ Esaki diodes, resonant-tunneling diodes (RTD), resonant interband tunnel diodes (RITD), metal/insulator/semiconductor tunnel diodes, and metal/insulator/metal tunnel diodes. To limit the scope of this article we focus on devices that exhibit the characteristic *N*-shaped current–voltage behavior of the original Esaki diode. This limitation still covers the greatest body of work on tunnel diodes.

The RTD was first demonstrated by Chang *et al.* (1974), and, subsequently, the RITD was demonstrated by Söderström *et al.* (1989) and Luo *et al.* (1989). In addition to these semiconductor embodiments, the RTD has also been formed in metal– and semimetal–semiconductor heterojunctions (Suemasu *et al.*, 1992; Brehmer *et al.*, 1995) and amorphous semiconductor heterojunctions (Hirose *et al.*, 1977; Miyazaki *et al.*, 1987).

In this article we cover both the physics and technology of the Esaki and heterostructure tunneling diodes. We have surveyed and compared the properties of tunnel diodes across a wide variety of materials including semiconductor groups IV, III–V, and II–VI, and mixed-material structures. Only a few applications for the tunnel diode exist today, but the tunnel diode's high intrinsic switching speed, the fastest of any semiconductor device, and the opportunities for ultrafast and low-power circuits continue to attract attention. Applications and technology prospects are the subjects of the final sections.

1. TUNNEL-DEVICE PHYSICS

The two broadest classes of tunnel diodes that exhibit the *N*-shaped characteristic of Fig. 1 are the unipolar, intraband RTD (Mizuta and Tanoue, 1995; Brown, 1994; RESONANT TUNNELING) and the bipolar interband Esaki diode (Sze, 1981). At first glance, these two classes of structures appear to share little in common. The physics of electron transport through the RTD is based on resonant tunneling through a double-barrier structure analogous to a Fabry-Pérot cavity, whereas the physics of electron transport through the Esaki diode is based on single-barrier tunneling across the energy-band gap at a *p-n* junction.

A unifying perspective for these devices emerges if one considers the conservation laws that they share, namely, conservation of total energy and conservation of transverse momentum (*transverse* refers to the direction perpendicular to the current flow; *longitudinal* refers to the direction parallel to the current flow). We begin by considering an ideal structure, free of scattering from impurities, alloy disorder, interface roughness, and phonons. Later, we will consider the case with scattering, where an incident electron can transfer into a state of different total energy and transverse momentum.

In both intraband and interband devices, the electron transport is typically in the same direction as the crystal growth, generally (100), and the devices have wide cross-sectional area relative to the Bloch wavelength. Since, in the ideal structure, there is no force acting in the transverse direction, transverse momentum is conserved. While devices of small cross-sectional area are built in research laboratories (Reed *et al.*, 1988; Mizuta and Tanoue, 1995), we consider only wide–cross-sectional area devices, since they are of current technological interest. Similar energy and momentum conservation arguments can be used to understand the effects of small–cross-sectional area devices, in which the transverse energies are quantized (Liu and Aers, 1989; Bagwell *et al.*, 1990).

Discussions of tunnel-device current tend to focus on the calculation of the quantum-mechanical transmission coefficient. The widely used approaches are discretizing the potential into a series of steps and then connecting the wave functions at each step using a transmission matrix (Mizuta and Tanoue, 1995), a direct matrix solution of the tight-binding localized-orbital Hamiltonian (Frensley, 1994; Ting and McGill, 1995), a recursive Green's-function solution (Støvneng and Hauge, 1991), a transfer-Hamiltonian approach (Mizuta and Tanoue, 1995; Payne, 1986; Duke, 1969), or a Wentzel-Kramers-Brillouin (WKB) approximation (Sze, 1981). We instead focus on the implications of energy and momentum conservation, quoting the form of the transmission coefficients as needed.

The characteristics of most interest for these devices are the peak current density and the peak-to-valley current ratio (PVR). For high-speed applications such as logic, high current density is required for fast charging and discharging of the device and circuit capacitances. For low-power operation such as in memory, low current density is needed to minimize the static power dissipation. We develop here the underlying physics for device design for high and low peak current-density devices, and the factors controlling the PVR.

1.1 Resonant-Tunneling Diode

Analysis of the RTD begins with Fig. 2, which displays the conduction-band energy–position and energy–momentum relationships. The double potential barriers constituting the RTD are shown in the energy–position (E_x–x) diagram at the right of Fig. 2. The conduction-band profile is translationally invariant in the transverse (yz) plane. The quasi-Fermi levels in the left contact, E_F, and right contact, $E_F - eV$, are split by the applied voltage V. The horizontal line between the barriers represents the energy $E_{x,\text{res}}$, of the resonant state. Just as in a high–electron-mobility transistor, the resonant energy represents the bottom of a two-dimensional electron gas (2DEG). It is the total energy E of the state with zero transverse momentum. As bias is applied, the resonant level is pulled down to the Fermi level of the emitter. At this point, when $E_{x,\text{res}} = E_F$, the current turns on. As the bias is increased, the resonant level $E_{x,\text{res}}$ is pulled deeper into the incident flux from the Fermi sea of the emitter.

The parabola, just left of center in Fig. 2, represents the longitudinal energy dispersion, $E_x = \hbar^2 k_x^2/2m^*$, where $\hbar$ is Planck's constant ($h/2\pi$, $h = 4.135 \times 10^{-15}$ eV·s), k_x is the electron wave vector in the longitudinal direction, and m^* is the electron's effective mass in the crystal, which is typically 10 to 100 times less than the free-electron mass $m_0 = 9.109 \times 10^{-31}$ kg. The resonant energy $E_{x,\text{res}}$ corresponds to a resonant incident momentum $\hbar k_{x,\text{res}}$.

The Fermi sphere shown in Fig. 2 represents the relationship between the electron momentum in the transverse and longitudinal directions at a constant energy given by the Fermi energy. The indicated disk represents the transverse momentum states with the appropriate energy for resonance, $E_{x,\text{res}}$. The states represented by this disk are the ones that contribute to the current (Iogansen, 1965; Luryi, 1985). The current is obtained by multiplying the incident current flux per unit longitudinal energy E_x by the intrinsic width of the resonance, Γ_i, and by the number of transverse states in the shaded disk. The incident current flux per unit longitudinal energy is $2env$, where e is the electron charge ($e = 1.602 \times 10^{-19}$ C), n is the electron density per unit length and

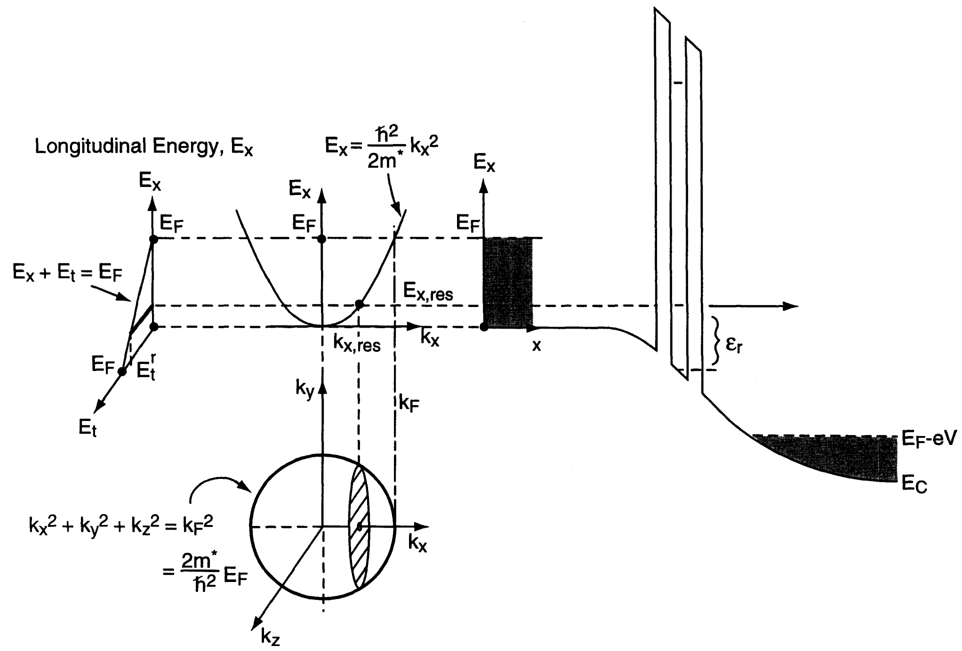

FIG. 2. Conduction-band profile of an RTD. $E_{x,\text{res}}$ is the total energy of the resonant state with zero transverse momentum. The parabola in the left contact (the emitter) represents the longitudinal energy dispersion. The Fermi sphere represents the momentum states in the emitter. The resonant states lie in the shaded circle. The triangle represents the same states in terms of energy. The resonant states lie on the horizontal line. The number of states on the line is the 2D density of states times the length of the line, $(m^*/2\pi\hbar^2)(E_f - \epsilon_r)$. The illustration was conceived by P. van der Wagt, Texas Instruments.

energy, $n = (2\pi\partial E_x/\partial k_x)^{-1} = m^*/2\pi\hbar^2 k_x$, $v = \partial E_x/\partial\hbar k_x = \hbar k_x/m^*$ is the velocity, and the factor of 2 is for spin degeneracy. Multiplying these factors together yields the incident current flux per unit longitudinal energy as $2e/h$. The number of transverse states is $1/(2\pi)^2$ times the area of the shaded disk. The area is $\pi(k_F^2 - k_x^2) = \pi(2m^*/\hbar^2)(E_F - E_{x,\text{res}})$. Multiplying the terms together gives the number of transverse states resonantly tunneling:

$$\frac{\text{number of transverse states}}{\text{unit area}} = \frac{m^*}{2\pi\hbar^2}(E_F - E_{x,\text{res}}). \tag{1}$$

Putting this all together, we get a resonant current flowing of

$$I_{\text{res}} = \frac{2e}{h}\Gamma_i \frac{m^*}{2\pi\hbar^2}(E_F - E_{x,\text{res}}),$$
$$E_c < E_{x,\text{res}} \leq E_F. \tag{2}$$

For a symmetric device, this simple derivation based on state counting differs by only a factor of $\pi/2$ from a rigorous derivation (Lake *et al.*, 1993). Note that the entire quantum mechanics of the problem is contained in Γ_i, the intrinsic resonance width. It is determined by the transmissivity of the left and right barriers (Lake *et al.*, 1993). The exact expression is

$$I_{\text{res}} = \frac{2e}{\hbar}\frac{\Gamma_L\Gamma_R}{\Gamma_L + \Gamma_R}\frac{m^*}{2\pi\hbar^2}(E_F - E_{x,\text{res}}),$$
$$E_c \leq E_{x,\text{res}} \leq E_F, \tag{3}$$

where Γ_L and Γ_R are the energy widths associated with tunneling out of the left and right barriers, respectively. The intrinsic resonance width resulting from tunneling through the barriers is $\Gamma_i = \Gamma_L + \Gamma_R$. The factor Γ_L is proportional to $v_x e^{-2\kappa d}$, where v_x is the incident longitudinal velocity, d is the left barrier width, and κ is the decay constant in the left barrier, $\kappa = \sqrt{2m^*(V_B - E_x)}/\hbar$. V_B is the potential of the left barrier. Γ_R is defined in the same way with respect to the right barrier. Equation (3) shows that the current density is exponentially sensitive to the barrier height and width.

Since the resonant energy tends to fall linearly with the applied bias, I_{res} increases linearly with bias. Once the resonant energy falls below the conduction band of the emitter, electrons can no longer tunnel while conserving both total energy and transverse momentum, and the current must flow through scattering channels (phonons, impurities, alloy, and interface disorder) or by thermionic emission.

This picture of resonant tunneling, to this point, mixes both energy and momentum. If we convert the momentum into energy, then the Fermi half-sphere for $k_x > 0$ becomes the Fermi triangle shown at the left of Fig. 2; $E_x = \hbar^2 k_x^2/2m^*$ and $E_t = \hbar^2(k_y^2 + k_z^2)/2m^*$. The shaded disk of transverse momentum is collapsed into the horizontal line of transverse energy. The number of resonant transverse states is then $(m^*/2\pi\hbar^2)E_{t,\mathrm{res}} = (m^*/2\pi\hbar^2)(E_{\mathrm{F}} - E_{x,\mathrm{res}})$, where $m^*/2\pi\hbar^2$ is the two-dimensional density of states (Beenakker and Van Houten, 1991). This is a useful way of viewing the source function.

The foregoing discussion works well for the unipolar, intraband RTDs. It is only entirely accurate when the Hamiltonian is separable. For three-dimensional emitters that contain a continuum of states in E_x, the differences between this idealized picture and the actual picture tend to get lost in the integration over energy. For two-dimensional emitters where electrons are being injected from a quantized state in the emitter, the picture can break down (Boykin *et al.*, 1995).

The above discussion has served to elucidate the common picture that one finds in the literature. However, we need to alter this picture to one that can also be used to analyze the interband, bipolar Esaki-type tunnel diodes. This picture is shown in Fig. 3. It is the one discussed by Ohno *et al.* (1990). The horizontal lines in the emitter represent the continuum of E_x states. Each energy E_x serves as the bottom of a two-dimensional subband represented by the parabolic dispersion. Note well that in contrast to Fig. 2, the parabolas in Fig. 3 represent the dispersion of the transverse energy E_t with respect to the transverse momentum $k_t = \sqrt{k_y^2 + k_z^2}$. The vertical axis on this plot is now *total energy E* as opposed to *longitudinal energy* E_x in Fig. 2. For an electron to tunnel, it must conserve total energy and transverse momentum. Figure 3 illustrates what this implies. All of the electrons in the emitter parabola that align with the well parabola can resonantly tunnel. The number of states in that parabola is directly read off to be $(m^*/2\pi\hbar^2)(E_{\mathrm{F}} - E_{x,\mathrm{res}})$, resulting in the same current I_{res} as before.

The energy of the resonance, ϵ_r, is determined by the transmissivity of the barriers and the width of the well. As a first approximation, the resonant level can be estimated by a particle-in-a-box calculation, $\epsilon_r = (\hbar^2/2m^*)(n\pi/w)^2$, where n is an integer equal to 1 for the first resonance, 2 for the second resonance, and so on; w is the width of the well, and ϵ_r in eV is measured from the bottom of the conduction band in the well (see

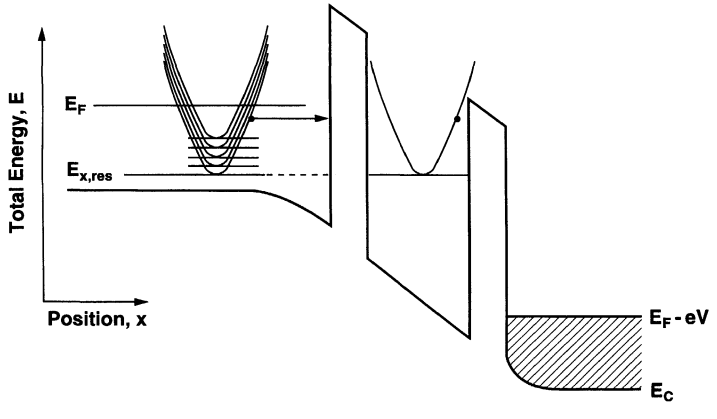

FIG. 3. A third picture of the incident states. Each longitudinal energy E_x is the bottom of a two-dimensional (2D) subband of transverse-momentum states. The resonant state in the well is also the bottom of a 2D subband of transverse-momentum states. The parabolas show the dispersion relations of the 2D subbands. The states in the emitter parabola that align with the parabola in the well can resonantly tunnel. This picture can be used for the interband tunnel devices.

Fig. 2). The well-width dependence of the resonant energy allows for good flexibility in engineering the voltage position of the peak current.

1.2 Esaki Diode

The band diagram of the traditional Esaki diode is shown under forward bias in Fig. 4(a). As bias is applied, electrons flow from the filled emitter states in the conduction band on the left to empty states in the valence band on the right. As bias is increased, the conduction band of the emitter is eventually raised above the valence band of the collector, electrons can no longer tunnel into a valence-band state while conserving both total energy and transverse momentum, and the current is reduced to a minimum determined by thermionic emission and scattering. As in Fig. 3, each longitudinal energy E_x serves as the bottom of a transverse subband. However, now the subbands are inverted from one another. For the two subbands shown, only those electrons can tunnel that lie in states on the intersecting ring shown in Fig. 4(b).

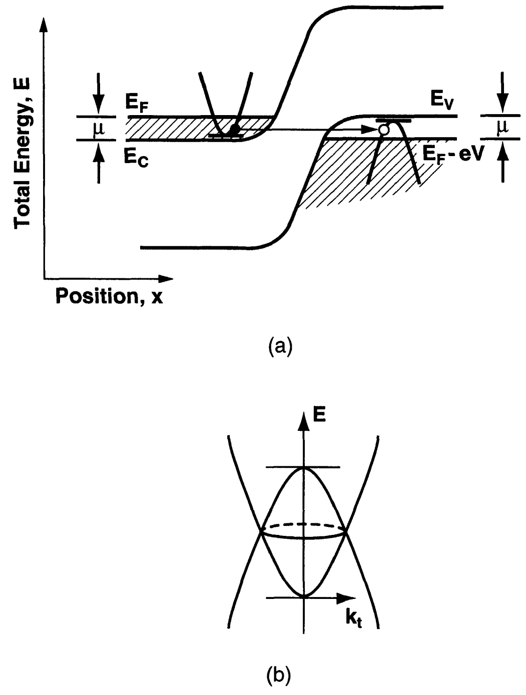

FIG. 4. (a) The band diagram of a traditional Esaki diode under forward bias. Each longitudinal energy E_x serves as the bottom of a 2D subband of transverse states; however, now the subbands are inverted from one another. (b) For the two subbands shown in (a), only those states that lie on the intersecting ring can tunnel conserving both total energy and transverse momentum.

To focus on the effect of energy and momentum conservation, we consider a direct-band-gap material and calculate the zero-temperature current assuming that the transmission coefficient is constant, the electron and hole effective mass are equal, and the doping is such that $\mu = E_F - E_c = E_v - (E_F - eV)$. The general expression for the current is

$$I = \frac{2e}{h}\int dE\,\frac{m^*}{2\pi\hbar^2}\int dE_t T(E,E_t) \times [f(E - E_F) - f(E - E_F + eV)], \qquad (4)$$

where $T(E,E_t)$ is the transmission probability, f is the Fermi factor $f(E) = [\exp(E/k_BT) + 1]^{-1}$, T is temperature, and k_B is Boltzmann's constant ($k_B = 8.617 \times 10^{-5}$ eV/K). At zero temperature, the Fermi factors are step functions that determine the limits on the integration over total energy; e.g., $f(E - E_F) = \theta(E_F - E)$. The total energy E is integrated between the two Fermi levels, E_F and $E_F - eV$. For an electron to tunnel from the left to the right in Fig. 4, its initial and final longitudinal energy, E_x, must lie above the conduction band on the left and below the valence band on the right, respectively. The limits on the integration over transverse energy, $E_t = (\hbar^2/2m^*)(k_y^2 + k_z^2)$, are understood by noting that $E_x = E - E_t$ in the conduction band and $E_x = E + E_t$ in the valence band. For a bias V such that $0 \le eV \le \mu$, the current is proportional to the integral

$$I \propto \left[\int_0^{eV/2} dE \int_0^{E-E_C} dE_t + \int_{eV/2}^{eV} dE \int_0^{E_V-E} dE_t\right] = eV\left(\mu - \frac{3}{4}eV\right), \quad 0 \le eV \le \mu, \qquad (5)$$

where we have taken the quasi-Fermi level of the right contact as the reference energy, i.e., $E_F - eV = 0$, so that $E_c = eV - \mu$ and $E_v = \mu$. Taking the derivative of Eq. (5) with respect to voltage, we see that the current peaks when $eV = \frac{2}{3}\mu$ (Sze, 1981). For a bias V such that $\mu \le eV \le 2\mu$, the current is proportional to the integral

$$I \propto \left[\int_{E_C}^{eV/2} dE \int_0^{E-E_C} dE_t + \int_{eV/2}^{E_V} dE \int_0^{E_V-E} dE_t\right]$$
$$= (\mu - eV/2)^2, \quad \mu \le eV \le 2\mu. \tag{6}$$

Since $E_C > E_F - eV$ and $E_F > E_V$, the total energy is now integrated only between E_C and E_V.

A plot of I vs V from Eqs. (5) and (6) is shown in Fig. 5. The turnoff of the ideal Esaki diode is gradual, determined by the decreasing number of states available for tunneling as the bias is increased. The turnoff of the ideal RTD is more abrupt, determined by the resonance width.

The tunneling transmission probability is usually approximated by the expression for Zener tunneling under a uniform electric field (Sze, 1981),

$$T = \exp\left(-\frac{\pi m^{*1/2} E_G^{3/2}}{2\sqrt{2}\hbar e\mathscr{E}}\right) \exp\left(-\frac{2E_t}{\bar{E}}\right), \tag{7}$$

where E_G is the band gap, $\mathscr{E}$ is the electric field, E_t is the transverse kinetic energy, and

$$\bar{E} = \frac{4\sqrt{2}\hbar e\mathscr{E}}{3\pi m^{*1/2} E_G^{1/2}}. \tag{8}$$

It is interesting to note that the transmission probability in Eq. (7) is only a function of the transverse kinetic energy and independent of the longitudinal energy E_x. Under a uniform electric field, the barrier presented by the band gap is the same for any E_x.

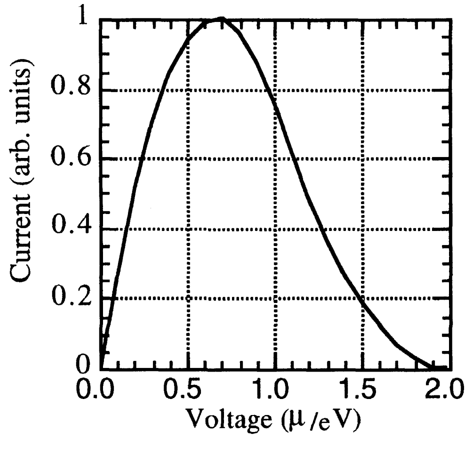

FIG. 5. Esaki-diode current–voltage characteristic calculated from Eqs. (5) and (6).

From the perspective of a device designer, Eqs. (7) and (8) teach that there is little flexibility in designing homojunction Esaki diodes for a specific current density. The electric field is set by the built-in potential of the p-n junction, which is determined by the magnitude and spatial abruptness of the doping transition. The band gap is fixed for a given material. Once the electric field is determined, only the device area can be used to modify the current density.

Recently, heterostructure Esaki diodes have been built (Tsai *et al.*, 1994; Day *et al.*, 1993); see Fig. 6. In these devices, the tunneling occurs between an electron 2DEG in the n^+ $In_{0.53}Ga_{0.47}As$ notch and the light-hole 2DEG in the p^+ $In_{0.53}Ga_{0.47}As$ notch. For these devices, the two subbands shown in Fig. 6 are the only two subbands that contribute to the current. (Actually, there is a heavy-hole subband that gives a small secondary peak in the I–V curve.) These structures are resonant triple-barrier devices (Iogansen, 1965; Malov *et al.*, 1988; Xu *et al.*, 1992; Payne, 1985), in which the resonant states on the intersecting ring of Fig. 4(b) coherently couple and split into bonding and antibonding states. For an alignment as shown in Fig. 4(b), in which the transverse energy of the electron and hole state is much greater than either the coherent splitting re-

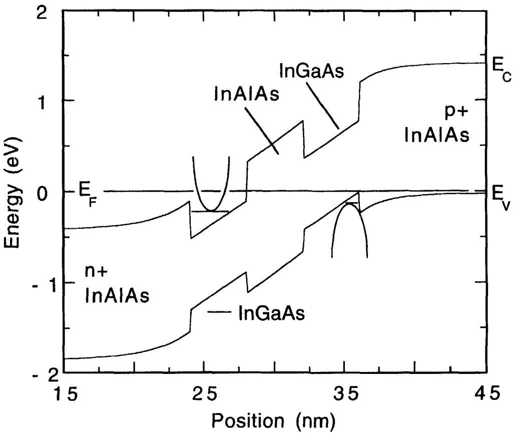

FIG. 6. Computed energy-band diagram for the published resonant interband tunnel diode of Tsai *et al.* (1994) exhibiting a peak-to-valley current ratio of 144 at room temperature. The parabolas represent the two-dimensional electron and hole subbands. (Computed using the heterojunction modeling program *Bandprof* of W. R. Frensley.)

sulting from the coupling or the intrinsic broadening resulting from leakage into the emitter and collector contacts, the number of tunneling states becomes independent of bias. There is no theoretical work explaining the shape of the *I–V* characteristics shown by Tsai *et al.* (1994) and Day *et al.* (1993). The *I–V* characteristics of the optimized devices that show the highest peak-to-valley ratio (see Fig. 1 of Tsai *et al.*, 1994, and Fig. 2 of Day *et al.*, 1993) exhibit the effects of quantum well charging discussed by Malov *et al.* (1988).

For interband tunneling in indirect-gap semiconductors such as silicon, only those conduction electrons in the longitudinal X valleys (on the k_x axis) can directly tunnel into the valence-band Γ valley while conserving both transverse momentum and total energy (see Fig. 7). The potential $V(x)$ breaks the crystal symmetry along the x axis so that k_x is no longer a good quantum number. k_y and k_z, however, must be conserved in the transition from the X valley of the conduction band to the Γ valley of the valence band. The transverse momentum in the longitudinal X valleys lies close to the k_x axis in the same region as the transverse momentum of the Γ valley valence-band states. The electrons in the transverse X valleys can only tunnel by gaining or losing the large transverse momentum difference between the transverse X valleys and the Γ valley. These electrons can obtain this momentum difference by picking up a Fourier component of a scattering potential. For a scattering potential to have a large momentum Fourier component, it must be well localized in space. The electrons in the transverse X valleys tunnel with the assistance of scattering from localized states in the band gap and from phonons. Theoretically predicted *I–V*'s resulting from scattering assisted tunneling are shown in Fig. 7 of Sze (1981).

There is one final resonant tunneling device, which is a hybrid of the conventional intraband RTD shown in Fig. 2 and the Esaki diode. It is the resonant interband tunneling diode (RITD) shown in Fig. 8 (Söderstöm *et al.*, 1989). In this device, electrons tunnel from the InAs conduction band on the left, through a light-hole 2DEG in the GaSb well, and back into the InAs conduction band on the right. When enough bias is applied, the hole 2DEG is pushed below the conduction band of the emitter, and electrons can no longer tunnel while conserving total energy.

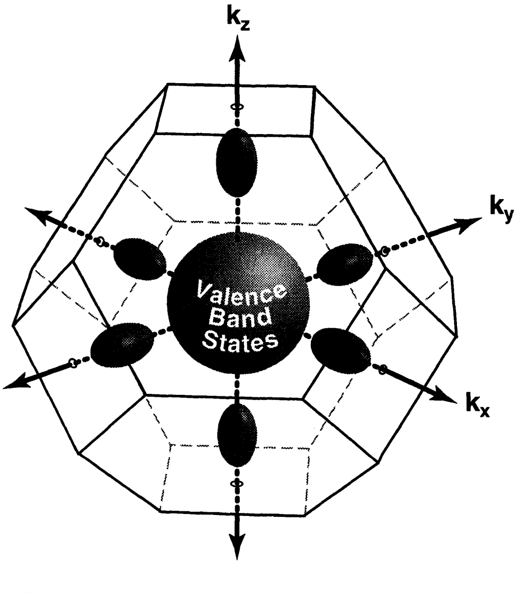

FIG. 7. For an indirect-gap semiconductor such as silicon, only the electrons in the longitudinal X valley (on the k_x axis) can directly tunnel into a valence-band state in the Γ valley while conserving both total energy and transverse momentum. The electrons in the transverse X valleys tunnel with the assistance of scattering from localized states in the band gap and from phonons.

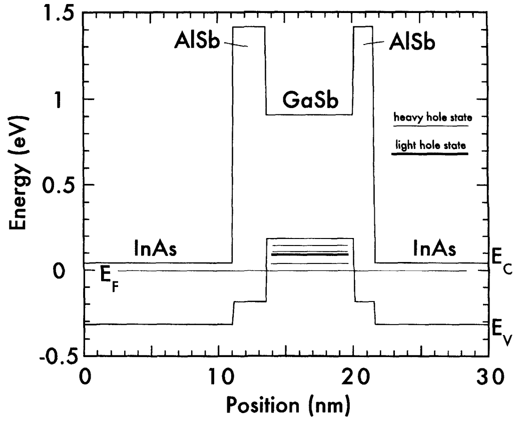

FIG. 8. Computed energy-band diagram for the published resonant interband tunnel diode of Söderström *et al.* (1989), exhibiting a peak-to-valley current density of 20 at room temperature. (Computed using the heterojunction modeling program *Bandprof* of W. R. Frensley.)

1.3 Valley Current

The valley current and turnon after the valley current for both RTDs and Esaki diodes is determined by the scattering from impurities, disorder, phonons, and other electrons, and thermionic emission. The scattering-assisted current is referred to as the *excess* current (Chynoweth *et al.*, 1961; Sze, 1981; Brown, 1994). For GaAs/Al$_x$Ga$_{1-x}$As RTDs, the room-temperature valley current is dominated by thermionic emission through the first excited state in the well or X states in the barriers (Brown, 1994). For the best In$_{0.53}$ Ga$_{0.47}$As/AlAs/InAs RTDs, the room-temperature valley current appears to be determined by scattering as opposed to thermionic emission (Smet *et al.*, 1992). Theoretical calculations comparing the effects in RTDs of acoustic phonon, polar-optical phonon, alloy, and interface roughness scattering indicate that the dominant scattering mechanisms of the four are polar optical phonon and interface roughness (Chevoir and Vinter, 1993; Roblin and Liou, 1993). The effect of electron–electron scattering and scattering from remote ionized donors in the contacts has not yet been theoretically investigated. Experimental evidence indicates that dopant segregation from the highly doped contacts to the undoped device region may strongly affect the PVR of RTDs (Cunningham *et al.*, 1993).

The notable difference between an RTD and an Esaki diode is that both elastic and inelastic scattering can contribute to the valley current of an RTD whereas only inelastic scattering can contribute to the valley current of an Esaki diode. For an RTD, Fig. 3 shows that there is always a high–transverse-energy state in the well into which an incident electron can scatter while conserving total energy. For an Esaki diode, Fig. 4(a) shows that for a bias greater than μ, there are no valence states into which an electron can elastically scatter. The excess current in Esaki diodes is attributed to localized states in the band gap combined with phonon scattering. If the thermionic emission is negligible, an Esaki-type device should, in principle, be capable of achieving a higher peak-to-valley current ratio than an RTD. In fact, the highest room-temperature peak-to-valley current ratio (PVR) of 144 has been observed in a heterojunction Esaki diode (Tsai *et al.*, 1994). This is about a factor of 3 above the best RTD (Smet *et al.*, 1992).

1.4 Speed

The speed of a tunnel diode can be characterized by the time it takes to switch from a stable bias point near the peak voltage (V_P) to a final voltage-stable bias point (V_F) beyond the peak; see Fig. 9. This will depend on the capacitance of the tunnel diode and on the change in charge between the initial and final states. If the capacitance is assumed to be approximately constant, then the change in charge can be written $\Delta Q = Q_F - Q_P = C(V_F - V_P)$, where Q_F and Q_P are the final and initial charge states and C is the capacitance. The time required to change the charge on the capacitor will depend on the current available for charging, $I_S(V) - I_{TD}(V)$, where $I_S(V)$ is the current that can be provided by the voltage source and $I_{TD}(V)$ is the I–V characteristic for the tunnel diode:

$$\tau = \int_{V_P}^{V_F} \frac{C(V_F - V_P)}{I_S(V) - I_{TD}(V)}\, dV. \tag{9}$$

The relation $I_S(V) - I_{TD}(V)$ is indicated by

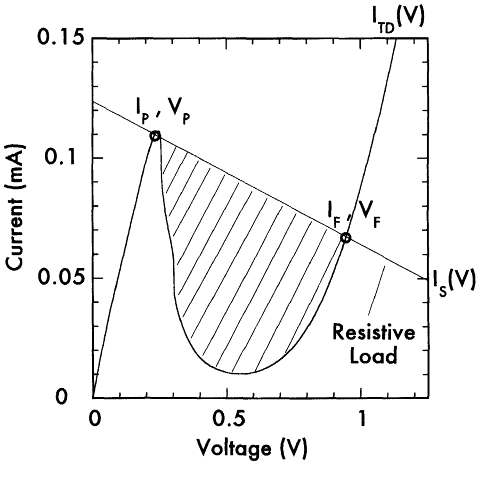

FIG. 9. Measured current–voltage characteristic for an AlAs/InGaAs double-barrier resonant tunneling diode (emitter area of 1 μm^2, wafer R7556). Superimposed on the experimental curve is the resistive load line $I_S(V)$ resulting in two stable bias points; the lined region denotes the current available for charging the device capacitance.

the lined region in Fig. 9. If we assume, after Diamond *et al.* (1989), that the capacitance is roughly constant and that the available current can be bounded by $I_s(V) \leq I_P$ and $I_{TD} \geq I_V$ (where I_P and I_V are the diode peak and valley currents, respectively), then a lower bound on Eq. (9) can be written:

$$\tau = \frac{C(V_F - V_P)}{I_P - I_V} = \left[\frac{C}{I_P}\right]\frac{V_F - V_P}{1 - I_V/I_P}. \tag{10}$$

From this relation, the switching speed is determined by the voltage swing, by the peak-to-valley current ratio I_P/I_V, and by an intrinsic factor I_P/C, called the speed index. While peak-to-valley current ratio is important, increasing PVR beyond 3 does not speed up the device significantly. Since for switching applications the speed index is the primary factor governing speed, we provide a survey of this factor across all semiconductor tunnel diodes in Sec. 3. The speed index of the resonant tunneling diodes is generally greater than that of the Esaki tunnel diode, since high current density and low capacitance are difficult to achieve simultaneously in the Esaki diode.

The capacitance of the tunnel diode is given by $C = \epsilon A/d$, where d is the thickness of the depletion layer. For uniform doping density this depletion-layer thickness varies with the square root of applied bias for both intraband and interband diodes. For the Esaki diode, the capacitance C is

$$\frac{C}{A} = \sqrt{\frac{q\epsilon N_A N_D}{2(V_{\text{bi}} - V)(N_A + N_D)}}, \tag{11}$$

where A is the junction area, q is the fundamental charge, N_A and N_D are the acceptor and donor atom densities, respectively, V_{bi} is the junction built-in voltage, and V is the applied voltage.

For the RTD, a unipolar device, the capacitance is inversely proportional to the combined length L_{RTD} of the accumulation region in the emitter, the depletion region in the collector, and the barrier–well–barrier region in the center (Brown, 1994). Like the Esaki diode, the capacitance depends inversely on the square root of the applied bias, but with the opposite bias dependence. In the Esaki diode the capacitance is generally increasing as the bias increases toward the peak voltage, while in the RTD the capacitance is decreasing with applied bias. Since the Esaki diode is very heavily doped, the length of the depletion region is much less than the length L_{RTD} of the RTD, and therefore Esaki diodes typically have larger capacitances than RTDs. In terms of both capacitance and current the RTD appears to be superior for high speed.

One should note, however, that this simple picture of the RTD capacitance decreasing monotonically with bias describes only the first-order behavior. Near resonance the capacitance peaks significantly in RTDs (T. Wei, *et al.*, 1993; Jo *et al.*, 1994). This contributes to the significantly lower measured versus theoretical speed indices shown later in Table 2.

2. FABRICATION

In 1969, Esaki tunnel diodes could be obtained commercially from as many as twelve suppliers (Baasch, 1969), but there are only a few companies that still produce them (Si and Ge). Resonant tunneling diodes are not commercially produced but can be obtained from many university and industrial laboratories. Much of the Esaki-diode fabrication experience from the 1960s and 1970s is lost, but there remains a number of excellent technology papers and patents that reveal the beautiful work of the early Esaki-diode development. Notably, for Ge-alloy tunnel diodes, see the article by Davis and Gibbons (1967) and the U.S. patent of Tiemann (1966).

2.1 Tunnel-Junction Formation

The Esaki diode requires the formation of an abrupt, heavily doped p^+n^+ junction with doping densities exceeding 10^{19} cm^{-3} on both sides of the junction. Commercial Esaki diodes are typically formed by an alloy process in which a metal containing the desired dopant is alloyed into a high-conductivity semiconductor substrate as illustrated in Fig. 10. Alloying has advantages for forming abrupt doping junctions, since generally, both the temperature and alloy time can be kept lower and shorter, respectively, than the corresponding epitaxial growth process. In addition, the process of alloying also serves

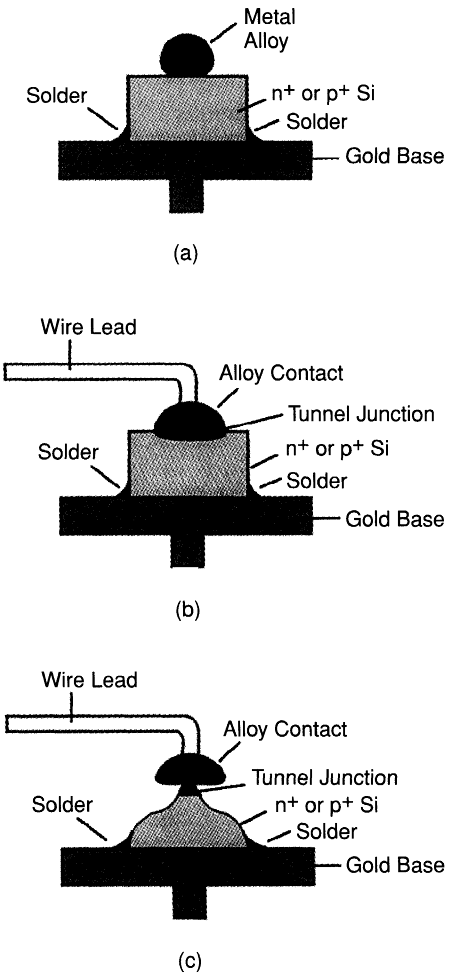

FIG. 10. Fabrication steps for an alloyed Esaki diode: (a) the high-conductivity semiconductor base material is soldered to a device header and the metal alloy containing the appropriate dopant is placed on the semiconductor, (b) the tunnel junction is formed by alloying and a wire attached, and (c) the tunnel junction is etched to obtain the desired current density.

to form the diode contact, making for a simple process, with low contact resistance. In addition to being simple, the alloy process is inexpensive relative to the cost of epitaxial-growth equipment.

Resonant tunneling diodes and other heterojunction tunnel diodes such as the heterojunction Esaki diode and the resonant interband tunnel diode are now primarily grown by molecular-beam epitaxy (MBE) (*q.v.*) (Matyi, 1994). Molecular-beam epitaxy is an ultrahigh-vacuum growth process in which the elemental semiconductors and dopants of the desired structure are evaporated at carefully calibrated and controlled rates onto a heated semiconductor substrate. The growth rate is typically about 1 monolayer of semiconductor per second (2–3 Å/s), which allows semiconductors to be engineered with layer-to-layer control of the crystal composition and doping. By MBE, semiconductor heterojunctions can be grown, one on top of another, to form the abrupt potential discontinuities needed for resonant tunneling and heterostructure tunnel diodes.

2.2 Device Processing and Integration

While considerable effort has been invested in the development of batch semiconductor processes for Ge and Si Esaki diodes, commercial tunnel diodes today are produced individually. Two commercial Esaki-diode configurations for high-speed applications are shown in Fig. 11, but the process of Fig. 10 is also still used. These processes begin by mounting the high-conductivity substrate material on a device header. A metal consisting of or containing the desired dopant is then arranged on the semiconductor. Example metals are (Watson, 1969), for a p^+ layer on n^+ Ge, In/Ga (95:5); for Si, Al/B; and for GaAs for an n^+ layer on a p^+ substrate, Sn works well. Alloy temperatures and times depend on the metal but are typically less than 500 °C and less than about 1 min.

In the alloying step the tunnel junction and contact metal are simultaneously formed. The peak current density, peak voltage, and peak-to-valley current ratio are all determined by the abruptness of the alloy junction and the absolute impurity densities. The absolute value of the current, however, can be controlled (reduced) after the junction is formed by reducing the area of the junction; this is typically achieved by an electrochemical etch.

In contrast to the Esaki diode, resonant tunneling diodes and resonant interband tunnel diodes are typically formed by a batch process such as is shown schematically in Fig. 12. This process consists of the steps of epitaxial growth, contact metallization, reactive ion etching or wet chemical etching to define the device area, mesa isolation, and

second contact metallization. In such a batch process, transistors can be formed side by side or connected vertically (Seabaugh *et al.*, 1993), and additional components such as diodes, resistors, and capacitors can be integrated.

2.3 Manufacturing Issues

The Esaki tunnel diode is a well-established commercial product with more than 20 years of market experience. For the resonant tunneling diode and heterojunction tunnel diodes, currently being explored for cofabrication with mainstream integrated circuits, questions about uniformity, reproducibility, and reliability are still being addressed.

2.3.1 Unformity The uniformity of RTD layer growth is primarily determined by the configuration of the MBE growth chamber, and most critically by the arrangement of the sources with respect to the substrate. For resonant tunneling diodes consisting of AlAs/InGaAs/AlAs double barriers, Moise *et al.* (1995a,b) have shown three-sigma variations in peak current, peak voltage, and peak-to-valley current ratio [from edge to edge of a 2-in. (5-cm) wafer] of 7.2%, 5.2%, and 4.9%, respectively. This represents better than one monolayer thickness control, as approximately 50% variation in the current is expected in this RTD for a single monolayer variation in the tunnel-barrier thickness. An example of the good local uniformity of RTDs obtained by MBE is shown in Fig. 13.

2.3.2 Reproducibility Because the current in tunnel diodes is dependent exponentially on tunnel barrier thickness, run-to-run reproducibility of the junction formation is more difficult to achieve than device-to-device uniformity across a wafer. To date, run-to-run reproducibility of peak current (the

most sensitive parameter) in resonant tunneling diodes is held within approximately ±12%. Further improvements in calibration procedures and control technology are expected to reduce this variation.

2.3.3 Reliability Esaki-diode reliability is well established for commercial and space use. Mean time before failure (MTBF) exceeding 100 000 hours (more than 11 years) has been reported by McDermott (1981) for tunnel-diode amplifiers in satellite communication systems. Again, reliability of RTDs is not fully qualified. Miura *et al.* (1990) have shown good endurance of $AlAs/In_{0.53}Ga_{0.47}As$ RTD oscillators; continuous operation has been reported for times exceeding 1000 hours at 90°C for oscillation frequencies between 0.6 and 1 GHz. dc bias stress tests at 80 °C have been performed on AlAs/InGaAs RTDs on InP (Seabaugh *et al.*, 1997); more than 10 400 hours (>1 year) have been logged without increase of the peak or valley current.

3. DEVICE PROPERTIES

In this section, we provide a survey and comparison of the device properties of Esaki, resonant interband, and resonant tunneling diodes across the explored range of semiconductor materials. Three tables are provided: Table 1 compares the p^+n^+ Esaki diodes; Table 2, the resonant interband tunnel diodes; and Table 3, the resonant tunneling diodes. The tables predominantly cover materials that exhibit room-temperature negative differential resistance or that give the best peak-to-valley current ratio for that particular substrate. The tables also list the key materials parameters for each structure. The p^+n^+ Esaki-diode parameters are fairly simple to envision; the RITD heterojunction alignments are not always obvious. Figures 6 and 8 show the energy-band diagrams for two of the entries in Table 2. These figures give the computed energy-band diagrams for the highest-PVR (144) tunnel diode and for the highest-PVR interband *n-p-n* tunnel diode, 20. For Table 3, an explanatory Fig. 14 is provided to define the listed parameters.

From the tables one can see that the highest speeds are obtained for the resonant tunneling diodes, and the highest peak-to-valley current ratios are obtained for the resonant interband tunnel diodes. While not shown in the table, speed index in alloy Ge diodes as high as 50 has been reported by Davis and Gibbons (1967).

3.1 Esaki Diode

Esaki diodes have been formed on a wide variety of common semiconductor substrates. In this section, we review the properties of these devices according to the columns in the periodic table from which the semiconductors are formed.

3.1.1 Group IV Silicon and germanium Esaki diodes are the only tunnel diodes commercially available today. Of these, the highest speed and peak-to-valley current ratio are obtained in the Ge diodes with switching speeds as fast as 22 ps obtained in packaged configurations such as the planar configuration shown in Fig. 11(b). The best speed index is also obtained from alloy Ge diodes with values at least as high as 50 reported by Davis and Gibbons (1967).

Esaki diodes formed of silicon carbide (SiC) on 6-H SiC substrates have shown the highest operating temperature of any tunnel diode (Dmitriev *et al.*, 1985). At room temperature the PVR is only about 1.4; however, the negative–differential-resistance region is well maintained to temperatures at least as high as 450 °C.

Table 1. Comparison of Esaki tunnel diodes operated at room temperature. Abbreviations: N_A, acceptor density; N_D, donor density; J_P, peak current density; V_P, peak voltage; PVR, peak-to-valley current ratio; *C*, junction capacitance per unit area, LPE, liquid-phase epitaxy; MBE, molecular-beam epitaxy; MOCVD, metalorganic chemical vapor deposition; MOMBE, metalorganic molecular-beam epitaxy; and RITD, resonant interband tunnel diode.

[g] Refers to emitter/collector spacer layers respectively.

[h] Measured extrinsic speed index, 630 mV in 2.2 ps, is 286 mA/pF.

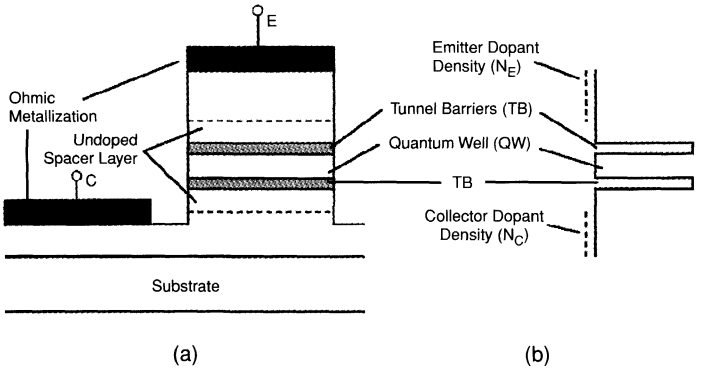

FIG. 14. Definition of terms for the resonant tunneling diode comparison Table 3: (a) schematic device cross section, (b) energy-band diagram.

3.1.2 Group III–V Peak-to-valley current ratios as high as 30 have been reported for p^+n^+ GaAs alloy tunnel diodes (Holonyak, 1960). High PVR (21) has also been obtained in the GaAs/$In_{0.1}Ga_{0.9}As$/GaAs Esaki diode of Richard *et al.* (1993), where the InGaAs layer is inserted at the *p-n* junction. For a given doping density, this technique of introducing a narrow–band-gap material at the tunneling junction is an effective way of increasing the peak tunneling current density. The wider–band-gap semiconductor, GaAs, on either side of the InGaAs provides a large band-gap blocking in the off-resonance condition, needed to keep the valley current low.

3.2 Resonant-Tunneling Diode

The resonant-tunneling diode has a wider design flexibility than the Esaki or resonant interband tunnel diode. Because the resonance condition does not depend on the overlap of valence- and conduction-band states, the resonant peak and valley voltages can be designed over a wide voltage range, from a few tens of millivolts to several volts. The highest peak voltage reported for the Esaki diode is 66 mV (for the InGaAs diode of Cohen *et al.,* 1995), whereas for RTDs the peak voltage can readily exceed 1 V.

The RTD can also be engineered for multiple current peaks by the introduction of multiple quantum wells. Shown in Fig. 15 is the measured *I–V* characteristic (Mikkelson *et al.,* 1994), of a triple-barrier, double-well RTD that has been designed for two resonance peaks. This design flexibility is not available in Esaki diodes and in RITDs; engineering of multiple current peaks with good PVR is difficult on account of the required close spacings of the resonant states.

3.2.1 Group IV There is little prior art on silicon-based electron resonant tunneling diodes. Ismail *et al.*'s (1991) demonstration of resonant tunneling in the $Si_{0.7}Ge_{0.3}$/Si/$Si_{0.7}Ge_{0.3}$ RTD (grown on a relaxed $Si_{0.7}Ge_{0.3}$ buffer layer) stands as the best demonstration of group-IV electron resonant tunneling on silicon. The room-temperature peak current density in these diodes was about 400 A/cm^2 with a PVR of 1.2. High peak-to-valley current ratios are not expected in this system

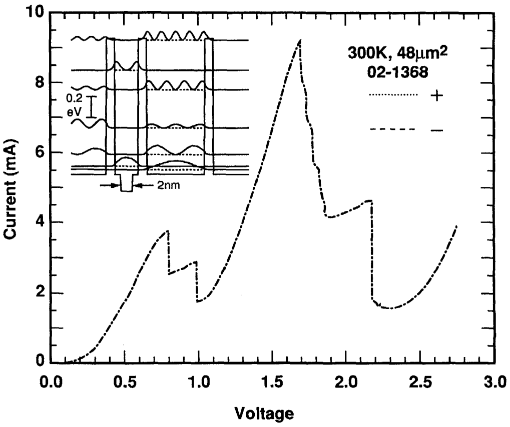

FIG. 15. *Room-temperature measured current–voltage* characteristics at room temperature for a triple-barrier, double-well resonant tunneling diode. Inset: computed energy-band diagram, transmission resonances, and wave functions. The dotted and dashed lines correspond to positive and negative voltage ramps, respectively; the two curves are essentially indistinguishable, showing a hysteresis-free behavior.

because of the low conduction-band offsets (less than 500 meV).

3.2.2 Group III–V The highest room-temperature peak-to-valley current ratios and highest current densities in the RTD have been obtained on the AlAs/InGaAs RTD on InP. Peak-to-valley current ratio of 52 by Smet *et al.* (1992) and peak current density of 460 kA/cm^2 by Broekaert and Fonstad (1990), both obtained on n^+ InP substrates, are the best results to date. As a result of this high current density, the fastest RTD switching speeds have also been measured in the III–V RTDs. For the AlAs/InGaAs RTD with 450 kA/cm^2, Shimizu *et al.* (1995) report a switching time of 1.5 ps. Comparable speed, 1.7 ps, has been reported by Özbay *et al.* (1993) for the InAs/AlSb RTD with peak current density of 330 kA/cm^2.

3.2.3 Group II–VI For the II–VIs, the only exploration of double-barrier resonant tunneling is for the HgCdTe/HgTe system by Reed *et al.* (1986). In this case, HgCdTe forms the barrier material, while HgTe is a zero–band-gap semimetal that makes up the quantum well. Characterization of this structure showed PVR as high as 1.4 at room temperature.

3.2.4 Mixed Crystalline Several heteroepitaxial systems utilizing crystalline metal and semimetal/insulator structures, and systems in which barrier and well materials come from different groups of the periodic table, have been demonstrated. These have met with limited success, most yielding tunneling diode characteristics with negative differential resistance only at low temperature. For example, Han *et al.* (1991) successfully grew the MnTe/InSb/MnTe RTD by molecular-beam epitaxy with peak-to-valley current ratio of about 1.7 at 77 K; the poor performance is attributed to scattering at the interfaces and edge leakage on the device sidewalls.

Much better results have been obtained in the $CaF_2/CoSi_2$ triple-barrier double-well resonant tunneling diode of Suemasu *et al.* (1992). In these crystalline structures grown by molecular-beam epitaxy, a peak-to-valley current ratio as high as 2 at room temperature has been obtained. Because the emitter is a metal, there is no band gap to block transmission through the quantum-well states after the states are moved below the Fermi level in the emitter. Because of the second quantum well, the peak current corresponds to the resonant *alignment* of quantum well states in adjacent wells; when the states depart from alignment at post-peak biases, the tunneling current is reduced.

Another of the mixed-crystalline RTDs to be explored is the semimetal/semiconductor AlAs/ErAs/AlAs system, which is grown on GaAs and uses n-GaAs as the contacting layers. Remarkably, the ErAs has a rock-salt cubic crystal structure, but it can be grown and fitted to the zinc-blende GaAs and AlAs crystals. Room-temperature negative differential resistance has been reported (Brehmer *et al.*, 1995). Improvements in these systems can be expected with improvements in crystal-growth processes.

3.2.5 Amorphous Resonant Tunneling Shortly after the demonstration of the first RTD by Chang *et al.* (1974), Hirose *et al.* (1977) reported resonant tunneling in the amorphous $SiO_2/Si/SiO_2$ structure grown by thermal oxidation in O_2 and with electron-beam deposition of amorphous silicon. Weak negative differential resistance was reported at room temperature. Since then, Miyazaki *et al.* (1987) have reported resonant tunneling in amorphous $Si_3N_4/Si/Si_3N_4$ double barriers, but without NDR. Fang *et al.* (1994) have reported a PVR of 9.4 at room temperature in an amorphous SiC/Si/SiC structure deposited on glass. The origin of the NDR in the amorphous SiC/Si structures is not clear since the materials contain many traps. It is conceivable that the NDR is produced by resonances through defect states.

3.2.6 Hole Resonant Tunneling Resonant tunneling diodes can be fabricated in the valence band as well as the conduction band. Because of technological interest in Si/Si_xGe_{1-x} heterostructures and because the band-gap difference between the Si and Si_xGe_{1-x} occurs predominantly in the valence band, this system has been the most widely studied. In this case the carrier transport is by holes and the particle tunneling due to hole resonant tunneling. The Si_xGe_{1-x} well can be strained, grown on relaxed Si (Liu *et al.*, 1988), or the Si barriers can be strained, grown on relaxed Si_xGe_{1-x} (Gennser *et al.*, 1990). Several works have experimentally and theoretically investigated the effect of confinement on the light-hole and heavy-hole states and the resonant tunneling peaks associated with each state (Shen *et al.*, 1992; Fu *et al.*, 1991). However, negative differential resistance has not been observed at room temperature. Theoretical calculations predict accurately the peak currents but underestimate the valley currents by several orders of magnitude (Shen *et al.*, 1992). There is no existing explanation for the large valley currents. At a temperature of 77 K, all reported peak-to-valley ratios are less than 2.0.

3.3 Resonant Interband Tunnel Diode

The best PVR (144) at room temperature of any tunnel diode is obtained in the structure of Tsai *et al.* (1994) shown in Fig. 6. Heterostructure *npn* interband tunnel structures such as that shown in Fig. 8 by Söderström *et al.* (1989) have also produced high room-temperature PVR (20). The heterostructure interband devices based on the GaSb/AlSb/InAs materials system offer a wide design flexibility (Collins *et al.*, 1991) with the low effective mass of InAs, the availability of both binary and ternary alloys, and the wide range of suitable band offsets. Most work on these materials has been done on GaAs substrates, because of the lower substrate cost and technological desirability of the GaAs substrate. Valley current in the interband tunnel devices such as the GaSb/AlSb/InAs heterostructures can be dominated by the parasitic thermionic emission of holes.

4. APPLICATIONS

Despite being the fastest semiconductor switching device, at this writing the tunnel diode is not widely used. Discrete Ge and Si Esaki diodes can be purchased from two U.S. companies, and the current size of the markets for these devices is only a few thousand components per year. The diodes are used in picosecond pulse generators, in microwave detectors in the 0.5–18-GHz band, and in miscellaneous special applications. Esaki tunnel junctions are also used in cascade solar cells to provide an Ohmic interconnection between epitaxially integrated III–V solar cells, but in this case the negative differential resistance is not important.

In the 1960s and 1970s tunnel-diode applications were believed to have broad market potential including high-speed and low-power signal processing, logic circuits, microwave detectors, amplifiers, oscillators, and pressure sensors. However, transistor technology eventually surpassed the speed of the alloy Esaki-diode technology, and the incompatibility of the fabrication technology with conventional integrated-circuit processing lines never allowed a full exploration of tunnel-diode circuits.

In the last decade, heterostructure technology has been applied to the tunnel diode, and a broader array of tunnel diodes has been developed. Unlike the early Ge Esaki diode, these devices are batch fabricated and integrable with conventional transistors and IC components.

4.1 Triggering, Pulse Forming, and Sampling

For triggering and pulse forming, the tunnel diode is used for high-speed switching, competing against the Schottky-barrier diode (Andrews, 1986). The basic triggering circuit topology* is shown in Fig. 16. When the circuit is switched to "on," the tunnel diode is biased to a point near its peak voltage by the constant-current source. With this bias an

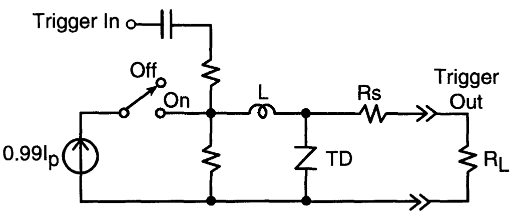

FIG. 16. Tunnel-diode trigger circuit consisting of a current source providing a bias of 99% of the peak current (I_p) to the tunnel diode (TD), a "Trigger In" signal that provides the additional current used to cause the TD to switch from low-voltage to high-voltage states, thereby generating the "Trigger Out" signal into the external load, R_L. The on/off switch is used to reset the TD from its high-voltage state to its low-voltage state. (Courtesy of J. Andrews, Picosecond Pulse Labs.)

---

*While there exists an IEEE standard symbol for the Esaki diode (Esaki Tunnel Diode Task Group, 1965), there is no industry standard for the newer resonant tunneling diodes.

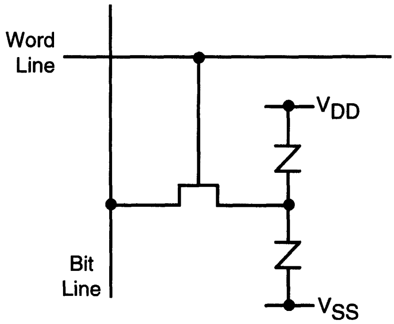

FIG. 17. Basic tunnel-diode memory cell consisting of a pass transistor and a pair of tunnel diodes. Power supplies, V_{DD} and V_{SS}, provide the appropriate biases to the tunnel-diode pair; the voltage difference, $V_{DD} - V_{SS}$, is typically less than 1 V.

input pulse at the "Trigger In" port provides sufficient current to exceed the peak current of the tunnel diode. The voltage across the tunnel diode then increases abruptly to a post-resonance voltage corresponding to the near-peak current bias. Using Esaki diodes, switching times for this transition (10% to 90%) can be less than 20 ps for a 230-mV signal into a 50-Ω load.

A monolithic RTD sampling circuit has been reported by Miura *et al.* (1990) with switching speeds of about 10 ps and estimated sampling frequency of 33 GHz. The fastest RTDs, measured in a similar configuration by Shimizu *et al.* (1995), have speeds of 1.5 ps.

4.2 Memory

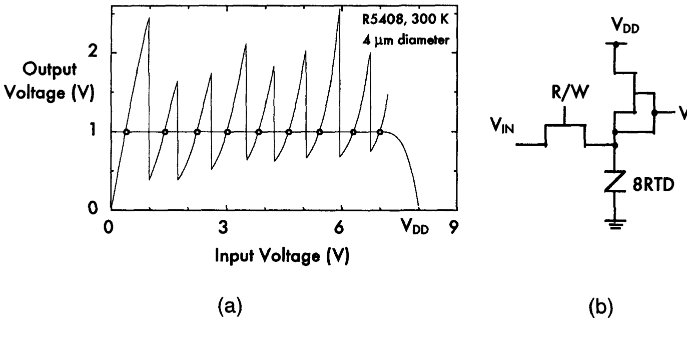
The Esaki tunnel-diode "twin" conceived by Goto *et al.* (1960) has been revisited in recent years with resonant tunneling diodes and considered for cache memory and high-speed shift registers. The basic bistable cell consists of the series combination of two RTDs where one RTD forms the load of the other. The RTD pair forms a bistable element, shown in Fig. 17, which can be written to and read from "via" gates attached at the midpoint of the "twin" junction.

Extending the "twin" concept, it has been shown by Seabaugh *et al.* (1992) that multivalued RTD memory can be constructed by the series combination of resonant tunneling diodes epitaxially integrated into a single device stack. Shown in Fig. 18 is the measured *I–V* characteristic of an 8-RTD stack used in a nine-state memory circuit.

An ultralow-power RTD/heterojunction field-effect transistor static random-access memory based on InP substrates has been demonstrated by van der Wagt *et al.* (1996). Over 200 times lower power is obtained over the best previous GaAs-based memory cell; in the same cell configuration, ultralow-power tristate memory has also been demonstrated. In this circuit, which can have the same topology as Fig. 17, the RTD currents are comparable to the leakage currents in the transistor, and the storage node capacitance is supplied by the high intrinsic capacitance of the bistable RTD pair. Read and write operations occur as in dynamic random access memory (DRAM), but the cell is static on account of the RTD pair bistability.

4.3 Analog-to-Digital Conversion

It has been shown by S.-J. Wei *et al.* (1993) and Potter *et al.* (1993) that a compact folded analog-to-digital converter (ADC) can be constructed from the combination of



(a)

(b)

FIG. 18. Nine-state resonant tunneling diode memory cell: (a) nine-state RTD current–voltage characteristic with the field-effect-transistor load line superimposed (the nine circles denote the stable operating points of the RTD/FET combination); (b) schematic circuit diagram. The symbol labeled 8RTD represents the series integration of eight resonant tunneling diodes. Input and output ports are labeled V_{IN} and V_O, respectively, the single power supply voltage is labeled V_{DD}, and the read/write pass transistor is labeled R/W.

stacked resonant tunneling diodes and transistors. A four-bit, 2-GSps monolithic flash converter containing RTDs has also been demonstrated (Broekaert *et al.*, 1997). These converters show promise for extending ADC performance to microwave input bandwidths with low bit resolutions (four to six bits).

4.4 Logic

For logic, the most promising circuits combine the tunnel diode with transistors (Chow, 1964; Capasso *et al.*, 1990; Seabaugh *et al.*, 1993), since circuits with the tunnel diodes alone cannot meet the fan-out requirements of general-purpose logic. In recent years, pipelined approaches have been proposed for ultrafast arithmetic circuits by Mohan *et al.* (1994), and concepts for superpass gates composed of resonant-tunneling-diode/transistor combinations have been proposed by Deng *et al.* (1995). Compact multivalued adder circuits have been described by Micheel *et al.* (1993) and are now being developed.

4.5 Oscillators

When the resonant tunneling diode is biased in the negative–differential-resistance portion of its *I–V* characteristic, the circuit will oscillate. These oscillations are commonly observed when making dc measurements through the NDR region. Power is generated by these oscillations and can be utilized as signal sources to extremely high frequencies. Oscillation frequency up to 712 GHz in resonant tunneling diodes has been demonstrated by Brown (1994). The design principles for tunnel-diode oscillators are well described in the book by Chow (1964).

4.6 Tunnel Photodiodes

The use of the Esaki tunnel diode as a light-triggered switch has been explored by Allen *et al.* (1969) and recently for the resonant tunneling diode by Moise *et al.* (1995b, 1997) and others. In this application the tunnel diode is biased to near its current peak with a resistive load, which provides two stable bias points in the unilluminated condition. On illumination with a subnanosecond pulse with a few milliwatts of peak power, the diode switches from a low-voltage state to a high-voltage state. To reset the circuit, the diode bias is momentarily clocked to a low bias. Cutoff for such a circuit is expected to exceed 10 GHz with a photosensitivity of at least 300 mA/W (Allen *et al.*, 1969).

The light triggering mechanism is fundamentally different for the two devices. In the Esaki diode, the incident light generates electron–hole pairs in the depletion region of the *p-n* junction. This contributes a photocurrent that causes the switching from a low-voltage to high-voltage state. In contrast to the Esaki diode, photogenerated electrons and holes in the RTD are separated and confined at the tunnel barrier interfaces, where they act to screen the electric field and alter the resonant tunneling peak voltage, thereby triggering the bistability.

5. SUMMARY AND PROSPECTS

Continued improvements in crystal-growth technology, particularly in molecular-beam epitaxy, have increased the possibilities for design and construction of resonant tunneling and Esaki tunnel diodes. The device possibilities are expanding with the development of silicon-based heterojunction technology. A long-standing impediment to the use of tunnel diodes has been the inability of the device to integrate with conventional transistor technology. This limitation is now being challenged by the emergence of III–V resonant tunneling-diode/transistor integrated circuits. If the performance improvements long anticipated for an integrated tunnel-diode/transistor technology are realized, one can expect tunnel diodes to become as commonplace as transistors in the not-too-distant future.

GLOSSARY

Epitaxy: The process of growing a crystalline material upon a crystalline substrate. Often the material grown has a different chemical composition from that of the underlying material, but with a similar crystal structure.

Esaki Diode: A heavily doped n^+p^+ junction diode wherein electrons in the conduction band of the n^+ region can tunnel into hole states in the valence band of the p^+ region.

Excess Current: The measured current in excess of the thermionic and resonant or interband tunneling current in the tunnel diode. This current can be accounted for by mechanisms such as impurity-assisted tunneling, interface-roughness scattering, excited-state tunneling, phonon-assisted tunneling, or edge leakage.

Heteroepitaxy: The growth of layered crystalline materials where the layers differ in chemical composition but have similar crystalline structure, such as AlAs on GaAs.

Heterojunction: A junction formed between dissimilar semiconductors.

Heterostructure: A combination of heterojunctions typically constructed to enhance some device property.

Homojunction: A semiconductor junction consisting of *n*- and *p*-type regions with the same semiconductor on either side of the junction.

Hysteresis: In the tunnel diode, a term referring to a current–voltage characteristic that differs depending on the direction (increasing or decreasing) of the voltage or current sweep and the previous bias state of the device.

Interband: Between two bands such as the conduction and valence band.

Intraband: Within a single band such as the conduction band (or valence band).

Linear Region: The voltage region of a resonant tunneling or Esaki diode before the peak in the current–voltage characteristic, where the current–voltage relation is nearly linear.

Longitudinal: Refers to a direction parallel to the current flow. In heteroepitaxial structures, this direction is the same as the crystal growth direction and is perpendicular to the heteroepitaxial layers.

Longitudinal Energy: Total energy minus transverse kinetic energy, $E - (p_y^2 + p_z^2)/2m^*$.

Negative Differential Resistance (NDR): The region of the *I–V* curve immediately following the peak current, in which the current decreases with increase in applied voltage.

Peak Current: A local maximum in the current–voltage characteristic of the tunnel diode, at which the derivative of the current with respect to the voltage becomes zero.

Peak-to-Valley Current Ratio (PVR): The ratio of the peak current to the valley current of the tunnel diode, often used as a figure of merit.

Resonant Tunneling: Tunneling enhanced by constructive interference resulting in a resonant buildup of the wavefunction within a cavity defined by tunnel barriers. The optical analogy for semiconductor resonant tunneling is the Fabry-Pérot cavity.

Total Energy, *E*: The potential energy plus the kinetic energy.

Transmission Coefficient: Ratio of the probabilities of the transmitted wave and the incident wave.

Transverse: Refers to a direction perpendicular to the current flow. In heteroepitaxial structures, this direction is perpendicular to the crystal growth direction and is parallel to the heteroepitaxial layers.

Tunnel Diode: A two-terminal device whose charge transport is governed by the principles of quantum-mechanical tunneling.

Tunneling: The act of passing through a classically forbidden region such as a potential barrier.

Valley Current: A local minimum in the current–voltage characteristic of the tunnel diode at which the derivative of the current with respect to the voltage becomes zero.

INTRODUCTION

Scanning tunneling microscopy (STM) is a laboratory technique capable of obtaining atomic-scale resolution images of surfaces. It can also be used for tunneling spectroscopy measurements that reveal a variety of surface electronic properties with similar spatial resolution. Moreover, under appropriately controlled conditions an STM can be used to move individual surface atoms and molecules with atomic-scale precision. For such a powerful instrument, the basic operating principles are remarkably simple. As illustrated in Fig. 1, a sharp metal tip is brought within 1 nm of the surface of an electrically conductive sample, and a few volts are applied between the two, enabling electrons to tunnel quantum mechanically across the tip–surface gap. The resulting tunnel current, typically on the order of 1 nA, depends exponentially on the gap: A change of 0.1 nm causes the current to change by a factor of ~10, giving STM atomic-scale sensitivity. If the gap is regulated to keep the current constant while the tip is scanned laterally, adjacent profiles of the surface topography can be assembled into an image via computer. As shown in Fig. 2, images of the surface topography can then be displayed in gray scale (with high points brighter) or artificially rendered as a 3D surface (usually with exaggerated height).

STM has its origins in the "topografiner" developed in the early 1970s (Young *et al.*, 1972), that included most of the elements of an STM but operated with a larger tip-to-surface gap (>1 nm, at which distance electron transport occurs via field emission). Deficiencies in both the mechanical and electrical systems at that time limited the resolution to a few nanometers vertically and ~0.5 μm laterally. These problems were overcome about ten years later by Gerd Bin-

nig and Heinrich Rohrer at the IBM Rüschlikon laboratory, who succeeded in creating an instrument with stable vacuum tunneling and precision scanning capabilities—the conditions required for atomic resolution imaging—for which they were awarded the 1986 Nobel prize in physics (Binnig *et al.*, 1982a,b). STM has revolutionized the study of surfaces and is rapidly becoming a required tool in every surface-characterization laboratory. In addition, it has led to the development of a host of related techniques, collectively known as scanning-probe microscopies, and has spawned an industry aimed at providing reliable, easy-to-use commercial instruments.

Given the many comprehensive books and review articles about STM that are available (see Further Reading), only the experimental details and theoretical concepts essential for a general understanding of the operation and application of STM are presented here. The technical components of the microscope are discussed first, followed by the theoretical principles of operation. Applications are then presented that illustrate the capabilities and limitations of STM under optimal conditions. Lastly, some related techniques are discussed.

1. MICROSCOPE COMPONENTS

To achieve atomic-scale resolution, the mechanical and electrical components of an STM must enable the tip to be positioned within approximately 1 nm of the surface and then controlled both vertically and laterally with a precision of <0.01 nm. This precision requires low-vibration mechanical systems combined with low-noise electrical circuitry. Myriad ways have been developed to achieve the required mechanical stability; the more common elements are illustrated in Fig. 3. The STM must include a coarse approach mechanism, such as the "inchworm" motor shown, capable of bringing the tip into tunneling range with the sample. Once in range, a scanning transducer controls the vertical and lateral position of the tip over the sample. The sample and scanner are mounted in a rigid framework to minimize the effect of mechanical resonances. A vibration isolation system, often based on a magnetically damped spring suspension, is usually required to reduce transmission of external vibrations. Photographs of a complete ultrahigh-vacuum (UHV) -based system is shown in Fig. 4, including the UHV system required to maintain a pristine sample surface.

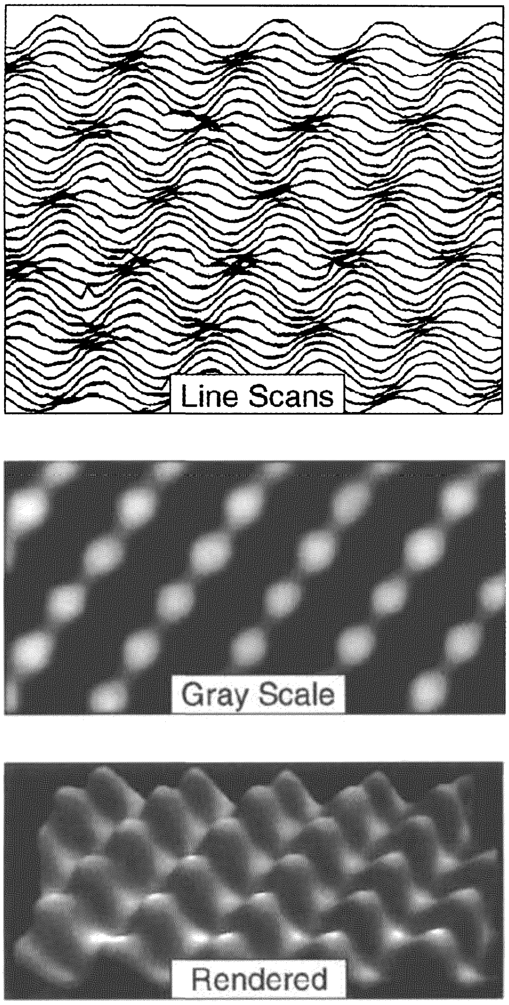

FIG. 2. Three common ways of presenting an STM image: as a set of line scans; in gray scale, with higher points brighter; and as an artificially rendered surface.

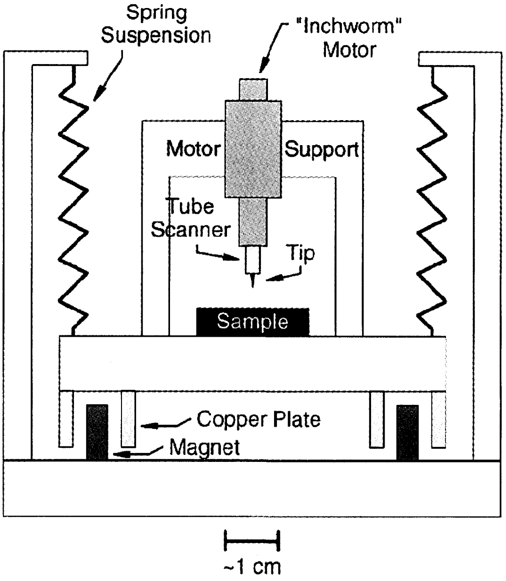

FIG. 3. Common elements of an STM, including a tip mounted on a piezoelectric tube scanner, a coarse-approach mechanism (in this case an "inchworm" motor), and a damped vibration-isolation system.

1.1 Scanner

The position transducer is the central element of the STM and is almost universally composed of the piezoelectric ceramic PZT [Pb(Zr,Ti)O$_3$]. This material expands or contracts approximately linearly with the voltage applied across it (see PIEZOELECTRIC DEVICES). Although early STM designs used a tripod of three orthogonal bars to control motion in three dimensions, a tube geometry is more common now on account of its inherent rigidity. The design of a typical tube scanner is shown in Fig. 5 (Binnig and Smith, 1986). A thin-walled tube of PZT is coated with metal on the inner and outer surfaces, with the outer surface divided into four equal quadrants by narrow metal-free regions. The inner surface is then used as the electrode for the vertical displacement (z), and the opposing pairs of outer electrodes are used for lateral motion (x and y). In this geometry a voltage applied between the inner and outer electrodes causes the tube to change length. Opposite voltages applied across opposing outer electrodes will induce one side of the tube to contract and the other to expand, causing a net lateral displacement (along with a small vertical displacement that can usually be ignored). For example, a 15-mm-long, 2.5-mm-radius, 0.75-mm-thick tube of a common commercial PZT material driven by voltages between $+150$ and -150 V would provide an overall scan range of 1.0 μm vertically and 2.8 μm laterally.

1.2 Coarse Approach

The tip–surface gap can usually be reduced to <0.1 mm via optical inspection. The basic requirement of the subsequent

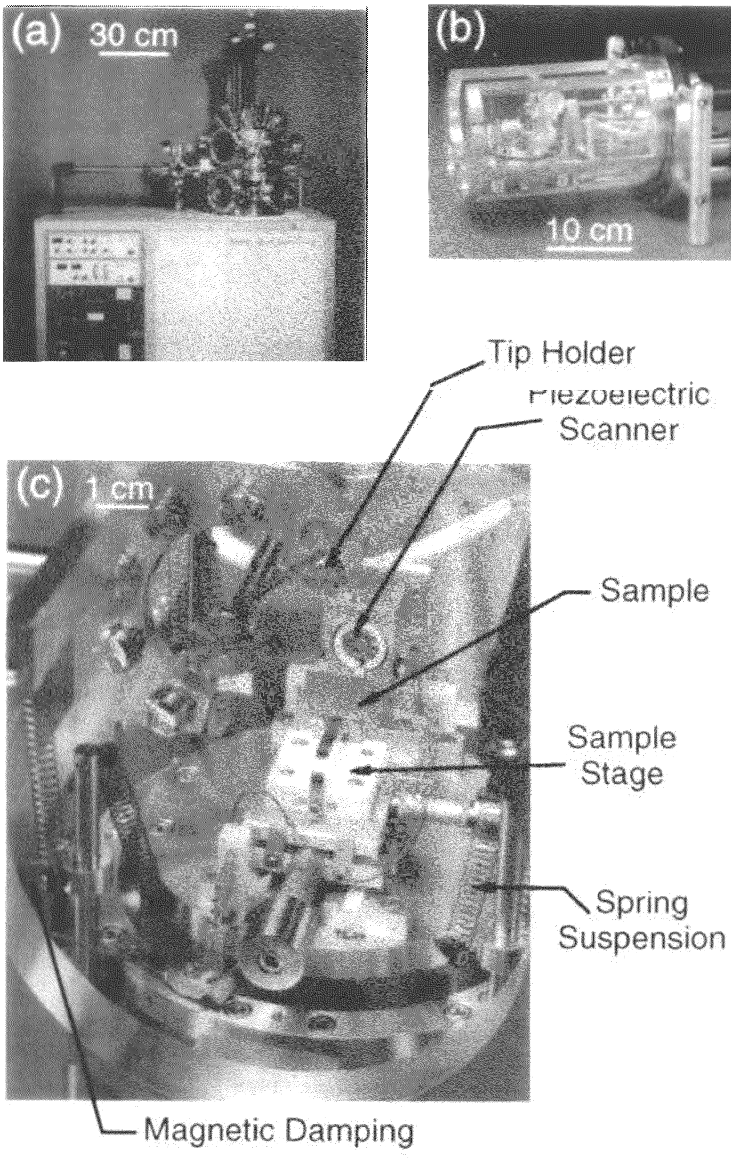

FIG. 4. Photographs of a commercially available STM (AutoProbe® VP, Park Scientific Instruments, Sunnyvale, CA). (a) Complete ultrahigh-vacuum system. (b) STM mounted on vacuum flange. (c) Close-up of STM showing the tip holder being transferred to the scanner.

coarse approach is that the remaining gap be reduced in steps less than the *z*-deflection range of the piezotube. This requirement allows a step to occur with the piezotube retracted, followed by a controlled expansion toward the surface (in a search for tunneling), without crashing the tip into the surface. Myriad ways have been developed to achieve this result. Two common techniques, the "inchworm" motor and the inertial slider, are depicted in Fig. 6. In an inchworm motor [Fig. 6(a)], a shaft is clamped inside a piezotube by additional piezoelectric material. If the position of the outer tube is fixed at one point, an inchwormlike series of clamping/unclamping and extension/retraction events will move the shaft. For simplicity, a tube scanner and tip can be mounted directly onto the end of an inchworm shaft (as in Fig. 3). Alternatively, an inchwormlike

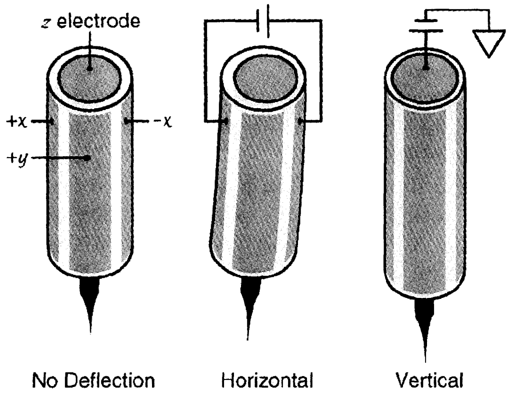

FIG. 5. Operation of a piezoelectric tube scanner with a four-quadrant outer electrode for horizontal motion and single inner electrode for vertical motion. A horizontal deflection occurs when a voltage is applied across opposing outer electrodes. A vertical deflection occurs when a voltage is applied to the inner electrode with respect to the four outer electrodes.

device can be used to push/pull the sample or scanner along a sliding mechanism.

Inertial motion uses asymmetrical acceleration to induce asymmetrical stick-slip motion of a mass. For example [Fig. 6(b)], if the transducer is first contracted slowly enough to prevent sliding, the mass will move with it; if the transducer is then expanded rapidly enough to induce sliding between the mass and its contact with the transducer, the mass will remain in place during the expansion, thereby effecting a net movement toward the anchor point. A variety of implementations of this strategy have been developed, with the tip, scanner, or sample stage acting as the mass.

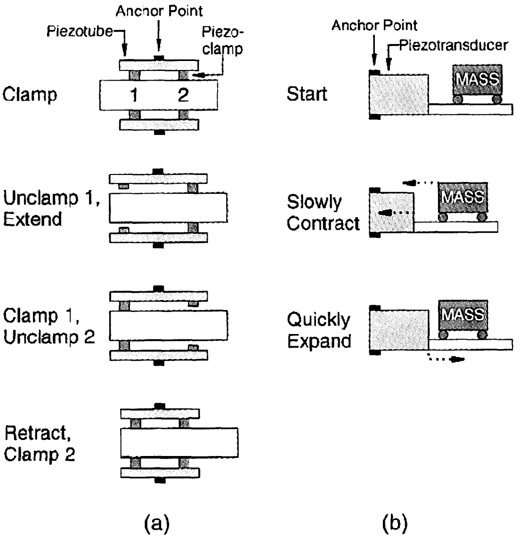

FIG. 6. Operating principles for two common coarse-approach mechanisms. (a) An "inchworm" motor employs a piezotube and piezoclamps to move an inner shaft by a series of clamping/unclamping and extension/retraction events. (b) Inertial motion of a free mass can be achieved by asymmetrical acceleration.

1.3 Vibration Isolation

The amplitude of any vibrations between the tip and surface must be reduced as much as possible to achieve optimum resolution. To achieve atomic-scale resolution the noise must be well below 0.01 nm within the frequency response of the tunneling control system (typically ~10 kHz). Because the amplitude of floor vibrations and other acoustic noise in this frequency range typically ranges from 0.1 to 1 μm, this is a considerable challenge. The transmission of these vibrations can be reduced by making the components of the STM as rigid as possible, especially those in the mechanical loop between the tip and sample, and mounting the scanner-plus-sample assembly on a vibration-isolation stage. There are two basic approaches to vibration isolation. The first involves suspending the assembly from one or more sets of springs with resonant frequencies of a few hertz. Because a spring suspension has little inherent damping (it will easily oscillate at its resonant frequency), external damping is usually added in the form of permanent magnets suspended between copper plates (see Fig. 3). So called eddy-current damping works by electromagnetically inhibiting the relative motion between the magnets and the high-conductivity metal plates. The second approach to vibration isolation is to mount the instrument on a stack of heavy metal plates separated by rubberlike spacers. Although this approach is generally less effective than a spring system, it is easier to build and simpler to operate.

1.4 Control Electronics

The essential elements of the control electronics, as included in Fig. 1, are a current amplifier; a feedback-control system; a position-control system, including digital-to-analog converters (DAC), analog-to-digital converters (ADC), and high-voltage amplifiers to control the scanner; and a computer for overall program control and image display. The tunneling current is typically in the range of 0.1–10 nA, and to keep it constant via feedback it is usually converted to a reference voltage ~1 V; this requires a current-to-voltage amplifier with a gain of 10^8–10^{10} V/A and noise below the equivalent of 10 pA (readily achievable with commercial electronic components). Because the current varies exponentially with the tunneling gap, an amplifier that converts the input signal to its logarithm is usually employed between the current-to-voltage amplifier and the feedback in order to linearize the system response. Proportional and/or integral feedback is used to generate a voltage to control the height of the tip above the surface. Because this voltage represents the surface topography, it is sent to the ADC for storage and display. The main function of the position-control system is to convert the computer-generated low-voltage DAC signals into the appropriate high-voltage signals for control of the scanner position. To record a topography image, the tip is scanned back and forth across a surface area, taking small steps perpendicular to each scan line, while periodically recording the tip height. The result is a two-dimensional array of height values that can be displayed as an image (see Fig. 2).

1.5 Tip Preparation

The tunneling tip is the most critical component of the STM, as it ultimately determines the resolution and overall image quality. Both the shape of the tip and the types of atoms on the end affect the images; in the ideal case, tunneling occurs through a single atom at the apex of a microscopically sharp metallic tip. As the number of atoms on the apex of the tip increases, the resolution degrades, although atomic resolution can still be achieved with a cluster of a few atoms. If the surface being studied is very flat (on the nanometer scale), only the atomic-scale shape of the tip apex is important, because only those atoms near the end will contribute to tunneling. In contrast, on rougher surfaces the recorded topography may be a noticeable convolution of the surface topography and the microscopic tip shape. Because the tunneling current depends not only on the gap but on the electronic structure of the tip as well (see Sec. 2), a nonmetallic atom or cluster on the tip apex may also affect the image.

The most common materials used for tips are tungsten and platinum-iridium-alloy wires. Although good resolution can sometimes be obtained using a crudely cut wire—when nature conveniently leaves a single atom or small atom cluster on the jagged apex of the cut—more reproducible results are obtained with tips electrochemically etched to a sharp point. Pt-Ir is often used for tunneling in air because of its resistance to oxidation; W is preferred for UHV applications, in part because of the knowledge gained about its preparation for use in field-ion microscopy (FIM; see FIELD ION MICROSCOPY). W tips can be easily etched to a microscopic radius of <10 nm and, fortunately, it is not uncommon for there to be an atomic-scale cluster on the end as required for atomic-scale resolution.

2. PRINCIPLES OF IMAGING AND SPECTROSCOPY

The inherent resolution of STM is a direct consequence of the quantum-mechanical tunneling between the tip and surface. This current depends both on the width and height of the tunneling barrier, and on the electronic structure of the tip and surface. By measuring the interdependence of the various tunneling parameters, i.e., bias voltage, tunneling current, and tunneling gap, images and spectra of a variety of surface electronic properties can be recorded in addition to topography. In this section, an overview of the essential physics of these processes is provided.

2.1 Tunneling Physics

Figure 7(a) illustrates an idealized potential-energy diagram for the electrons in a metal sample and tip a distance s apart, with work functions ϕ_s and ϕ_t, respectively, and a positive bias voltage V applied to the sample. In a classical picture, the work function, which is the energy required to move an electron at the surface from the Fermi level

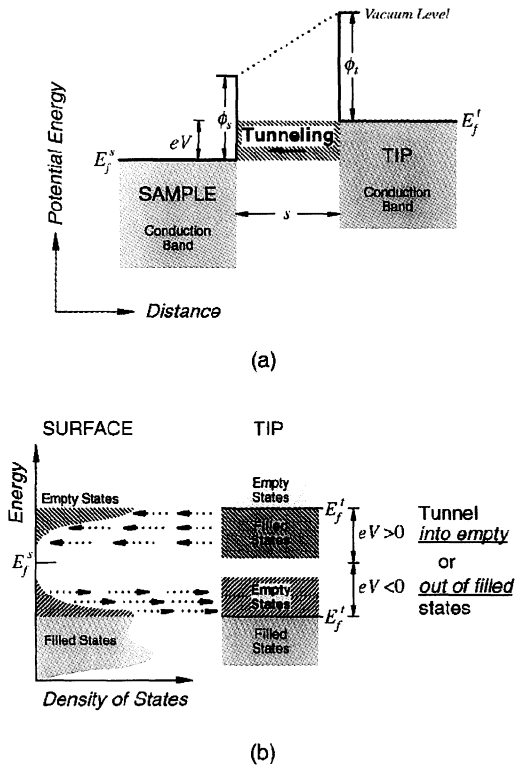

FIG. 7. (a) Schematic of quantum-mechanical tunneling between a metal tip and metal surface a distance s apart. The tunneling barrier is determined by the work functions of the surface and tip, ϕ_s and ϕ_t, respectively, and the bias voltage applied between the two, V. For the case shown, surface positive with respect to the tip, electrons tunnel from bands below the Fermi level of the tip (E_F^t) to those above the Fermi level of the surface (E_F^s). (b) Detailed schematic of the role of the density of states near E_F on the tunneling process both into and out of empty and filled states, respectively, on a semiconductor surface.

(E_F) to the vacuum, prevents electron transport between the two electrodes. Quantum-mechanical tunneling, however, can occur as a result of the overlap of electron wave functions that span the gap. If the potential-energy barrier is treated as a simple trapezoid, the probability for an electron on the tip at energy E with respect to E_F^t to tunnel to the surface can be approximated as

$$T(s,E,eV) \approx \exp\left\{-2s\left[\frac{2m}{\hbar^2}\left(\bar{\phi} - E - \frac{eV}{2}\right)\right]^{1/2}\right\}, \tag{1}$$

where $\bar{\phi}$ is the average work function of the tip and sample, m is the electron mass, e is the electron charge, and $\hbar$ is Planck's constant. For small bias voltages, the probability of tunneling for tip electrons near E_F^t can be further approximated as

$$T(s) \approx \exp(-2\kappa s), \tag{2}$$

where κ is the vacuum decay constant, $(2m\bar{\phi}/\hbar^2)^{1/2}$, about 10 nm^{-1} for typical work functions.

2.2 Density-of-States Effects

The net tunneling current depends on the total number of sample and tip–surface electronic states that overlap within the energy range for which tunneling can occur, as schematically shown in Fig. 7(b). When a positive bias voltage is applied to the sample (or conversely, a negative voltage is applied to the tip), electrons in occupied states on the tip can elastically tunnel into the energy-equivalent empty states in the conduction band on the sample. Similarly, a negative sample bias allows electrons occupying filled states on the surface to tunnel into empty states on the tip. The probability for each of these tunneling events is given by Eq. (1). Mathematically, the net tunneling current can be approximated as

$$I \propto \int_{-eV}^{0} \rho_t(E)\rho_s(eV + E)T(E,eV)dE, \tag{3}$$

where ρ_s and ρ_t are the energy-dependent densities of states for the sample and tip, respectively. For metals (including the tip), ρ is approximately constant near the Fermi level, with states being uniformly filled below E_F and empty above. On semiconductor surfaces ρ may be a strongly varying function of energy (possibly including energies where it is near zero as depicted in Fig. 7), thereby dominating the voltage dependence of the tunneling current.

2.3 Imaging Modes

The primary operational mode of STM is *constant-current imaging,* where the height of the tip is recorded as it is rastered over the surface while the tunneling current is kept constant. When tunneling occurs from sample to tip, the result is a *filled-state* topographic image; tunneling from tip to sample provides an *empty-state* image. On a perfectly crystalline surface the corrugation of the topography from atom to atom (i.e., peak-to-valley height) typically ranges from 0.001 to 0.01 nm on metals and 0.01 to 0.1 nm on semiconductors. If the density of states is relatively uniform across a surface, and modulated only by the location of surface atoms (as is usually the case for metals), the topography will represent a simple contour of constant height of the tip above the surface atoms. Frequently, however, $\rho_s(E)$ varies across the surface from atom to atom, and at some energies it may not even be a maximum over the atom cores. In such cases the images will look different at different bias voltages (the topographic maxima may even move), making interpretation difficult. The density-of-states dependence [Eq. (3)] leads to a central tenet of STM: *Constant-current topography measures (at best) the surface of constant integrated density of states, a surface that is generally bias dependent and may not correlate with the positions of the surface atoms.* This tenet also reveals another limitation of STM: *It is not directly sensitive to the chemical identity of surface atoms.* Fortunately, by complementing topographic images with spectroscopic information (as described below) and the results of other surface characterization techniques, it is often possible to infer the chemical composition of a surface. Furthermore, these limitations chiefly affect atomic-resolution studies of single-crystal surfaces and are not usually of consequence when topography on the nanometer scale is of primary interest.

A second common method of acquiring STM images is known as *current imaging.* In this mode, images are acquired by recording the tunneling current while the tip is rastered at constant height. The result is an image of the variation of the integrated density of states at a fixed height above the surface atoms. This method can only be used on very flat surfaces where the roughness is less than the tunneling gap but has the advantage of being very fast because only minimal feedback is required.

Another standard data acquisition mode is *multi-bias imaging,* where multiple constant-current topographs are recorded simultaneously with different bias voltages. Such images, typically recorded by repeating each scan line at multiple biases before advancing to the next line, reveal the spatial and energy dependence of the integrated density of states at the surface and are often useful for interpreting atomic-scale features. A number of examples can be found in Sec. 3.1.

2.4 Tunneling Spectroscopy

By measuring the dependence of the tunneling current on the tip–surface gap or the bias voltage, spectra containing information about the work function or density of states on the surface can be obtained. Furthermore, because tunneling only occurs over an area <1 nm^2 on the surface, such spectra reveal these properties on an atomic scale. The average work function can be extracted by measuring I as a function of s at fixed V. From Eqs. (2) and (3) we find that

$$\bar{\phi} \approx \frac{\hbar^2}{8m}\left(\frac{d\ln I}{ds}\right)^2. \tag{4}$$

The I-s measurements, sometimes referred to as barrier-height spectra, can be performed periodically over the surface to create an image of the average work function.

Scanning tunneling spectroscopy most often refers to a second type of measurement: the dependence of I on V at fixed s. This measurement is usually made by temporarily disabling the feedback, holding the tip in place, and ramping V while measuring I. I-V spectra reveal features of the local density of states on the surface, as expressed in Eq. (3). Because the exponential dependence of the tunneling probability on V [Eq. (2)] may conceal features in the spectra associated with variations of the density of states, the differential conductance, dI/dV, is often displayed instead of I. If we neglect any role of the tip density of states,

$$dI/dV \propto \rho_s(eV)T(eV). \tag{5}$$

The effects of $T(eV)$ can be further compensated for by normalizing dI/dV to the total conductance, I/V, revealing most clearly the features associated with the surface density of states:

$$\frac{dI/dV}{I/V} \propto \rho_s(eV). \tag{6}$$

I-V spectra can be made at every point in a topographic image to create a set of spectroscopy images that show the spatial variation of the density of states as a function of voltage. The interpretation of specific *I-V* spectral features is usually made by comparison with analogous photoemission and inverse photoemission spectra (see PHOTOEMISSION AND PHOTOELECTRON SPECTRA).

3. APPLICATIONS

One of the more remarkable aspects of STM is the wide range of environments in which it can operate: a stable tunnel current can be maintained in almost any nonconducting medium, including air, liquid, or vacuum. STM operation is also relatively forgiving when it comes to sample preparation: the main requirement is that the sample conduct ~1 nA at ~1 V. This flexibility allows a wide range of applications. Because of the inherent surface sensitivity of STM, it is most widely applied in the field of surface science—the study of the structural, electronic, and chemical properties of surfaces, interfaces, and thin films—a field important to a wide range of technologies, including catalysis, semiconductor device fabrication, electrochemistry, and chemical sensors. The technique is especially useful for elucidating the properties of nanometer-sized surface structures. The operating flexibility of STM combined with the ability to acquire spectroscopic images has also led to its application in the study of novel electronic properties of materials, such as charge-density waves and superconductivity. Finally, the close proximity of the tip to the surface enables one to modify surfaces with atomic-scale precision.

Although STM images and spectra can be recorded under a variety of conditions, the sensitivity of the tunneling current to any perturbation, such as the adsorption of a contaminant atom or molecule on the tip or sample, or mechanical vibration, is such that the best results are obtained with carefully prepared tips and surfaces within the controlled environment of a UHV chamber, electrochemical cell, or helium-filled cryogenic refrigerator. With the aim of best illustrating the unique microscopic and spectroscopic capabilities of STM, most of the applications chosen for this section were obtained under such optimal conditions.

3.1 Structure of Crystal Surfaces

The surface of a crystal can be described by its "Miller indices" (*hkl*). For a cubic crystal, the indices define a vector perpendicular to the surface in terms of the axes of the crystal lattice, $h\hat{\mathbf{x}} + k\hat{\mathbf{y}} + l\hat{\mathbf{z}}$. For example, a (111) surface is perpendicular to the long diagonal of the cube. On account of the loss of three-dimensional periodicity on a surface, the exposed atoms on most crystal faces move from their bulk lattice positions, a rearrangement referred to as surface reconstruction. The reconstruction is described by additional notation, $(m \times n)$, that refers to the size of the *unit cell,* which is the periodic structural unit on the surface, in relation to that of the bulk. For example, a (2×1) reconstruction on a cubic (001) surface would have a unit cell twice as large in the x direction and of equal size in y as on the bulk-terminated surface.

The ability to obtain real-space, atomic-resolution images of single-crystal surfaces has revolutionized the study of surface structure, particularly on surfaces with complex unit cells or point defects. This advance has had a major impact in surface science because determining the structure of clean surfaces is the first step to understanding their electronic and chemical properties. Note that whereas on metal surfaces the interpretation of STM topography is relatively straightforward, on other surfaces it is often necessary to complement STM results with other surface characterization techniques or theoretical calculations to assign topographic features properly to surface structures.

3.1.1 Metals One of the more dramatic illustrations of surface reconstruction is the so-called "herringbone" $(23 \times \sqrt{3})$ structure on Au(111), images of which are shown in Fig. 8. STM was instrumental in the determination of the complex structure of this large-scale reconstruction (Wöll *et al.,* 1989), which entails a contraction of the lattice at the surface such that there are 23 atoms for every 22 bulklike lattice sites. This contraction creates a herringbone-like superstructure of partial dislocation ridges [raised areas in Fig. 8(a)] where surface atoms

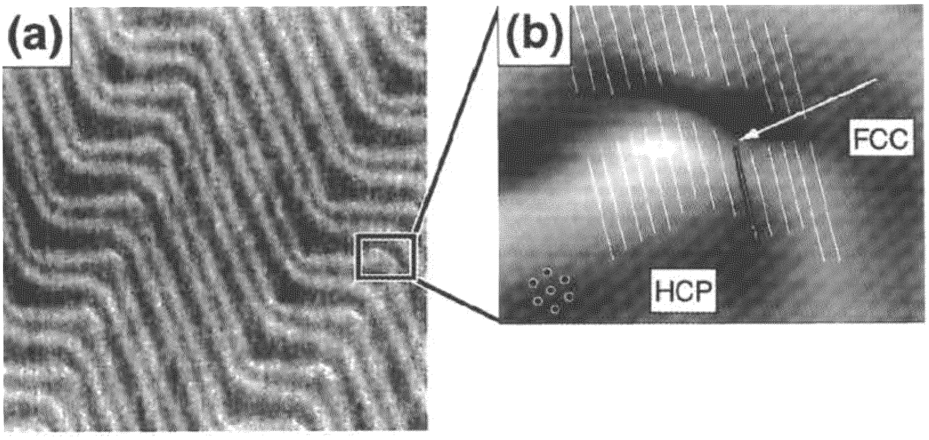

FIG. 8. Filled-state, constant-current STM images of the $(23 \times \sqrt{3})$ reconstruction on Au(111) in UHV. (a) 54 × 54 nm view showing the "herringbone" pattern (0.15-V bias, 0.5-nA current, 0.02-nm height range) (Altman and Colton, 1992, reprinted with permission of Elsevier Science—NL). (b) Atomic-resolution close-up, 6.6 × 5.2 nm, of the bulged herringbone corner where the transition between FCC and HCP stacking occurs (0.9 V, 0.5 nA) (Stroscio *et al.,* 1991). The approximate locations of some surface atoms are marked with dots; the change in height from one to the next is about 3 pm. White lines follow rows of surface atoms across the herringbone corner, highlighting the additional row on the HCP side (indicated by the arrow).

switch back and forth between their bulk positions [face-centered cubic (fcc)] and hexagonal close-packed (hcp) lattice sites. At each "knee" in the superstructure there is a surface dislocation (where the 23rd row of atoms ends), as seen with atomic resolution in Fig. 8(b). This example highlights the extreme sensitivity of STM: the surface atoms, less than 0.3 nm apart, are visible as peaks in the topography only 3 pm high.

3.1.2 Semiconductors Because of the covalent nature of the chemical bonds in a semiconductor, states within a few electron-volts of the Fermi level tend to be more spatially localized than on metal surfaces. Therefore, atomic-resolution STM images of semiconductor surfaces can be loosely described as images of the interatomic bonds and "dangling bonds" at the surface. This localization of the electronic states leads to somewhat larger corrugations than on metals, making atomic-resolution images relatively easier to acquire on semiconductor surfaces. However, because the states may not be localized around the atom cores and may be distributed differently for filled versus empty states, determining the structure from STM images is more complicated.

The local nature of the electronic states on semiconductor surfaces is very apparent in constant-current images of GaAs(110) (see Gallium Arsenide). The Ga and As atoms at the surface, which would both normally be in the surface plane, move slightly in and out of the plane in a simple (1 × 1) relaxation. The electronic effect of this structural relaxation, as shown in Fig. 9, is that the empty electronic states within a few volts of E_{F} are strongly localized on the surface Ga atoms, whereas the filled states are strongly localized on the As. The net result is that a different half of the surface atoms are seen in each image (as first reported by Feenstra *et al.,* 1987). Note that the surface shown in Fig. 9 also includes a point defect, a single missing As atom, highlighting the unique capability of STM to observe directly such structures and their affect on neighboring atoms (Lengel *et al.,* 1994).

The first surface structure ever observed with atomic resolution with an STM was the (7 × 7)-reconstructed (111) surface of silicon (Binnig *et al.,* 1983). STM images like those displayed in Fig. 10 were the critical pieces of the puzzle allowing the structure of this surface to be determined (Takayanagi *et al.,* 1985). Because constant-current images of Si(111)-(7 × 7) are so eye-catching (and relatively easy to acquire in UHV), they are probably the most widely displayed of all STM images and therefore warrant an expla-

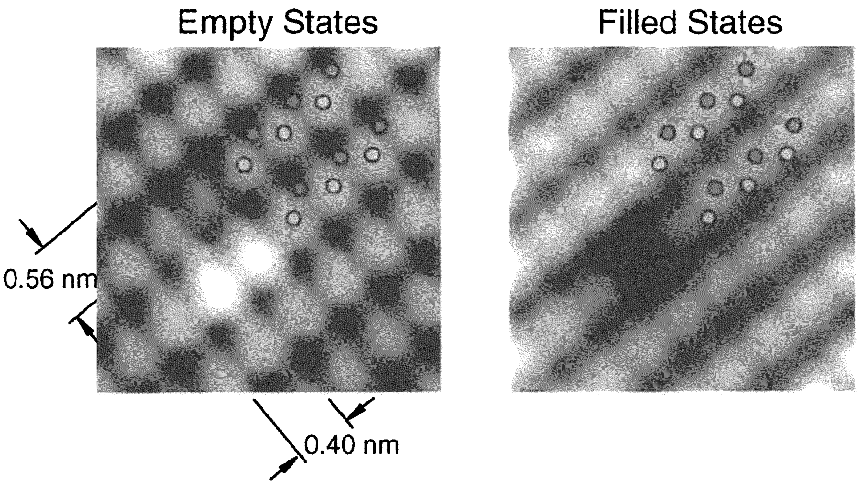

FIG. 9. Atomic-resolution empty- (2.0 V) and filled-state (1.8 V) constant-current images of the same area of a GaAs(110) surface in UHV. The locations of surface Ga atoms (light circles) and As atoms (dark circles) are indicated; the height change from atom-to-atom is about 0.02 nm in the images. The defect observed is a single surface As vacancy (after Lengel *et al.*, 1994).

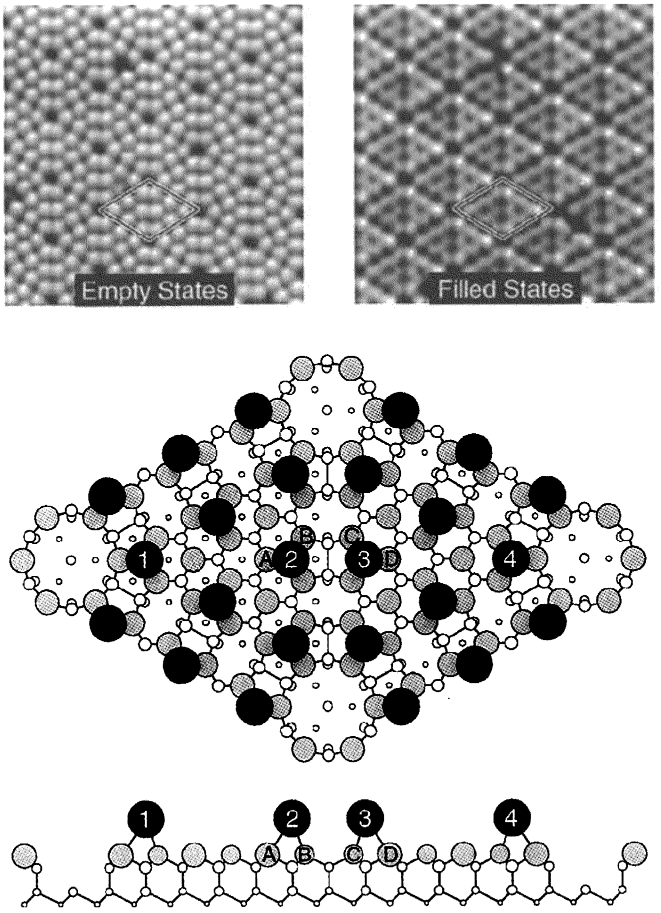

FIG. 10. The (7 × 7) reconstruction of Si(111) in UHV. Both empty- and filled-state constant-current images are shown (14 × 14 nm, ±2.0 V, 0.2-nm height range); one diamond-shaped (7 × 7) unit cell, 4.66 × 2.69 nm, is indicated (courtesy of A. A. Baski and the author). The structure of the unit cell is shown in top and side view (through the long diagonal) with the topmost atoms largest and darkest. Some of the atoms are labeled to aid correlation between the two views (after Takayanagi *et al.*, 1985).

nation. Although the structure observed in the images may appear relatively simple, the actual reconstruction is quite elaborate, involving atoms in the top three layers of the surface (Fig. 10). The topmost atoms, referred to as "adatoms," have one unfilled surface dangling bond each—the only features observed in the empty-state image. The atomic-scale features observed in the filled-state image are associated with the bonds between the adatoms and the second-layer atoms, and partially occupied dangling bonds on the second-layer atoms.

3.1.3 Oxides It is well established that the catalytic properties of oxide materials depend on the structure of their surfaces, including the density and configuration of steps, point defects, and extended crystal defects that intersect the surface. Although oxide materials are generally nonconductive, sometimes surface defects or some intrinsic material property makes them conductive enough for study with STM. For example, an STM image of the (100) surface of the mixed-valence compound $Mo_{18}O_{52}$ is shown in Fig. 11 (Rohrer *et al.*, 1993). The structure of this material can be described as a stack of MoO_3-like slabs shifted slightly from one to the next, with the shifts referred to as crystallographic shear planes. These shear planes are observed directly in the image where they intersect the surface and create a periodic array of steplike structures. Atomic-scale structures on the surface can also be resolved, including features associated with different MoO_x polyhedral groups.

3.2 Adsorption and Film Growth

Most surface-dependent technologies depend on the chemical interaction of a surface with gaseous or liquid reactants, and/or the properties of thin films deposited on a surface. Because surface chemistry is generally heterogeneous, occurring at different rates and by different mechanisms depending on the specific local arrangements of surface atoms, the direct atom-by-atom view afforded by STM makes it a particularly effective tool for studying surface reactions and thin-film growth. By observing a surface as a function of reaction parameters, such as time, temperature, and exposure to reactants, the rates and mechanisms for the individual surface sites and reaction pathways can be studied. Note that although STM can be used to study both atomic and molecular films, interpretation of atomic-resolution images is simpler when the types of chemical species on the surface (and their relative concentrations) are already known.

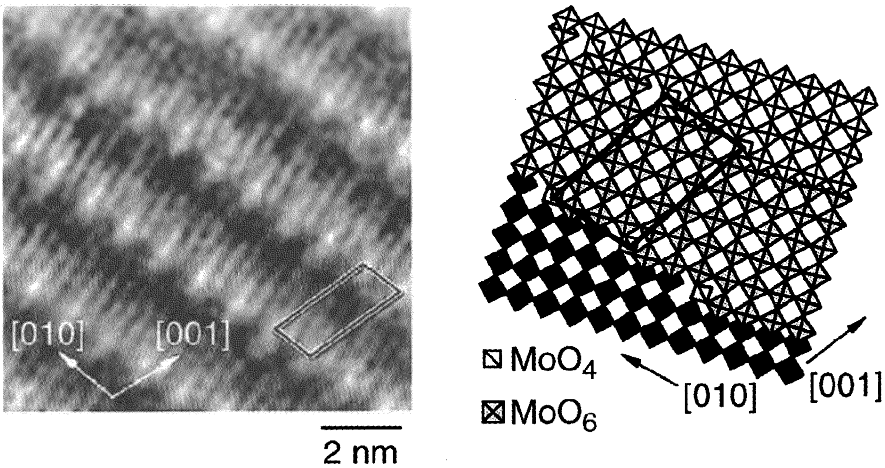

FIG. 11. Filled-state constant-current image of $Mo_{18}O_{52}(100)$ (1.6 V, 0.25-nm height range) and corresponding structural model. The planar repeat unit is indicated by the black box. The model is a polyhedral representation shaded by height (darker is lower). The sample was prepared in air and then imaged in UHV (Rohrer *et al.*, 1993, reprinted with permission of Elsevier Science—NL).

3.2.1 Atom-Resolved Surface Chemistry

The ability of STM to observe surface reactions in real time is demonstrated by the series of images displayed in Fig. 12 (Besenbacher *et al.,* 1994). These frames from an STM "movie" were recorded while a Ni(110) surface at room temperature in UHV was exposed to H_2S gas. Prior to exposure, the surface was covered with oxygen, forming a (2 × 1) reconstruction consisting of rows of alternating Ni and O atoms; only features associated with the Ni atoms are seen in the STM image [Fig. 12(a)]. The H_2S reacts with the O atoms to form H_2O gas, leaving S behind on the surface. As O atoms are removed at the start of the reaction, the neighboring Ni atoms accumulate in small S-covered islands, creating S-covered holes nearby [Figs. 12(b)–12(d)]. As the reaction proceeds, these small islands suddenly become unstable and are replaced by isolated atomic-width rows [Fig. 12(e)]. Eventually the surface becomes completely covered with such rows, forming an ordered S-induced (4 × 1) reconstruction, one that will not form at room temperature in the absence of O. The STM re-

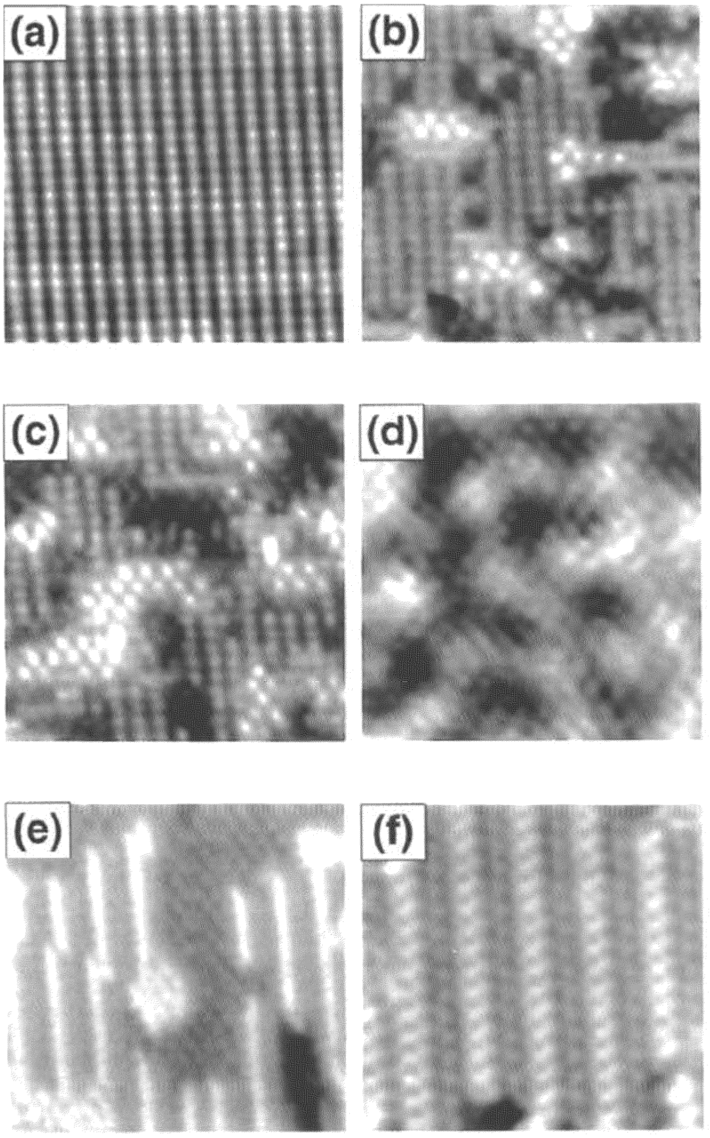

FIG. 12. Filled-state images recorded during the room-temperature reaction of H_2S with oxygen-covered Ni(110) in UHV; $H_2S_{(gas)} + O_{(surface)} \rightarrow H_2O_{(gas)} + S_{(surface)}$. (a) 0, (b) 4.0, (c) 10.6, (d) 26.6, (e) 33.3, and (f) 46.6 mbar·sec. All the images are about 9.5 × 9.5 nm, except (f), which is 7.5 × 7.5 nm (Besenbacher *et al.,* 1994, reprinted with permission of the American Vacuum Society).

sults revealed that the very small islands produced by the local removal of O create especially reactive sites for S adsorption, thereby facilitating the accumulation of S required to form the (4 × 1) structure.

The heterogeneous nature of surface reactions is highlighted by STM studies of the oxidation of Si(111)-(7 × 7), where the complex reconstruction (Fig. 10) creates a variety of inequivalent adsorption sites. As shown by the empty-state images in Fig. 13 (Martel *et al.*, 1996), when a clean Si(111) surface at room temperature is exposed to O_2 gas in UHV, the oxygen initially reacts almost exclusively with the atoms at the corners of the diamond-shaped unit cells (known as "corner hole adatoms"). The reaction results in two types of features at the corner holes, referred to as "bright" (B) and "dark" (D) sites. In addition, dark features are observed both individually and in pairs (DD). The STM images, when combined with the results of spectroscopy and other characterization techniques, revealed that the corner holes are preferred reaction sites by virtue of their higher density of states near E_F and that the reaction produces three types of species: an oxidized silicon adatom (B), an O_2 molecule bonded to an oxidized adatom (D), and an O_2 molecule bonded to a second-layer atom and interacting with two adjacent adatoms (DD). Identification of all three species is an important step toward attaining a complete understanding of the oxidation reaction.

3.2.2 Thin-Film Morphology Just as the reaction of a surface with a gas can be followed via STM, the morphology of deposited films can be monitored during growth. Film growth involves a host of processes, including adsorption, diffusion across the surface, nucleation of islands, and sticking to island or terrace edges; studies of how the morphology depends on growth conditions elucidate these reactions. For example, in Fig. 14 the temperature-dependent film morphology observed with a variable-temperature STM is shown for a tenth of a layer of Ag deposited on Pt(111) in UHV (Röder *et al.*, 1993). At 80 K the atoms migrate short distances upon deposition, forming small Y-shaped clusters (with an average of 19 atoms in each). As the temperature is increased, faster diffusion allows more of the deposited atoms to reach a Pt surface step where they become trapped, producing the morphology observed at 130 K. At this temperature migration of atoms along island edges is still hindered, however, giving the islands a jagged shape. At 170 K the temperature-dependent mobility is large enough to allow almost all nucleation to occur at step edges, which become noticeably smoother. Finally, at 300 K the film grows as round-edged is-

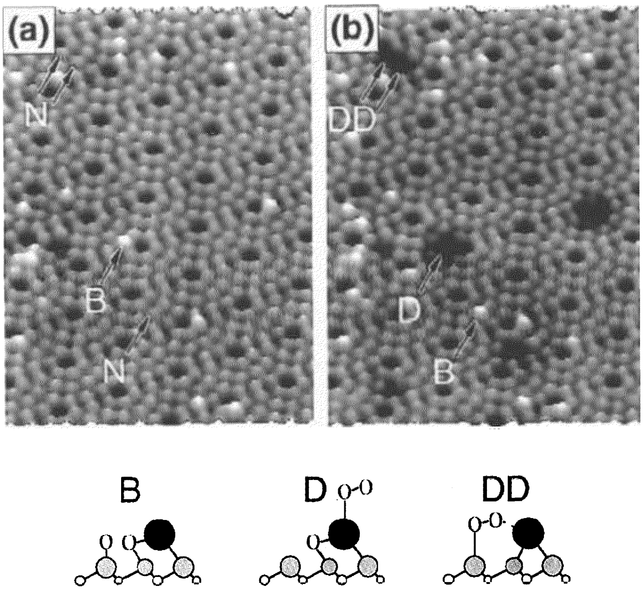

FIG. 13. Empty-state images (14 × 21.5 nm) of a Si(111)-(7 × 7) surface during the early stages of oxidation in UHV: after exposure to (a) 0.067 and (b) 0.133 mbar·sec of O_2. The arrows point to typical reaction sites: not reacted (N), bright (B), dark (D), and two adjacent dark sites (DD). Structural models for the reacted sites are also shown (after Martel *et al.*, 1996).

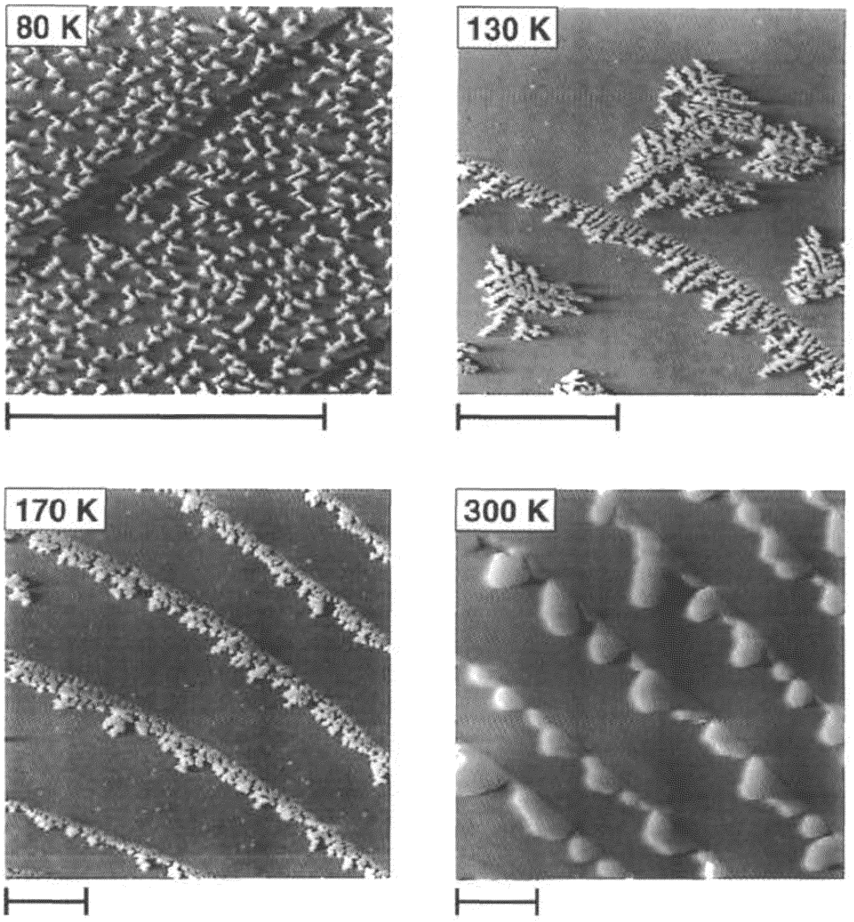

FIG. 14. Filled-state variable-temperature STM images of the growth of 0.1 layer of Ag on Pt(111) in UHV. The scale bars are all 50 nm, and the images are gray-scales of the *derivative* of the topography (which highlights edges) (Röder *et al.*, 1993, reprinted with permission of Elsevier Science—NL).

lands flowing out from the step edges, close to the equilibrium morphology. These STM results, combined with other images recorded as a function of film thickness, led to a detailed understanding of the atomic-scale kinetics and mechanisms of Ag growth on Pt(111), experimentally confirming general theories about nucleation and growth (Brune *et al.*, 1994).

In addition to furthering our general understanding of growth processes, STM can be used more simply as a direct method of characterizing the nanometer-scale morphology of multilayer films. This is an important application given that many thin-film–based technologies require films to be as nearly perfect as possible for optimum performance. The type of information attainable is illustrated in Fig. 15, where an STM image of a 4-μm-thick GaSb (gallium antimonide) film grown on a GaAs(001) substrate in UHV is displayed. The film was deposited by molecular-beam epitaxy (*q.v.*) for possible use in an electronic device (Thibado *et al.*, 1996). The surface consists of spiral-like mounds approximately 5 nm high, with each "step" on the surface a single atomic layer (about 0.3 nm). The striking morphology results from the crystal lattice of GaSb being 7% larger than that of GaAs, which causes crystal dislocations to form in the deposited films. These dislocations, which are detrimental to electronic devices, thread up through the film and emerge at the surface to produce a step. This type of characterization allows the effects of various growth con-

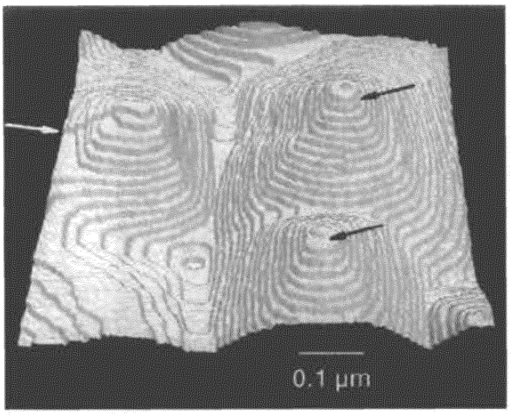

FIG. 15. The topography of a 4-μm-thick GaSb film grown on a GaAs(001) substrate by molecular-beam epitaxy in UHV. Each step in the constant-current image is about 0.3 nm high. The arrows point out where threading dislocations emerge at the surface and create steps. (Courtesy of P. M. Thibado, B. R. Bennett, B. V. Shanabrook, and the author.)

ditions to be directly observed, thereby simplifying the effort to improve the film quality.

3.3 Electrochemistry

Electrochemical technologies rely on processes that occur at the solid–liquid interface. Whereas in air and vacuum one can control the type and concentrations of reactants along with the substrate temperature; in an electrochemical environment an additional parameter can be varied: the electrochemical potential (see ELECTROCHEMISTRY). Control of this potential allows one to vary the thermodynamics of electrochemical reactions, including both reversible and irreversible processes such as oxidation, reduction, deposition, and changes in surface reconstruction; STM allows the atomic-scale nature of these processes to be directly observed *in situ*. One such process is exhibited in the series of STM images in Fig. 16, recorded during the oxidation of the naturally occurring semiconductor galena (PbS) in a solution of $NaClO_4$ (Higgins and Hamers, 1995). The reaction, $PbS \rightarrow Pb^{2+} + S + 2e^-$, is seen to occur almost exclusively via removal of atoms at step edges. Furthermore, impurities (I) are observed to cause etch pits (P) in the surface. Combined with STM images recorded during electrochemical reduction cycles, the complex surface electrochemistry of galena was elucidated on the atomic scale for the first time.

3.4 Surface Electronic Structure

Although some effects related to surface electronic structure were indirectly revealed in the applications discussed above, atomic-scale electronic properties can be more directly studied using the various imaging and spectroscopy modes described in Sec. 2. In this way the local electronic properties (including work function, conductivity, and density of states) of clean surfaces, point defects, isolated adsorbed atoms and molecules, nanometer-scale islands, and thin films can be observed. (See also ELECTRONIC STRUCTURE OF SURFACES.)

3.4.1 Conductance versus Structure One of the simplest and most direct applications of tunneling spectroscopy is the examination of the local conductance as revealed by the shape of *I-V* spectra recorded over different surface structures. A nice illustration of this application is the study of the conductance of different Cs structures observed on GaAs(110) in UHV (Whitman *et al.*, 1991). As Cs is deposited on the surface at room temperature, it first forms one-dimensional (1D) atomic chains, then a 2D array of planar clusters, and finally a disordered film of 3D clusters (images not shown). As displayed in Fig. 17, *I-V* spectra recorded on clean GaAs(110) have the expected tunnel-diode shape, with zero current (and zero differential conductance) within the semiconductor bulk band gap. Spectra recorded over the Cs structures, however, show that the local "band gap" decreases as the structures change from 1D to 3D. The 3D structures appear metallic, i.e., there is nonzero conductance at E_F (zero sample voltage). These spectroscopy results furthered our understanding of the properties of nanometer-scale metal-on-semiconductor structures.

3.4.2 Chemically Selective Imaging Local variations in the density of states that are associated with particular surface atoms or molecules can sometimes be exploited to provide atom-selective topographic contrast.

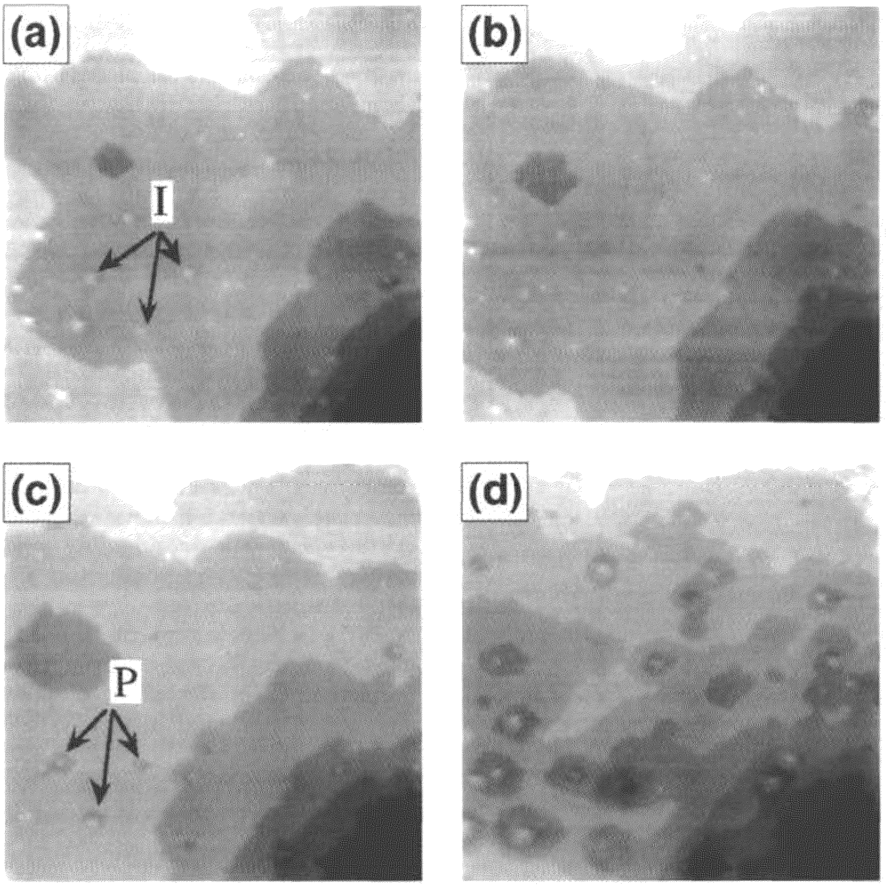

FIG. 16. A selection of constant-current images of PbS(001) acquired during electrochemical oxidation in $NaClO_4$. All images are 200 × 200 nm, with each successive gray level corresponding to a change in height of 0.3 nm. The images were recorded with a tunneling current of 0.17 nA, tip voltage of 0.94 V, and a sample voltage that changed from (a) 0.20 to 0.24, (b) 0.29 to 0.33, (c) 0.38 to 0.43, and (d) 0.38 to 0.34 V during image acquisition. Some surface impurities (I) and the resulting etch pits (P) are labeled (Higgins and Hamers, 1995, reprinted with permission of Elsevier Science—NL).

An extreme example is the (110) surface of GaAs discussed in Sec. 3.1.2 (Fig. 9), where only Ga (As) features are seen in empty (filled) states. A subtler, more elegant example is found in a study of Cr films deposited on Fe(001) (Davies *et al.*, 1996), the results of which are presented in Fig. 18. Metal "sandwiches" composed of alternating thin layers of ferromagnetic (e.g., Fe) and nonmagnetic (e.g., Cr) layers have novel magnetic properties of potential use in magnetic recording technologies. The properties are not always as expected, however, and this STM study revealed a possible cause. Rather than forming a simple overlayer, Cr alloys with the substrate, with Cr atoms randomly embedding into the surface. The Fe atoms displaced by this process intermix with additional Cr atoms to form isolated single-layer islands. Tunneling spectra recorded over the embedded Cr atoms differ from Fe spectra, with an extra peak in the conductance about 0.3 V below E_F; this extra conductance causes a small bump (~0.01 nm high) over every Cr atom in the constant-current topography recorded at negative sample bias. That spectral feature and the associated atom-selective images led directly to an understanding of the Cr/Fe interface structure.

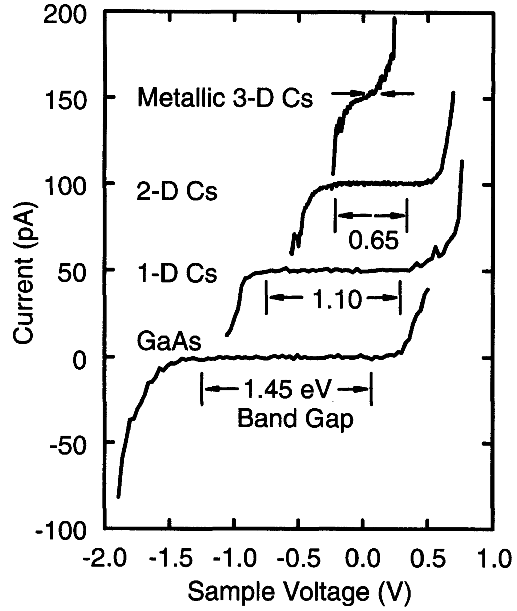

FIG. 17. Current-versus-voltage tunneling spectra recorded on clean and Cs-covered GaAs(110) in UHV. With increasing Cs coverage long 1D chains, then 2D planar clusters, and finally a disordered 3D overlayer are observed (images not shown). The apparent "band gap" observed for each structure is indicated (Whitman *et al.*, 1991).

3.5 Bulk Electronic Structure

The different chemical environment at a surface with respect to that in the bulk usually results in distinct structural and electronic properties. Exceptions to this situation occur in materials with strong covalent bonding in 2D layers and weak noncovalent bonds holding the layers together: When the weak bonds are broken to expose a surface, the surface atoms do not differ greatly from those at the interlayer interfaces, and STM can therefore be used to observe bulk properties. This is very fortuitous because the 2D nature of such materials often gives them scientifically fascinating properties. For instance, one important class of these layered materials, transition-metal dichalcogenides, exhibit both superconducting and charge-density-wave (CDW) phases (see COLLECTIVE PHENOMENA IN SOLIDS).

For superconducting phases, STM can be used to directly study spatial variations in the energy gap, the effect of point defects and impurities, and magnetic-field effects. Because charge-density waves are periodic variations of the charge density near E_F (caused by electron–phonon coupling), they

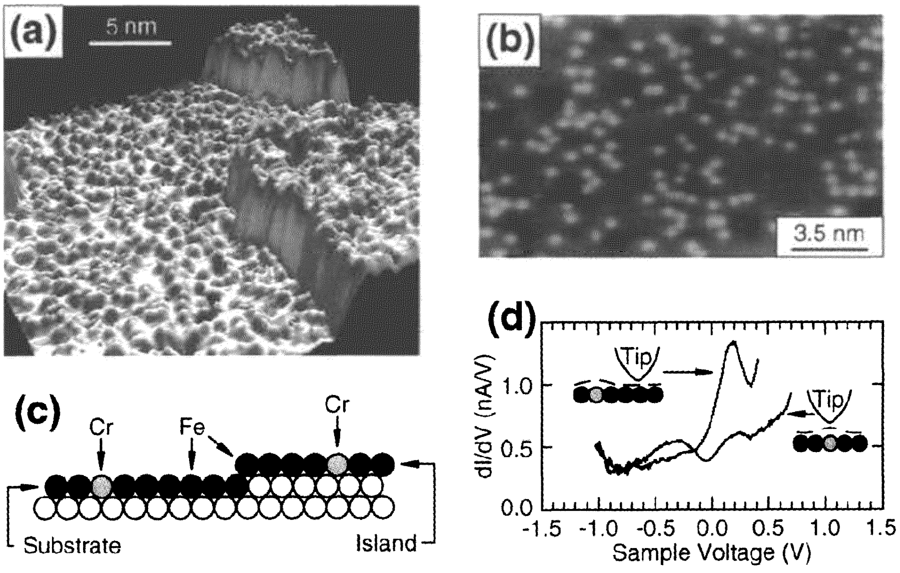

FIG. 18. (a) Filled-state image (1.1 V) of 0.4 layer of Cr deposited on Fe(100) at 290 C in UHV. Each step is 0.14 nm high, and the small bumps in the topography are approximately 0.01 nm high. (b) A higher-resolution view of the Cr-induced bumps. (c) A structural model for the Cr film. The Cr atoms are embedded in the substrate, with displaced Fe atoms forming single-layer islands. (d) Conductance spectra recorded over a Cr or Fe surface atom (after Davies *et al.*, 1996).

can also be directly imaged with STM, as shown in Fig. 19 for TaS_2 (Liu *et al.*, 1996). On pure TaS_2 crystals the CDW is observed as a large hexagonal corrugation (0.2–0.4 nm) with a period distinctly different from the smaller corrugation (<0.1 nm) associated with the underlying crystal lattice. Bulk impurity atoms (Nb) introduce dislocations and other forms of local disorder into the CDW but do not affect the long-range orientational order. More detailed image analysis as a function of impurity concentration showed that the CDW lattice evolves from a crystalline state to an amorphous liquidlike state with increasing concentration—a significant discovery about the nature of this material.

3.6 Atom Manipulation and Nanolithography

The nanometer-scale nature of the tip–surface interaction combined with the unprecedented degree of position control available with the STM make it a revolutionary instrument for surface modification. There are four fundamental processes inherent to surface modification: removal of surface atoms, deposition of new material, lateral translation of adsorbed atoms, and induction of surface chemical reactions. All of these processes can be actuated on the atomic scale via the three basic control parameters in an STM: the tip properties, including the material composition and shape of the tip; the tunneling current; and the electric field in the tunnel junction (a function of the gap and the bias voltage). Depending on the degree of control and the intensity of the tip–surface interactions, modifications can be made from the micron to the atomic scale. Although practical applications of such "nanolithography" have yet to be realized, the STM is a new tool with which to explore the properties of nanometer-scale structures and the limits of physical lithography.

3.6.1 Electron-Stimulated Patterning

The needlelike shape of etched STM tips provides extremely effective focusing of the emitted electrons, in both tunneling and field-emission modes. Even though the total current is very small, this focusing makes the current density quite large: 10^{11}–10^{12} times higher than a conventional electron beam with the same current. Combined with the large electric field in the tunnel junction ($\sim 10^7$–10^8 V/cm), that current density makes the STM an efficient tool for breaking surface chemical bonds. Figure 20 demonstrates this phenomenon as applied to lithography on Si(001) (Lyding *et al.*, 1994), the substrate on which the semiconductor industry is based. The surface was first covered with atomic hydrogen, which reacts with the surface Si atoms, passivating their dangling bonds and making the surface unreactive to most other gases. Raising the sample bias voltage above ~4 V gives the electrons enough energy to break the H–Si bond and

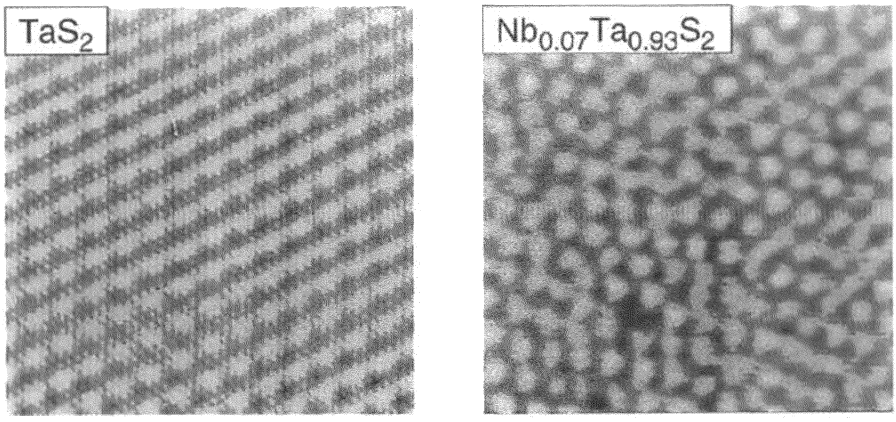

FIG. 19. Constant-current filled-state images (15 × 15 nm, 50 mV, 1 nA) of $Nb_xTa_{1-x}S_2$ crystals recorded in a nitrogen-filled glove box at 380 ($x = 0$) and 315 K ($x = 0.07$). The large-period corrugation is due to a charge-density wave that is incommensurate with the crystal lattice (the smaller, shorter-period corrugation) (Liu *et al.*, 1996, reprinted with permission of the American Vacuum Society).

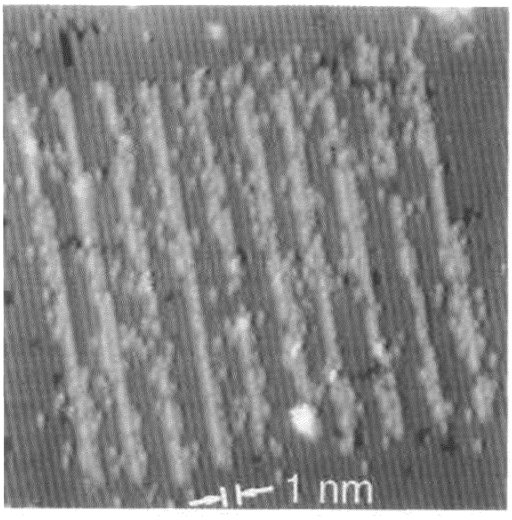

FIG. 20. Filled-state image (37.5 × 37.5 nm) of nanometer-scale lithography of Si(001) − (2 × 1) with an STM in UHV. The surface was first covered with atomic hydrogen, forming (2 × 1)-reconstructed rows of H–Si = Si–H (the dimmer rows visible in the image). The H was then locally removed (bright rows) by scanning the desired areas with a high sample bias and current (4.5 V, 2.0 nA) (Lyding *et al.*, 1994, reprinted with permission of the American Institute of Physics). The lines are ≤1 nm wide on a 3-nm pitch.

thereby locally remove H from the surface. (The H-free areas appear brighter in filled-state images because of a larger density of states on the bare Si atoms.) This removal can be confined to lines only one or two Si atoms wide. When the patterned passivated surface is exposed to a reactant such as O_2, only the H-free areas react (not shown).

3.6.2 Positioning Single Atoms Perhaps the most dramatic use of an STM has been to perform the ultimate surface modification: the controlled manipulation of individual surface atoms (Eigler and Schweizer, 1990). Using an STM operating in UHV at a cryogenic temperature (4 K), IBM scientists have precisely positioned adsorbed atoms by carefully placing the tip in contact with them one at a time and gently sliding them across the surface. (The atoms are otherwise immobile at this low temperature.) A sequence of images recorded during the assembly of a ring of 48 Fe atoms on Cu(111) is displayed in Fig. 21. When the first image was recorded, one-quarter of the ring had already been assembled and the additional Fe atoms required positioned nearby. A striking consequence of the construction of this "quantum corral" is the formation of electron standing waves within the ring, observable with the STM through its sensitivity to charge-density modulations (Crommie *et al.*, 1993). These waves are produced when surface electrons are reflected by the Fe atoms within the ring and interfere with themselves—a direct observation of the wave nature of electrons as described by quantum mechanics.

4. RELATED TECHNIQUES

The basic elements of the STM, a sharp probe held in close proximity to a sample surface with precise position control, have evolved into a remarkable number of related scanning-probe microscopies capable of measuring an astonishing array of structural, electrical, and chemical properties, often with nanometer-scale spatial resolution (see, for example, Wiesendanger, 1994). Four of the most common of these techniques, all commercially available, are briefly described here.

Atomic-force microscopy (AFM), the simplest extension of STM, allows the study of nonconductive samples by using the force of the tip–surface interaction as the control parameter. In an AFM the tip usually consists of a micron-sized silicon nitride pyramid on the end of a silicon nitride microcantilever a few hundred microns long, fabricated using semiconductor lithography and etching techniques. By maintaining a constant tip–surface force (as measured by the deflection of the cantilever and typically in the range of 10^{-8}–10^{-9} N), the tip can be rastered across a surface to observe topography routinely with ~1 nm resolution. Moreover, a variety of imaging and spectroscopy modes have been developed to measure force-related phenomena, including friction, adhesion, and indentation. In addition to being a powerful research tool, AFM is widely used for routine high-resolution microscopy on account of its ability to image almost any type of material under ambient conditions.

In magnetic-force microscopy (MFM) the spatial variation of the magnetic force interaction between a magnetic tip and sample is

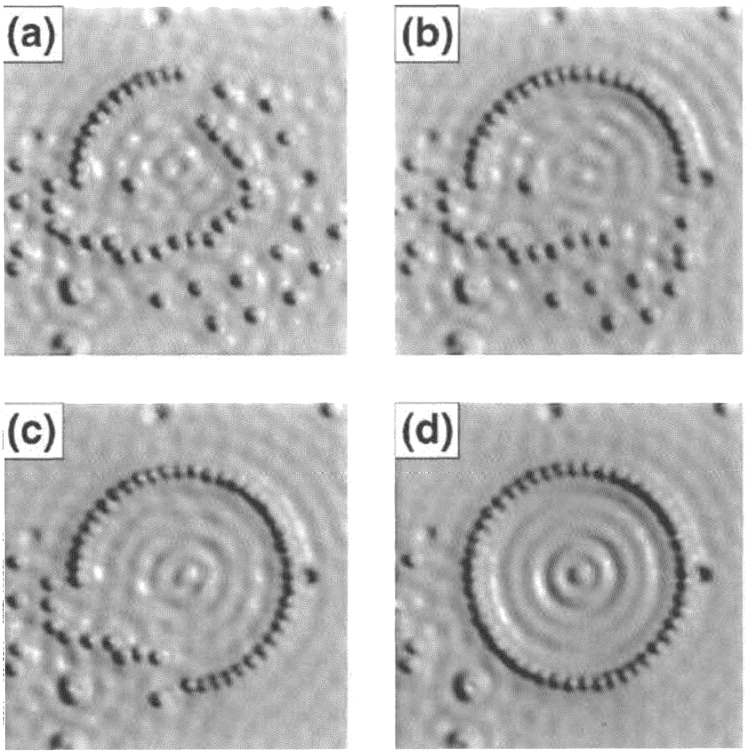

FIG. 21. (a)–(d) Sequential constant-current empty-state images (0.01 V, 1.0 nA) recorded during the assembly of a circle of Fe atoms on Cu(111) at 4 K in UHV. The average diameter of the circle is 14.25 nm. The structure was assembled one atom at a time using the STM tip. The concentric rings seen in the image are variations in the local density of states (not atomic heights) associated with standing waves created by surface electrons trapped inside the circle of Fe atoms (a "quantum corral"). (Courtesy of M. F. Crommie, C. P. Lutz, and D. M. Eigler.)

measured, usually by mounting a magnetic tip on the end of an AFM-style cantilever. In this way, images of the stray magnetic field (or its gradient) above a surface can be acquired with a spatial resolution of 20–100 nm. Because MFM works under ambient conditions and on samples with nonmagnetic coatings or surface contamination, it is particularly useful for characterizing magnetic recording media.

Near-field scanning optical microscopy (NSOM) or scanning near-field optical microscopy (SNOM) replaces the STM tip with an optical fiber drawn to a point of ~100 nm diameter. The fiber is coated with metal everywhere but on the end, thereby defining a nanometer-scale aperture that is held ~10 nm from the sample. The evanescent light either reflected from or transmitted through a sample is then collected with high spatial resolution. Whereas the resolution of conventional optics is limited by diffraction, collecting the light in this "near-field" regime enables a spatial resolution much less than the wavelength of the light. In addition to providing high-resolution optical microscopy, spectroscopy can be performed on the collected light allowing the optical characterization of material defects, nanometer-scale structures, and molecular properties (via fluorescence detection).

Ballistic electron-emission microscopy (BEEM) was developed in order to characterize electron transport through buried interfaces, typically between a thin film and a substrate with different electrical properties (e.g., a metal film on a semiconductor). Whereas STM is a two-electrode technique (the tip and the sample), BEEM adds a third electrode, a current collector on the edge of the thin film. The tip injects electrons into the thin film, almost all of which reach the buried interface without energy loss. Current observed at the collector is therefore a measure of electron scattering at the interface; it can be recorded as a function of the tip position along with an STM image, providing a simultaneous image of the buried interface. Furthermore, by measuring the dependence of the collector current on the sample bias, spectroscopy of interface electronic transport can also be performed.

ACKNOWLEDGMENT

GLOSSARY

Adsorption: The process whereby an atom or molecule becomes bonded to a surface.

Dangling Bond: An unbonded molecular orbital on a surface atom of a covalent or ionic crystal.

Density of States: The number of electronic levels per unit energy in a material.

Fermi Level (E_F): The energy of the highest occupied electronic state in a material at 0 K.

Miller Indices: Notation (*hkl*) used to describe a surface of a crystal. For a cubic crystal, the indices define a vector perpendicular to the surface, $h\hat{\mathbf{x}} + k\hat{\mathbf{y}} + l\hat{\mathbf{z}}$, where $\hat{\mathbf{x}}$, $\hat{\mathbf{y}}$, and $\hat{\mathbf{z}}$ are the crystal axes.

Piezoelectric Ceramic: A material that expands or contracts when an electric field is applied across it. (See PIEZOELECTRIC DEVICES.)

Reconstruction: A rearrangement of the atoms on a crystal surface that changes their symmetry with respect to bulk positions. When the rearrangement is periodic it is denoted by the size of the unit cell, $(m \times n)$, with respect to the natural crystal structure, (1×1).

Surface Science: The study of the structural, electronic, and chemical properties of surfaces, interfaces, and thin films. (See AUGER SPECTROSCOPY; CATALYSIS; CHARACTERIZATION AND ANALYSIS OF MATERIALS; CVD (CHEMICAL VAPOR DEPOSITION); ELECTRON DIFFRACTION; ELECTRON MICROSCOPY; ELECTRONIC STRUCTURE OF SURFACES; FIELD ION MICROSCOPY; MOLECULAR BEAM EPITAXY; and PHOTOEMISSION AND PHOTOELECTRON SPECTRA.)

Surface Step: The place on a crystal surface where the height changes by one or more discrete layers of atoms.

Tunneling: The quantum-mechanical process whereby an electron is transported across a classically forbidden energy barrier.

Ultrahigh Vacuum (UHV): A pressure $<1 \times 10^{-7}$ Pa, low enough to prevent contamination of a surface by residual gases for many minutes.

Unit Cell: The periodic structural unit on a crystal surface.

Work Function: The energy required to move an electron at the Fermi level from the surface into the vacuum. (See ELECTRONIC STRUCTURE OF SURFACES.)

INTRODUCTION

The gas turbine or gas turbine engine is a unique member of the family of heat engines that work on the principle of sequential compression, heat addition, and expansion of a working fluid. The gas turbine engine derives its uniqueness from its use of single-phase gas as working fluid rather than a two-phase liquid/vapor system such as characterizes the steam turbine; its use of steady flow compression and expansion in a turbo-compressor driven by a turbo-expander; and continuous heat addition at essentially constant pressure. The use of steady flow compression, heat addition, and expansion are the special characteristics that distinguish the gas turbine engine from those cycles (such as the Otto, Sterling, and Diesel) that are based on periodic batch processes that accomplish compression, combustion, and expansion in a closed volume such as the piston chamber of a reciprocating engine.

A typical modern gas turbine engine, used for marine propulsion and industrial power applications but, as is frequently the case, actually derived from the power section of an aircraft engine, is shown in Fig. 1.

1. PHYSICAL AND TECHNICAL PRINCIPLES

1.1 The Brayton Cycle and the Gas Generator

The gas turbine engine cycle involves a single-phase gaseous working fluid, most often air and the products of combustion. As with most heat engines, the gas turbine engine functions on the basis of compression of a relatively cool working fluid, followed by heat addition to the compressed working fluid and followed by expansion or work extraction from the hot, high-pressure working fluid. Since more work can be extracted from the hot high-pressure working fluid than is required to compress the cooler fluid, there is a surplus of mechanical energy left

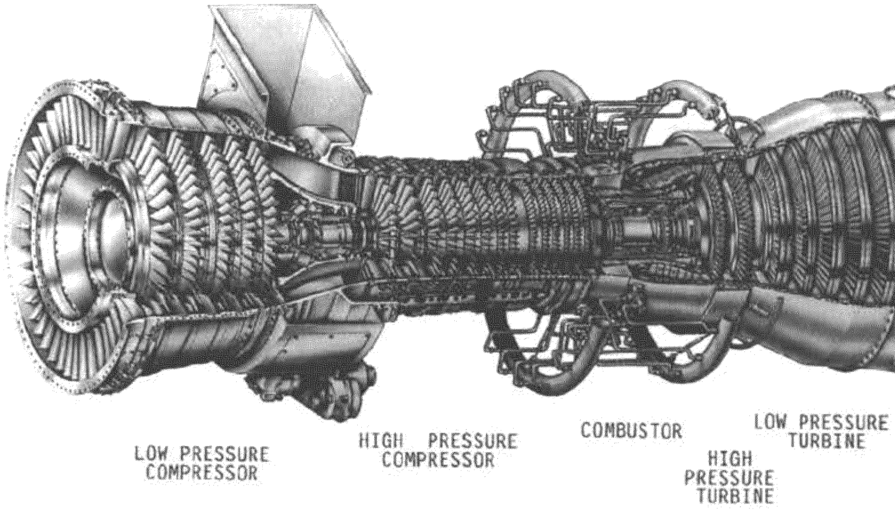

FIG. 1. A typical modern gas turbine engine, the GE LM6000 derived from an aircraft engine for marine and industrial application (courtesy of the General Electric Co.).

as a net output after subtracting the energy required to power the compression process.

The compression and expansion (or work extraction) are accomplished by, respectively, turbo-compression and turbo-expansion components, which impart energy to or extract energy from the steady stream of working fluid. The heating of the working fluid is accomplished in a steady flow process at essentially constant pressure either by heat exchange with an external heat source or, more usually, by continuous internal combustion of a gaseous or liquid fuel in the air that is the usual working fluid of the thermodynamic cycle. The constant-pressure combustion is one of the unique features of the gas turbine engine that characterize the Brayton cycle. When designed as an internal combustion engine, the system is, of necessity, an open cycle. That is, the existing working fluid cannot be cooled and returned to the inlet since its oxygen has been converted to products of combustion, and it cannot sustain combustion a second time. The vitiated air is discharged from the engine, and the working fluid is constantly replenished at the compressor inlet with fresh air.

The expansion process is most often carried out in two distinct steps, manifested by two distinct turbine components. In the first, or high-pressure, turbine, the working fluid is expanded through only a portion of the available pressure ratio, enough to supply the energy to drive the compressor. This combination of compressor, combustor, and high-pressure turbine is referred to as the gas turbine engine core or gasifier or gas generator. Its output, sometimes referred to as gas horsepower, is a continuous stream of high-pressure, high-temperature working fluid that contains the net useful energy output of the engine. In some instances such as with the jet engine, the stream of high-pressure, high-temperature gas is the appropriate net product of the gas turbine engine. But, more often, the core is followed by a second expansion component referred to as the low pressure or power turbine, operating on an independent rotor at an independent rotational speed, which extracts the available mechanical energy from the core discharge stream and delivers it to the load that is being driven. In this arrangement, the level of power can be modulated by varying fuel flow and letting the core rotational speed vary, without affecting the rotational speed of the driven load.

1.2 Energy Conversion and System Efficiency

The heat released by burning a typical hydrocarbon fuel in air is typically 18 650 BTU/lb_m (or 43 370 kJ/kg) of fuel. If this process were 100% efficient, it would produce power for every unit of fuel flow of 7.45 hp/(lb$_m$/h) [or 12.0 kW/(kg/h)]. In actual fact, the fundamental thermodynamic limitation termed the Carnot efficiency (η_{Carnot}), relating the peak gas temperature achieved in the cycle ($T_{\max}$) and the temperature of the inlet gas ($T_{\min}$), restricts the efficiency to a value of

$$\eta_{\text{Carnot}} = 1 - (T_{\min}/T_{\max}). \tag{1}$$

The cycle efficiency is further limited by the fact that the Brayton cycle involves heat addition to the working fluid at constant pressure rather than at the idealized constant temperature of the Carnot cycle. The peak pressure achieved in the Brayton cycle also affects the efficiency of energy generation. This then implies that the upper bound of the energy production per unit fuel flow is generally no more than 60% efficient, implying that the lower bound of specific fuel consumption (SFC) for an engine is 0.224 (lb$_m$/h)/hp [or 0.139 (kg/h)/kW]. In actual practice, the specific fuel consumption will be even higher than this lower bound because of less than ideal performance in the individual components of the prime mover, including leakage of high-pressure working fluid (air or products of combustion); leakage of heat from the high-temperature working fluid to the lower-temperature engine bay; pressure losses in the passages through which the working fluid moves from component to component; diversion of a portion of the air to cool high-temperature parts; and inefficiencies in the compression, combustion, and expansion components of the engine.

High cycle peak temperatures and pressure ratios are of considerable importance in achieving low SFC. Modern gas turbine engine power-producer sections, particularly where they are derived from advanced aircraft engines, may have cycle pressure ratios as high as 40:1 and peak cycle temperatures on the order of 2800 °F (or 1573 °C).

1.3 Cycle Elaboration

As shown in Fig. 2 in schematic form and in thermodynamic representation of variation of temperature vs entropy, variations of the basic Brayton cycle [Fig. 2(a)] such as regeneration [Fig. 2(b)], intercooling [Fig. 2(c)], and reheat [Fig. 2(d)] are used alone or in combination to improve the gas turbine engine's efficiency of energy conversion and/or to increase the amount of power available from a given size machine with a limited through-flow of working fluid (Wilson, 1984).

1.3.1 Regeneration Depending on the configuration of the heat exchanger used, this is also referred to as recuperation. As shown in Fig. 2(b), heat may be extracted from the low-pressure working fluid at the engine's discharge and used to preheat the high-pressure working fluid discharged by the compressor before it enters the combustor. The heat that is transferred makes possible a direct saving of fuel that would have otherwise been expended in the combustor of an unregenerated engine.

1.3.2 Intercooling The amount of energy required to compress a gas is proportional to the temperature of the gas. A significant saving in the energy consumed by the compression process can be achieved by splitting the compressor into two or more stages, as shown in Fig. 2(c), and cooling the working fluid between each pair of successive stages of compression. Intercooling generally results in an increase in power production for a given size engine but requires a heat sink for the heat rejected in the intercooler.

1.3.3 Reheat This is also referred to as interburning. The amount of energy that can be extracted from the expansion of a pressurized working fluid is directly proportional to the temperature of the fluid. Therefore, as shown in Fig. 2(d), additional work can be obtained from an engine of a given size by splitting the turbine into two or more stages and inserting a burner or burners between each successive pair of stages. The principle is very limited in its application because heat insertion at low pressure is less efficient than heat addition at high pressure, so that reheat generally degrades the fuel economy of the engine. The reheat combustor is also a challenging component design because of its operation at higher inlet temperature and lower pressure than the main combustor.

2. DESIGN, FUNCTION, AND OPERATION

2.1 Key Components

The basic components of the gas turbine engine are the compressor(s), the combustor, and the turbine(s).

2.1.1 Compressors The efficient turbocompressor, which delivers a steady stream of high-pressure working fluid to the combustor, is fundamental to the gas turbine engine. The compression of the working fluid flowing in an annular passage is accomplished by means of an annular set of airfoils or blades mounted on the rim of a high-speed rotating disk, which accelerates the stream by imparting to it some of the tangential velocity of the rotor. The rotor is followed by an annular set of stationary airfoils or vanes that decelerate or diffuse the stream providing a net increase in the pressure.

Since the pressure rise in a single consecutive pair of rotating and stationary sets of airfoils (i.e., a stage) is limited by the diffusion (or stall) characteristics of the airfoils, the high pressures required by efficient gas turbine engine cycles are generally achieved by multiple-stage machines.

Although the compressors of early gas turbine engines were radial- or centrifugal-flow components, axial-flow compressors have been developed to achieve higher efficiency levels, lighter weight, and, for aircraft usage, lower frontal areas. They are therefore the prevailing approach in all gas turbine engines except for the smallest sizes where the axial-flow airfoils are not rugged enough for engine duty. In these small machines, we find single- and two-stage centrifugal compressors, as well as hybrid axi-centrifugal components—one or more axial stages followed by a centrifugal stage.

Multiple-stage compressors with pressure ratios above 5:1 or 10:1 involve extremely wide variation of flow conditions to the individual rows of airfoils in the front and the rear of the compressor as the speed and pressure ratio vary through the operating range. Such mismatch is aggravated by other operational circumstances such as nonuniform pressure distributions delivered by the inlet duct and/or rapid changes in the spool speed. Ultimately, the large angles of attack seen by individual airfoils will cause them to stall and result in unstable operation of the engine called surge. Such surge may cause flame-out or other malfunctions that result in loss of power and physical damage to the engine. Various approaches have evolved to afford high-pressure compressors the required amounts of stall margin. As shown in Fig. 1, a very high-pressure compressor may be split into two sections—the low- and high-pressure sections—each operating on a separate spool at its own speed and driven by its own turbine. An alternative or supplementary approach to the design of high-pressure compressors (called variable geometry) is to provide pivots for each stator vane in certain stages of the compressor along with actuators that will vary the pitch angle of the vanes as a function of the spool speed and compressor inlet conditions to avoid the large angles of attack and the stall and surge that might ensue.

2.1.2 Combustors The combustor of the modern gas turbine engine, sometimes referred to as the burner, is usually an annular chamber, in the middle of the core between the compressor exit and the turbine entry, and surrounding the center shaft(s) by which the turbine(s) aft of the combustor drives the compressor(s) forward of the combustor, as shown in Fig. 1. Fuel is introduced at the upstream end of the combustor through injectors that may exploit one of several mechanisms to condition the fuel for the combustion process. With a high-pressure fuel or atomizing system, the fuel is introduced through very small orifices in the nozzle, which generate a very fine spray. With an intermediate fuel-pressure system, sometimes referred to as the air-blast injection system, the droplets may not be fine enough to permit ignition-efficient combustion, and so various types of shear layers are introduced into the airstream in proximity to the injector to break up the droplets further. With a low-pressure fuel system or a vaporizing system, the injectors may also be located in a hot region of the combustor so that the fuel is preheated and completely vaporized before entering the combustor.

The combustion process is confined in a liner or shell, cooled by unburned air, which serves not only to contain the flame but also to provide passages for air jets, lateral to the main direction of the flow, which promote and stabilize the flame, and dilute its high-temperature zones to a more uniform level of temperature that can be tolerated by the downstream turbine. One or more electric spark igniters are placed strategically in the chamber to light the flame in the course of starting the engine.

2.1.3 Turbines These are also referred to as expanders. An annular row of stationary airfoils referred to as nozzles is used to accelerate and impart tangential motion to the high-temperature, high-pressure stream of working fluid exiting from the annular discharge passage of the combustor. That high-velocity stream impinges on a row of airfoils, referred to as blades or buckets, arranged in an annular space at the perimeter of a high-speed rotating disk, which acts in the manner of a windmill to extract energy from the stream. Since the amount of energy that can be extracted from a single pair of stationary and rotating blade rows (or turbine stage) is generally limited by such factors as maximum transonic gas velocities, a multiple stage turbine is often required to complete the energy extraction process, as illustrated in Fig. 1. Where compression is accomplished in more than one compressor component, a separate turbine component is required to drive each compressor in addition to what is usually a separate turbine to extract and deliver the useful power output.

2.2 Subsystems

The gas turbine engine control accepts a variety of signals from sensors situated around the engine that provide data such as measurements of key pressures and temperatures within the engine, rotative speed(s) of the engine's spool(s), actual position of the engine's variable geometry, torque in the engine's output shaft, rate of fuel flow to the engine's combustion system, and a signal from the operator or pilot or system controller indicative of the demand for power. On the basis of these data, the control then energizes actuators that manipulate fuel valves and other variable geometry of the engine to provide stable power at the demanded level and, when requested, provide smooth and fast changes in power level. The control must also provide for starting and shut-down of the engine, must protect the engine from surge, overspeed, over-temperature, and over-torque, and, in the event of any failure, must provide for residual power or for a safe shutdown. Early generations of gas turbine engines used hydro-mechanical controls, but modern systems are generally based on digital electronic devices.

Another important subsystem of gas turbine engines is an accessory gearbox, generally driven by the engine's core rotor, and feeding power to the engine's electric generator, and the engine's fuel, oil, and hydraulic pumps. A starting system (a hydraulic, pneumatic, or electric motor) is also mounted on the gearbox to drive the spool up to a speed where it is pumping enough air to permit combustion and is able to generate enough energy to be self-sustaining. The fuel system includes the fuel pumps, regulating valves, flow dividers, and fuel nozzles. A lubrication system is included for the rotors' bearings, including oil pumps, oil nozzles, scavenge pumps, oil filters, and an oil tank with an air/oil separator. The ignition system includes a high-voltage unit to energize the igniter. In aircraft, an anti-icing system provides hot air and/or electrical heating to parts in the engine inlet that might otherwise get clogged with ice during flight through super-cooled moisture in the atmosphere. Electrical and/or hydraulic and/or pneumatic actuators drive the engine's variable geometry.

3. MATERIALS AND MANUFACTURE

The gas turbine engine has been the focal point for much of the innovation and progress in advanced light-weight and high-temperature structural material development in recent decades, and in the new manufacturing processes that are required to produce the designs that fully exploit their potential.

3.1 Light-Weight Materials

Because of the high premium put on light weight, the aircraft gas turbine engine has been one of the primary application for the development of high-strength structural alloys of titanium. Although it is used extensively in high-speed rotating structures of aircraft engines, there has been some retrenchment from earlier, more ambitious applications because of problems encountered in titanium fires. Carbon fiber/organic resin matrix composites have been used for structural components and more recently for high-speed turbofan blading, which must withstand the extraordinarily high-impact loading of bird strikes and foreign object ingestion. For somewhat higher-temperature applications, future developments are aimed at exploiting the potential of metal matrix composites, and of intermetallics such as titanium aluminide, and ceramics in monolithic and composite form.

3.2 High-Temperature Materials

The considerable thermodynamic benefit of high turbine inlet temperature has placed enormous demands on virtually all the mechanical, aerodynamic, heat transfer, metallurgical, and manufacturing process arts. The blades of the turbine rotate at velocities at transonic or supersonic speed in a centrifugal acceleration field thousands of times that of gravity, and the entire turbine must operate in a chemically active transonic gas stream that contains abrasive particles and whose temperature is well above the melting temperature of the material of which the blades are made. Where the working fluid of a typical Otto or Diesel engine will reach peak cycle temperature for only an instant in the compression/combustion/expansion cycle so that the cylinder wall stabilizes at a temperature well below peak cycle temperature, the turbine of the gas turbine engine must stabilize at peak cycle temperature continuously when the engine is operated at peak power. The blades and other parts of the turbine must also endure thousands of cycles of large changes in temperature and stress as the engine is started and shut down and as power is varied during the course of its normal operation.

From the earliest application of high-temperature steel alloys, gas turbine engine metallurgy has progressed through development of cobalt- and nickel-based alloys strengthened by precipitation hardening. Many modern superalloys cannot be cast into an ingot with uniform properties and are produced by consolidating alloy powders by hot isostatic pressing. Mechanical alloying and dispersion strengthening are used in some cases. Future development is aimed at the use of intermetallics and ceramic matrix composites, as well as monolithic ceramics for stationary components.

At high temperatures, the grain boundary is the weakest link in a conventional superalloy system. The effect of grain boundaries is minimized in turbine blades by growing elongated grains, aligned in the direction of the principal stress, using a casting process known as directional solidification. In recent times, turbine blades have been directionally solidified as a single grain, thus eliminating grain boundaries altogether.

3.3 High-Temperature Cooled Turbine Blades

Not withstanding the very high useful operating temperature capability of currently available turbine blade alloys, gas turbine engines are routinely run at gas temperatures several hundred degrees Celsius above the melting point of these materials. This extraordinary feat is accomplished by cooling the blades with small quantities of high-pressure air that bypasses the combustor. The cooling schemes involve convective, impingement, film, and transpiration heat-transfer mechanisms, which require hundreds of small holes to be drilled into the blades and structural components of the high-temperature turbine. Such advanced drilling processes as electrochemical machining (ECM), electrical discharge machining (EDM), laser drilling, and abrasive water-jet machining have been perfected in this context. The cooling schemes also require minute convoluted passages to be built into the high-temperature structural parts. Where those parts are cast, those passages are usually produced by introduction of precisely molded and positioned ceramic cores into the casting molds. These delicate cores have been developed to withstand the abusive pouring temperatures of the high-temperature alloys for the long periods of time taken to grow the single crystals or directional crystals that constitute the finished cast part. The cores are removed from the casting by leaching in an autoclave.

4. APPLICATIONS

Gas turbines have found extensive application in stationary power plants, and in marine, vehicular, and aircraft applications.

4.1 Stationary Power Plants

Although the steam turbine is by far the most common power generation device in stationary power plants, gas turbine engines have found a variety of applications in special niches. Since their peak cycle temperature is much greater than the temperatures commonly achievable in steam turbine cycles, gas turbine engines are used as the topping cycle in combined (gas turbine/steam turbine) power plants where the gas turbine engine's exhaust gases are used to fire the boilers of the lower-temperature steam turbine system. Such plants are among the most efficient in operation. The gas turbine engine is also the system of choice in remote and relatively inaccessible locations such as ocean oil-drilling platforms and pipeline pumping stations, where relatively small power requirements do not justify the introduction of electrical power grids. Gas turbines are also used where emergency standby power, independent of the power grid, is needed on very short notice. The economic advantage of small gas turbine engine applications is magnified in cogeneration applications where the waste heat from the gas turbine engine exhaust can be exploited for space heating or industrial processes. The gas turbine engine is also applied in unique circumstances where its relatively short procurement cycle and more modest investment cost may overcome its inability to use lower-cost coal.

4.2 Vehicular Applications

Although they showed great promise in the 1970s and 1980s, gas turbine engines have never developed any major application in automobiles. In order to compete in thermodynamic efficiency with the common Otto-cycle reciprocating engine (particularly at important idle condition where the gas turbine engine is at a disadvantage), they require very high firing temperatures and the use of efficient, compact heat exchangers for regenerative thermodynamic cycles. Both of these requirements involve costly design features that make the final product cost noncompetitive, although the application of structural ceramics encourages many to think that this disadvantage may yet be overcome. Gas turbine propulsion has found application in railroad locomotives, in some large, long-distance trucks and buses, and in military vehicles where their light weight, compactness, and durability are greatly valued.

4.3 Marine Applications

Gas turbines are the modern powerplant of choice in small- and medium-sized naval ships because of their light weight, compact size, quick start-up characteristics, and competitive fuel economy.

4.4 Aircraft Applications

In all but the very smallest and lowest-speed general aviation aircraft, virtually all modern aircraft engines are based on the gas turbine engine core as prime mover. From helicopter turboshaft engines to supersonic transport powerplants, the gas turbine engine is harnessed to provide for aircraft propulsion. Propulsive thrust in aircraft is generated by a propulsor—one or more stages of turbomachinery that accelerate portion of the oncoming airstream. Generalizing Newton's second law of motion to deal with a continuous stream, the reaction force or thrust (F) on the device that accelerates the stream is found to be proportional to the product of the rate of mass flow (M) of the stream though the propulsor and the change in velocity of the stream (ΔV) imparted by the propulsor:

$$F = M(V_j - V_o) = MV_o(\Delta V/V_o), \tag{2}$$

where V_o is the inlet air velocity relative to the propulsor and is taken to be the flight velocity and V_j is the exhaust or jet velocity relative to the propulsor. An important consequence of this relationship is that a propulsor designed for very low-speed aircraft such as the rotor of a helicopter must accommodate large amounts of airflow compared to the airflow through the gas turbine engine that powers the propulsor. On the other hand, at very high supersonic flight speeds, the ideal propulsor requires approximately the same flow quantity as the gas turbine powerplant so that the gas turbine engine gas generator itself can be used as the propulsor (i.e., the jet engine) to accelerate the propulsion airstream without resort to a power turbine driving a separate propulsor. In the intermediate range of flight speeds between the low-speed helicopter and the supersonic transport, we find a continuous spectrum of propulsion systems, as shown in Fig. 3, which utilize both the jet from the gas turbine engine power producer and a propulsor (typified by a propeller and a high bypass fan) driven by energy extracted by a power turbine from the exit stream of the gas turbine power producer to create propulsive thrust.

5. ECONOMIC AND ENVIRONMENTAL ASPECTS

5.1 System and Fuel Economy

In fuel-burning stationary power plants, the gas turbine engine is at an economic disadvantage since it cannot be easily adapted

to burn low-cost coal. But it has found important special applications where its compactness, light weight, simple site preparation requirements, speed of start-up, lower capital cost, lack of need for heat rejection, and ready availability of waste heat application in cogeneration applications make up for its fuel cost disadvantage.

In ship applications, its high-power fuel efficiency, light weight, and compactness make the gas turbine engine the power plant of choice for high-speed applications such as naval craft. The same attributes would make the gas turbine engine a principal choice for land vehicles but for two competitive disabilities: the gas turbine engine's poor fuel consumption at low part power and its relative high cost. Application of the regenerative cycle has made possible its successful application to military tanks, but its cost disadvantage is yet to be overcome in realization of its potential for mass application to land vehicles.

As previously noted, the gas turbine engine is virtually unchallenged as the power plant of choice for all aircraft from helicopters to supersonic transports, except for the very smallest helicopters and light aircraft requiring no more than several hundred horsepower. This universal advantage is due not only to the gas turbine engine's excellent fuel economy and versatility in achieving nearly ideal propulsive efficiency in any flight regime, but also is due, in no small part, to its light weight, which implies reduced lift and hence reduced drag for a given aircraft, and to its low frontal area that translates directly into low drag.

5.2 Exhaust Emissions

Since the working fluid in the turbine section of the gas turbine engine is composed of the products of combustion from the combustion chamber, the engine's exhaust emissions (Bahr, 1980; Barrett, 1991) are typical of those of any heating or power plant operated with fossil fuels. One class of emissions of key concern consists of incompletely burned hydrocarbon fuel—smoke (soot), unburned hydrocarbons (HC), and carbon monoxide (CO). Major reduction of all these emissions has resulted from deeper understanding of the combustion mechanisms that generate the emissions and development of design approaches that inhibit their formation. The attainment of low smoke levels requires engine combustor designs with both leaner primary-combustion–zone fuel-air mixtures and more effective fuel-air mixing within the primary zone, compared to those of then-existing combustors. HC and CO are primarily generated at idle and other low engine-power conditions. The combustor design features needed to reduce HC and CO levels involve provisions for improving fuel atomization quality at low-power conditions, enhancing primary-zone fuel-air mixing quality at these operating conditions and minimizing combustion quenching due to fuel impingement on the combustor liners.

A second class of nonvisible emissions of concern is oxides of nitrogen (NO_x), which are also by-products of combustion. When gases containing oxygen and nitrogen are heated to elevated temperatures, generally above 1900 K, some oxidation of the nitrogen occurs, mainly to nitric oxide (NO), together with small amounts of nitrogen dioxide (NO_2). Early measures at NO_x reduction, applicable primarily to stationary powerplants, involved water injection into the combustor to cool the local elevated temperature zones. Modern combustor design practice involves obtaining both the required lean and uniform primary zone mixtures at high-power conditions and of providing adequately rich primary zone mixtures at idle and other low-power conditions.

While not considered to be a pollutant emission in the same sense, the carbon dioxide (CO_2) emissions of gas turbine engines are also of possible concern in context of the greenhouse effect on world climate. Abatement of CO_2 can only be achieved by reduction of the specific fuel consumption of the engine or via the use of alternative fuels with lower carbon content such as natural gas. Some sulfur oxides (SO_x) emissions are also generated by gas turbine engines. However, the quantities are very small because the sulfur contents of typical turbine engine fuels are extremely low.

Regulation of emissions is usually specified on the basis of the application, with separately specified and administered regulations applicable to stationary power plants and aircraft.

5.3 Noise Emissions

Two basic types of noise signature can be emitted from gas turbine engines. First, broadband or "white" noise, characterized by a roaring or hissing sound, is generated when random turbulence is produced, either by flow over engine blade, vane, and duct wall surfaces or in the mixing layers of the engine airflow streams. The frequency spectrum is typically a broad, smooth "hump" having a characteristic peak and associated peak frequency. The second type of noise produced is discrete tone noise, characterized by a distinct whistle or whine, and is typically a sharp spike of noise occurring at a specific frequency, and often having harmonics or overtones.

In general, the entry compression turbomachinery (i.e., fan of an aircraft engine or the low-pressure compressor) and the discharge turbine (i.e., the low pressure or power turbine) produce both broadband or "white" noise and strong, discrete frequency tones, usually at integer multiples of blade-passing frequency of the rotor blades. The combustor and the jet exhaust mixing layers produce predominantly broadband or "white" noise. Also, stages of entry compression turbomachinery that operate at supersonic tip speeds will often emit multiple-pure-tone or "buzz-saw" noise, which is characterized by discrete tones occurring at integer multiples of fan shaft rotational frequency.

In stationary, vehicular, and marine applications, it is possible to install sound absorbing enclosures for the engine and sound attenuating inlet and exhaust systems. A major challenge remains in aircraft applications (Gliebe, 1992; Smith, 1989) where weight and volume are at a premium, where the propulsor (typically the fan) is considerably larger than the basic power generating core, and where the velocity of the exhaust jet must be maintained at relatively high levels, of the order of the aircraft's maximum flight speed.

Early generations of aircraft gas turbine engines were simple jet engines or low-bypass turbofans with extremely high exhaust jet velocities where broadband noise predominated. The principal means of suppression was to provide the exhaust stream with mixers that induced intense mixing between the jet stream and the external air stream within the confines of an enclosed duct. The current trend in the development of aircraft engine propulsion systems is to employ cycles with higher and higher bypass ratios, in order to achieve high propulsive efficiency. As bypass ratio increases, the noise from the broadband sources (i.e., the exhaust jet and the combustor) decreases rapidly, while the noise from the tone sources (i.e., the fan, low-pressure compressor, and low-pressure turbine) increases, until the dominant sources are the tone sources. Methods for reducing the tone noises caused by unsteady interactions include the following:

1. reducing the magnitude of the unsteady flow field felt by each turbomachinery blade—i.e., minimize upstream blade wake defects, minimize downstream obstacle pressure fields, reduce or eliminate inflow distortions and separations, etc.;
2. selecting the blade number to minimize the acoustic efficiency of the resulting unsteady interaction, including using cutoff, whereby the acoustic pressure waves decay exponentially inside the duct; and
3. employing duct liners, generally based on arrays of Helmholtz resonators embedded in the duct walls, to suppress the generated acoustic pressure waves inside the duct before they escape from the inlet or exhaust.

GLOSSARY

Angle of Attack: The angle between the gas or fluid flow and the mean line of the airfoil's leading edge.

Blade: A compressor or turbine airfoil.

Bucket: A rotating turbine airfoil.

Burner: A combustion system.

Bypass Ratio: The ratio of that portion of the mass flow discharged by the propulsor that bypasses the power producer to that portion that passes through the power producer.

Cogeneration: Power production by an integrated and self-contained power plant that makes practical use of the exhaust heat.

Combustor: A combustion system.

Composite: A material that has been strengthened and/or stiffened by incorporation of fibers of a dissimilar material.

Compressor: In gas turbine engine usage, the component composed of one or more pairs of stationary and rotating airfoils that impart(s) pressure to a continuous flow of the working fluid.

Compressor, Axi-centrifugal: A compressor with one or more axial flow stages and one centrifugal stage.

Compressor, Axial Flow: A compressor where the principal direction of flow is parallel to the centerline of rotation of the compressor.

Compressor, Centrifugal: A compressor where the principal direction of flow is in the radial direction or normal to the centerline of rotation of the compressor.

Compressor, Radial Flow: See **Compressor, Centrifugal.**

Cooling, Convective: Cooling effected by transfer of heat to a flow of coolant internal to the structure being cooled.

Cooling, Film: Cooling effected by the laying down of a barrier film of coolant over the external surface of the structure to be cooled.

Cooling, Impingement: A form of cooling where the coolant is sprayed in jets onto the surface of the structure to be cooled.

Cooling, Transpiration: Cooling by passing the coolant through a porous member of the structure to be cooled.

Core, Casting: An insert embedded in a casting mold to form a hollow chamber in the completed casting.

Core, Engine: That part of the engine composed of the basic compression component(s), the combustor, and the basic expansion component(s) that drive the compressor(s) and that, as an integrated unit, deliver mechanical energy in the form of a steady flow of high-pressure, high-temperature gas.

Cycle, Brayton: The basic gas turbine engine cycle, with continuous flow and with constant-pressure heat addition.

Cycle, Open: A thermodynamic cycle where the working fluid is *not* returned to the engine inlet.

Cycle, Thermodynamic: The sequence of variation in the thermodynamic properties of the working fluid of an engine that characterizes the sequence of processes of compression, heat addition, heat extraction, and expansion in the course of the engine's operation.

Cycle, Topping: A thermodynamic cycle with a very high exhaust temperature that is used to provide the heat input for a lower-temperature cycle.

ECM: Electrochemical machining.

EDM: Electrical-discharge machining.

Efficiency, Carnot: Efficiency of a reference thermodynamic cycle indicative of the maximum achievable fuel economy with ideal components.

Efficiency, Propulsive: The ratio of the energy expended in propelling a vehicle to the energy delivered to the propulsor.

Emission(s): Most often refers to the undesirable chemical constituents of the gas turbine engine exhaust but is also used to refer to the noise emitted by the engine.

Engine, Gas Turbine: See Introduction.

Entropy: A thermodynamic property whose variation in compression and expansion processes is indicative of the deviation of the process from the ideal.

Expander: See **Turbine.**

Fan: A turbo-compressor used in aircraft engines as a propulsor.

Flame-out: An uncommanded loss of combustion.

Gasifier: See **Core, Engine.**

Generator, Gas: See **Core, Engine.**

Injector, Fuel: See **Nozzle/Injector, Fuel.**

Interburning: See **Reheat.**

Intercooler: A heat exchanger that extracts heat from the working fluid in the midst of the compression process.

Intercooling: Extraction of heat from the working fluid in the midst of the compression process.

Jet Engine: The simplest form of aircraft engine, composed of a gas turbine engine core and a jet nozzle. Sometimes used generically to indicate any type of aircraft gas turbine engine.

Liner, Combustor: The shell in which the combustion process is contained.

NO_x: Oxides of nitrogen.

Noise, Broadband: Noise having a frequency spectrum that is typically a broad, smooth "hump" having a characteristic peak and associated peak frequency.

Noise, Buzz-Saw: See **Noise, Multiple-Pure-Tone.**

Noise, Multiple-Pure-Tone: Noise that is characterized by discrete tones occurring at integer multiples of fan shaft rotational frequency.

Noise, Tone: Noise, characterized by a distinct whistle or whine, which is typically a sharp spike of noise occurring at a specific frequency, and often has harmonics or overtones.

Noise, White: See **Noise, Broadband.**

Nozzle, Exhaust: See **Nozzle, Jet.**

Nozzle, Jet: A convergent or convergent/divergent duct that is used to accelerate the exhaust flow from a gas generator or fan in process of generating propulsive thrust.

Nozzle, Turbine: A single stationary turbine airfoil or an entire row of stationary turbine airfoils.

Nozzle/Injector, Fuel: The device used to precondition and inject a liquid or gaseous fuel into a combustion chamber.

Nozzle/Injector, Fuel, Air Blast: An injector that introduces a strong shear layer and turbulence in the surrounding airstream to assist in conditioning the fuel spray for combustion.

Nozzle/Injector, Fuel, Atomizing: An injector that depends primarily on impelling the fuel at very high pressure through a very small orifice to produce a very fine spray.

Nozzle/Injector, Fuel, Vaporizing: An injector that depends on preheating the fuel to condition it for combustion.

Pitch Angle: Angular orientation of a turbomachinery airfoil or propeller blade, as measured from the plane of rotation.

Propulsor: The propeller or helicopter rotor or fan that develops the propulsive thrust from the mechanical energy delivered by the gas turbine engine.

Recuperation: A form of regeneration.

Recuperator: A form of regenerator.

Regeneration: A variation of the gas turbine cycle wherein heat is extracted from the exhaust stream and added to the working fluid that enters the combustor, in order to reduce the fuel required by the cycle.

Regenerator: The heat exchanger that accomplishes regeneration.

Reheat: Addition of heat to the working fluid in the midst of the expansion process.

Resonator, Helmholtz: An aerodynamic oscillator, multiple units of which are used in arrays as noise suppressors in gas turbine inlet and exhaust ducts.

SFC: Specific fuel consumption, the ratio of rate of fuel burned to the thrust or power produced by the engine.

SO_x: Oxides of sulfur.

Spool: A rotor of the gas turbine engine that includes the rotating disks and airfoils of a turbine and the compressor it drives or a rotor composed of a turbine and a drive shaft to an external load.

Stage: An integrated pair of rotating and stationary airfoils constituting a subsystem of a compressor, or a pair of stationary and rotating airfoils constituting a subsystem of a turbine.

Stall: The breakdown of the airflow pattern over a row of compressor airfoils with consequent loss of diffusion and compression capability.

Stall Margin: The increment of pressure ratio that a compression system can obtain at a given operating rotational speed without encountering system surge.

Surge: Unstable operation of a gas turbine engine when operated about a limiting pressure ratio at a given rotational speed.

Thrust: Reaction force supplied to the mount points of an aircraft gas turbine and/or propulsor to propel the aircraft.

Turbine: The component composed of one or more pairs of stationary and rotating airfoils that extracts energy from a continuous flow of the working fluid.

Turbine, Gas: See Introduction.

Turbine, High Pressure: The first turbine in a system with more than one turbines.

Turbine, Low Pressure: The last turbine in a system with more than one turbines.

Turbine, Power: A turbine specifically dedicated to driving an external load.

Turbo-compressor: See **Compressor.**

Turbo-expander: See **Turbine.**

Turbofan: An integrated aircraft engine that includes a gas turbine engine and a fan.

Turbojet: See **Jet Engine.**

Turbomachinery: A gas turbine engine's compressor and turbine.

Turboprop: An integrated aircraft engine that includes a gas turbine engine and a propeller.

Turboshaft: A gas turbine engine that delivers mechanical power through a rotating shaft to an external mechanical load.

Vane: A stationary airfoil of a compressor.

Variable Geometry: Elements of the gas turbine engine's configuration such as the pitch angle of the stator vanes or the throat area of the jet nozzle that can be varied during operation.

INTRODUCTION

Fluids in motion are most often in a complex disordered state that is referred to as turbulent. This behavior results from instabilities in laminar flow when the fluid velocity is increased beyond a critical value. Examples of turbulent fluid motion abound in nature and in technological applications. Sometimes the turbulence is evident, as in a buoyant turbulent plume of smoke billowing from an industrial plant on a cold clear night or in the complex eddies downstream of a bridge abutment. Sometimes it is invisible but obviously present, such as in the discomfort of buffeting on an airplane trip, and on other occasions the turbulence even goes unnoticed, as in the cylinder of an internal combustion engine or in the atmosphere where it has much to do with the daily weather patterns. So too, the white-hot burning gases on the surface of the sun are in turbulent motion, as are the gases between the stars. The Great Red Spot in the atmosphere of Jupiter has been conclusively shown to come from an instability in a turbulent mixing layer.

The need to understand and predict turbulence is a concern in many branches of engineering. Turbulent boundary layers forming on the wings and fuselage of aircraft greatly affect lift and drag characteristics. Pressure fluctuations in turbulent flow may lead to unwanted noise that has to be controlled. One of the most important characteristics of turbulence is its ability to transport mass, momentum, and heat efficiently. This is put to practical benefit by mechanical engineers in heat exchangers and by chemical engineers in mixing vessels. It is a problem to be coped with by environmental engineers concerned with air and water pollution. Even bioengineers have to take turbulence into account; the flow of air and blood in the human body is sometimes turbulent, especially under diseased conditions.

Although observations and sketches of turbulent flows were made by Leonardo da Vinci, the beginning of modern turbulence research required the formulation of the differential equations of fluid motion by Navier and Stokes in the nineteenth century. Osborne Reynolds (1884) was the first to study systematically the transition from laminar to turbulent flow in a pipe. He intuited that a flow can remain laminar only so long as viscous momentum diffusion is large enough to eliminate small disturbances in the flow. The latter continuously appear through natural causes, such as slight irregularities in the shapes of boundaries or in the initial state of the fluid, or even perhaps through microscopic flow perturbations (Tsuge, 1974).

A measure of the relative magnitude of inertial and pressure forces to viscous forces is given by the nondimensional Reynolds number, *Re*. When it is larger than a critical value, viscous forces are insufficient to damp out small disturbances, and they quickly amplify to measurable differences in the evolving velocity and pressure fields, appearing as the random motion associated with turbulence. In engineering practice, very large values of *Re* are common; e.g., $Re \approx 10^9$ in the flow past surface ships. This makes clear how far removed from the laminar state many practical flows are.

Reynolds (1895) later analyzed turbulent motion by decomposing the variables in the Navier–Stokes equations into mean and fluctuating parts. He initiated the practice of averaging the Navier–Stokes equations to derive a set of relations now referred to as the Reynolds-averaged Navier–Stokes equations or RANS. These may be made the basis for directly computing the mean velocity of a flow field without first computing actual realizations of the flow. A fundamental limitation of this approach is that the averaging process introduces additional unknowns into the equations in the form of quadratic products of the velocity fluctuations. These terms account for the turbulent momentum flux, and a separate method must be devised to predict them. Turbulence modeling is concerned with different strategies to approximate turbulent transport rates so that predictions of the mean velocity field can be made.

The problem of how to predict turbulent flow accurately in general circumstances remains for the most part unsolved. Nonetheless, many fundamental aspects of turbulent-flow behavior are reasonably well understood, helping to pinpoint the source of difficulty faced by prediction schemes. A primary problem is that turbulence occurs over a wide range of scales varying from the smallest, where mechanical energy is dissipated into internal energy, to scales as large as that of the bodies containing the turbulence or responsible for its generation. Further complicating the picture is the fact that despite being chaotic, turbulent fluid flow tends to be organized into a hierarchy of vortical structures at different scales that mutually interact with great complexity.

Much of the research in the first half of the twentieth century concentrated on analyzing idealized turbulent flows free of complications caused by anisotropies due to mean shear. Pioneering works by G. I. Taylor (1935), von Kármán and Howarth (1938), and many others introduced statistical analyses, which took advantage of special symmetries to gain an understanding of physical processes such as turbulence decay. Kolmogorov (1941) postulated that small-scale turbulent motions are isotropic at high Reynolds numbers and share common properties independent of how the turbulence is generated. There is a growing body of evidence confirming this hypothesis and delineating the conditions under which it is true (e.g., Saddoughi and Veeravali, 1994; Antonia and Kim, 1994).

Although it has long been known that in some sense turbulent flows have "structure," research in the last several decades has been marked by the discovery that the dynamics of shear flows, including the Reynolds stresses and other important properties, are closely associated with the presence of coherent and apparently self-replicating vortical structures (Wallace, 1990). The first investigations of coherency were almost exclusively experimental, using conditional statistical analysis made feasible by the advent of dedicated laboratory digital data-acquisition systems and computers. In recent years good numerical solutions of both wall-bounded and boundary-free turbulent flows have given an unprecedented view of the dynamics of vortical structures at relatively low Reynolds numbers. In such direct numerical simulations (DNS) all flow variables of interest are determined throughout the full flow domain, permitting novel explorations of the three-dimensional nature of the coherent structures and their relationship to turbulent transport (Bernard *et al.*, 1993).

DNS also represents a means for predicting turbulent flows of engineering interest in which no modeling is involved. Mean flow properties are obtained by averaging over the computed flow realizations. Because such schemes are computationally intensive and require enormous amounts of computer memory, they are severely limited in their range of application. The first successful simulations were performed for relatively simple turbulent flows, such as a channel at low Reynolds numbers (Kim *et al.*, 1987). Flows of somewhat greater complexity are now being studied, such as in a square duct (Huser *et al.*, 1994) or with riblets (Goldstein *et al.*, 1995).

Recent years have seen the rise of methods that are a compromise between direct simulations and RANS computations. Referred to as large eddy simulations (LES), these seek to decompose the velocity field into a filtered part, which is computed as the solution of the filtered Navier–Stokes equation, and a subgrid part that models the small-scale motions. Since the smaller-scale subgrid motions are more isotropic and thus more likely to have a universal character than larger ones, there is some hope that a generally applicable subgrid model can be developed. At the present time, many issues need to be resolved before it will be clear how best this goal can be achieved.

1. PRELIMINARIES

1.1 Notational and Mathematical Considerations

The components of the three-dimensional velocity field corresponding to the (x_1,x_2,x_3) coordinate directions will generally be denoted by U_i, $i = 1, 2, 3$, though on occasion the alternative notation (U,V,W) will be used to indicate velocities in the (x,y,z) directions, respectively. The streamwise direction will be denoted by x while y is the inhomogeneous and z the homogeneous cross-stream direction, respectively. In view of the importance of mean quantities in studying turbulent-flow problems, it is useful to make the Reynolds decomposition of the flow fields into mean and fluctuating parts. For example, the velocity and pressure fields may be written in the form

$$U_i = \bar{U}_i + u_i, \tag{1}$$

$$P = \bar{P} + p, \tag{2}$$

where the overbar denotes an appropriate average, and clearly $\bar{u}_i = 0$ and $\bar{p} = 0$. Averages may be considered to be over ensembles of realizations of the flow field as in

$$\bar{U}(\mathbf{x},t) = \frac{1}{N}\sum_{j=1}^{N} U^j(\mathbf{x},t), \tag{3}$$

where $U^j(\mathbf{x},t)$ is the jth realization out of N. If the mean flow is approximately steady, a time average

$$\bar{U}(\mathbf{x},t) = \frac{1}{T}\int_{t-T/2}^{t+T/2} U(\mathbf{x},s)ds \tag{4}$$

can also be defined, where it is understood that the time interval T is long compared to the time scales of the turbulent field. That the two definitions (3) and (4) give the same mean is likely, but it is not known to be true rigorously.

Products of fluctuating quantities give turbulence correlations. For example, the turbulent kinetic energy is a one-point correlation defined by

$$k = \overline{u_i u_i}/2, \tag{5}$$

where here and elsewhere repeated indices are to be summed for $i = 1, 2, 3$. Relative to the local mean velocity, k gives a useful measure of the local turbulence intensity since, whenever it is zero, the flow must be laminar. Consideration of the relative magnitude of the individual terms in (5), i.e., the variances $\overline{u_1^2}$, $\overline{u_2^2}$, and $\overline{u_3^2}$, gives an idea of the degree to which the local turbulence levels are anisotropic, i.e., have a directional dependence. If the turbulence is homogeneous, then all of the mean flow statistics, including $\bar{U}_i$, are independent of spatial position.

Multiple-point correlations may also be

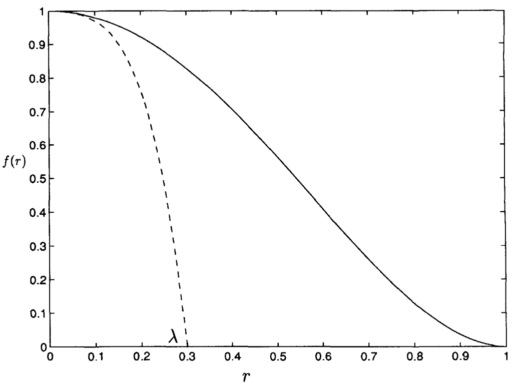

FIG. 1. The two-point longitudinal velocity correlation coefficient $f(r)$ (solid line). The intercept with the r axis of a parabolic approximation to $f(r)$ (dashed line) gives the Taylor microscale λ. The integral scale Λ is defined as the area under $f(r)$.

defined, as in the two-point double and triple correlations given by

$$\mathcal{R}_{ij}(\mathbf{x},\mathbf{r}) = \overline{u_i(\mathbf{x})u_j(\mathbf{x} + \mathbf{r})} \tag{6}$$

and

$$\mathcal{S}_{ijk}(\mathbf{x},\mathbf{r}) = \overline{u_i(\mathbf{x})u_j(\mathbf{x})u_k(\mathbf{x} + \mathbf{r})}, \tag{7}$$

respectively. For simplicity, the dependence on time t is not indicated explicitly in these relations. The particular cases $f(r) \equiv \mathcal{R}_{11}(r\mathbf{e}_1)/\mathcal{R}_{11}(0)$ and $g(r) \equiv \mathcal{R}_{22}(r\mathbf{e}_1)/\mathcal{R}_{22}(0)$ are referred to as the two-point longitudinal and transverse correlation coefficients, respectively. Here, $\mathbf{r} = r\mathbf{e}_i$, $\mathbf{e}_i$ is a unit vector in the x_i direction, $f(0) = g(0) = 1$, and $f(r)$, $g(r) \to 0$ as $r \to \infty$. Correlations such as (6) and (7) open up the possibility of examining structural characteristics of the flow field; i.e., they may reveal the presence of spatial organization to the velocity field that is not apparent from single-point statistics. $\mathcal{R}_{ij}$ and $\mathcal{S}_{ijk}$ also have benefit for characterizing phenomena at different scales. For example, $\mathcal{R}_{ij}$ provides a convenient basis for defining turbulence length scales at opposite extremes. Specifically, the Taylor microscale λ is a measure of small-scale dissipative phenomena, while the integral scale Λ measures the largest distance over which correlation persists in a turbulent flow field as well as the dimensions of the largest structures in the flow. The microscale is defined as the distance from the origin at which a parabolic approximation to $g(r)$ is zero, as illustrated in Fig. 1. For homogeneous flow conditions it is not hard to show that

$$\overline{\left(\frac{\partial u}{\partial y}\right)^2} = \frac{2\overline{u^2}}{\lambda^2}. \tag{8}$$

In contrast, Λ is defined as the integral under the $g(r)$ curve; i.e.,

$$\Lambda \equiv \int_0^\infty g(r)dr. \tag{9}$$

A fruitful way to explore the interactions between phenomena at different scales is through consideration of the energy spectrum tensor, $\mathcal{E}_{mn}(\mathbf{k})$, defined via Fourier transformation of $\mathcal{R}_{mn}(\mathbf{r})$:

$$\mathcal{E}_{mn}(\mathbf{k}) = (2\pi)^{-3} \int_{R^3} d^3 r e^{-i\mathbf{k}\cdot\mathbf{r}} \mathcal{R}_{mn}(\mathbf{r}). \tag{10}$$

Here, $\mathbf{k}$ is the wave-number vector, and possible dependencies of $\mathcal{E}_{mn}$ and $\mathcal{R}_{mn}$ on $\mathbf{x}$ or t are not written explicitly. The inverse Fourier transform implies that

$$\mathcal{R}_{mn}(\mathbf{r}) = \int_{R^3} d^3 k e^{i\mathbf{r}\cdot\mathbf{k}} \mathcal{E}_{mn}(\mathbf{k}). \tag{11}$$

Since $k = \frac{1}{2}\mathcal{R}_{ii}(0)$, (11) can be used to establish that

$$k = \int_0^\infty E(\kappa)d\kappa, \tag{12}$$

where the energy density $E(\kappa)$ is defined in terms of an average of $\mathcal{E}_{mm}$ over shells of radius $\kappa = |\mathbf{k}|$ in wave-number space. Equation (12) shows how the turbulent kinetic energy at each point in a flow can be decomposed among the different length scales as represented by κ.

Evolution equations for k, $\mathcal{R}_{ij}$, $\mathcal{E}_{ij}$, $E(\kappa)$, and other statistical quantities may be derived from the Navier–Stokes equation. Analysis and solutions of these form the basis for many studies of turbulence, as is made clear below.

1.2 Experimental Methods

Because of the impossibility of analytical solutions of the Navier–Stokes equations for turbulent flows and the restriction of DNS solutions to quite low Reynolds numbers for relatively simple geometries, experimental investigations of turbulence are still very much needed. There is a vast body of literature describing experimental results from a wide range of turbulent flows. There is only space here to mention some of the most important findings from these experiments.

Thermal anemometry, first developed in the 1920s, is still the experimental technique most frequently used in turbulence research (Blackwelder, 1981; Fingerson and Freymuth, 1983). The physical idea on which it is based is simple. A small-diameter (typically 1–5 μm) metal wire (usually tungsten, platinum, or platinum alloys) is heated to a temperature higher than the ambient temperature of the flow by an electrical current. The wire is cooled when heat is transferred to the flow, at a rate that depends nonlinearly on the flow velocity. Modern thermal anemometry usually incorporates the sensor wire as one leg of a Wheatstone bridge. The differential bridge voltage imbalance, caused by a differential change in the sensor resistance, is fed back through a high-gain amplifier. This brings the sensor resistance back to its operating condition by forcing more or less current through it. The voltage drop across the sensor, the resistance of which is held nearly constant in this mode of operation, is thus the physical variable measured. It is a nonlinear function of the velocity component cooling the sensor. Thermal anemometry has the advantage of providing long, continuous data records with good frequency response. Its major disadvantages are that it is intrusive, frequent calibrations are required, and additional sensors must be used to obtain more than one component of the velocity vector. Furthermore, at least nine sensors are needed to obtain all the components of the vorticity vector (Wallace and Foss, 1994). Measuring the velocity and/or the vorticity vectors at more that one location simultaneously in the flow requires even more sensors, together with the electronics to operate them. It is generally impractical to obtain such measurements.

In the last three decades various optical methods for measuring turbulence properties have been developed. The earliest of these is laser-Doppler velocimetry (LDV), a good introduction to which is given by Adrian (1983). This method utilizes the Doppler principle to the effect that relative to a particular observer, coherent light from a moving source exhibits a frequency shift depending on its velocity. Thus, the local fluid velocity can be determined from the frequency of the laser light beam scattered from tiny particles, faithfully following the fluid motion. LDV has very good frequency response and is nonintrusive except for the presence of the particles in the flow. The choice of size and density of the particles is important. Particles that are too large do not properly move with the local instantaneous flow field, while particles that are too small follow the Brownian motion of the fluid, responding to the fluid's temperature and not the continuum velocity field. Furthermore, too dense particles will not be neutrally buoyant. These constraints on the size and density of particles are particularly limiting in air flows. With more complex optics, more than one velocity component can be unambiguously sensed. Like thermal anemometry, however, use at more than one location in the flow requires a great increase in complexity and expense. Another drawback is that LDV data are obtained at irregular intervals depending on the random passage of particles through the measurement volume.

Recently, optical methods have been developed that rely on image processing of visualized particles to provide information about the velocity vector field projected onto full spatial planes of turbulent flows. Many of these methods, including particle tracking, particle imaging, digital particle imaging, and speckle velocimetry have been discussed and evaluated by Adrian (1991). Such methods also are conceptually simple. Most straightforwardly, in particle tracking velocimetry (PTV), where the particle number density is small, individual particles can be identified and their individual displacements tracked over short time intervals by a computer. With this information, the velocity components in the visualized planes can be calculated. With higher particle number densities, the displacement of local groups of particles can be tracked over two successive images using spatial correlations. This is commonly called particle imaging velocimetry (PIV). With even higher number densities, speckle patterns are formed from the phase differences of the overlapping images of individual particles. These local speckle patterns move with the turbulent motion and can be tracked in what is known as laser speckle velocimetry (LSV). Such particle motion methods are now being extended to three dimensions with holographic and stereoscopic imaging (Scherer and Bernal, 1988; Prasad and Adrian, 1993; Barnhart *et al.*, 1994; Meng and Hussain, 1995).

Even more recently, methods that invert the transport equation for a passive conserved scalar,

$$\frac{\partial C}{\partial t} + U_i \frac{\partial C}{\partial x_j} = \frac{1}{ReSc} \frac{\partial^2 C}{\partial x_j \partial x_j}, \tag{13}$$

where *Sc* is the Schmidt number, have been developed (Dahm *et al.*, 1992; Su and Dahm, 1996; Pearlstein and Carpenter, 1995). These methods require extremely high spatial and temporal resolution and imaging accuracy because the spatial and temporal concentration derivatives in Eq. (13) must be obtained from images of the rapidly evolving turbulent scalar. Furthermore, the velocity field computed from (13) is not unique. Additional constraints must be imposed on the solution in order to be assured of finding the physical velocity field.

Generally speaking, the same temporal and spatial resolution requirements in thermal anemometry also apply to the optical measurement methods. With the light sources, optics, film, and video technology available at present, it has been particularly difficult for imaging methods to measure the temporal evolution of turbulent flows.

1.3 Vorticity

The presence of prodigious amounts of vorticity is among the defining properties of turbulent flow. Regions of flow with significant vorticity are very often turbulent, whereas regions without vorticity are never turbulent. Understanding the dynamics of the vorticity field is indispensable to understanding turbulent flows. The vorticity vector, defined as the curl of the velocity vector, is expressed in tensorial component form as

$$\Omega_i = \epsilon_{ijk} \frac{\partial U_k}{\partial x_j}, \tag{14}$$

where ϵ_{ijk} is the alternating tensor. It may be shown using a vector identity that Ω_i is solenoidal, i.e., $\nabla \cdot \boldsymbol{\Omega} = 0$.

The vorticity corresponds to twice the instantaneous rate of rotation of a material fluid particle. Alternatively, given a surface enclosed by a small circuit in the fluid, the vorticity component normal to the surface at an arbitrary point may be interpreted as the circulation per unit area of the surface, where circulation is defined as the line integral of the tangential component of the velocity vector around the closed curve. This interpretation of vorticity comes from the fact that by the Stokes and divergence theorems, circulation is the integral of the normal vorticity component over an arbitrary surface bounded by a given circuit. By constructing the collection of vortex lines passing through a circuit, a vortex tube may be created. Its circulation is referred to as its "strength." By the divergence theorem, tube strength is constant for any closed circuit enclosing the vortex tube. The local vorticity increases inversely proportional to the cross-sectional area of the tube—as a reflection of conservation of angular momentum. On a solid surface the normal component of vorticity is zero, so that vortex lines must lie in the plane of the wall and are perpendicular to the streamlines there. Away from a bounding surface, vortex lines and streamlines are only orthogonal for two-dimensional and some axisymmetric flows and not for turbulent flows, which are inherently three dimensional. It also may be shown that vortex lines cannot end in the fluid. Instead, they must either form closed loops, extend to infinity, or intersect the wall at locations where the vorticity is zero.

1.3.1 Vorticity Equation Taking the curl of the Navier–Stokes equation gives the vorticity equation

$$\frac{\partial \Omega_i}{\partial t} + U_j \frac{\partial \Omega_i}{\partial x_j} = \Omega_j \frac{\partial U_i}{\partial x_j} + \nu \frac{\partial^2 \Omega_i}{\partial x_j \partial x_j}, \tag{15}$$

where ν is the kinematic viscosity. The left-hand side expresses the rate of change of the vorticity of fluid particles along Lagrangian paths. The first term on the right-hand side accounts for changes of Ω_i caused by stretching or reorientation of vortex lines, and the last one for effects of viscous diffusion. In inviscid flow, (15) can be used to prove Kelvin's theorem to the effect that the circulation of a material loop of fluid particles is conserved in time, as well as Helmholtz's theorem that vortex lines are also material lines in the absence of viscosity.

Finally, the conspicuous absence of pressure in the vorticity equation should be noted. Pressure and gravity forces act through the center of mass of particles and thus apply no moments to them. Only shear forces can change the vorticity of a fluid particle in incompressible flow.

1.3.2 Wall Production of Vorticity New vorticity entering an incompressible flow must originate at solid surfaces. These may be the bounding walls of confined flows or the nozzles, bluff bodies, or splitter plates that are the upstream source of free jets, wakes, or mixing-layer flows, respectively. If the Navier–Stokes equation is evaluated *at* the bounding surface (defined for simplicity here as the x-z plane), it reduces to (Lighthill, 1963)

$$\frac{\partial p}{\partial x} = -\mu \frac{\partial \Omega_z}{\partial y} \tag{16}$$

and

$$\frac{\partial p}{\partial z} = -\mu \frac{\partial \Omega_x}{\partial y}, \tag{17}$$

where μ is the dynamic viscosity. The right-hand sides of these equations represent the fluxes of the Ω_x and Ω_z components of vorticity normal to the wall. The wall-normal flux of Ω_y can be obtained from the solenoidal property of the vorticity vector and is given by

$$-\mu \frac{\partial \Omega_y}{\partial y} = \mu\left(\frac{\partial \Omega_x}{\partial x} + \frac{\partial \Omega_z}{\partial z}\right). \tag{18}$$

Thus, although the time rate of change of the vorticity of a particle within the flow is not affected by the pressure variations in the flow, the flux of new vorticity into the flow at the bounding surface depends on the pressure gradient instantaneously occurring over the surface.

2. GENERAL TURBULENCE CHARACTERISTICS

2.1 Turbulent Transport

The eddying motion associated with turbulence is considerably more effective in transporting momentum, vorticity, internal energy, scalar contaminants, and other flow properties than is molecular diffusion. Heightened transport rates near boundaries are of particular practical importance, as they lead to increased drag and augmented heat transfer. From the standpoint of turbulent flow prediction techniques based on solving directly for the mean velocity field, the ability to estimate turbulent transport rates is of primary importance. This may be seen from the RANS equations:

$$\rho\left(\frac{\partial \bar{U}_i}{\partial t} + \bar{U}_j \frac{\partial \bar{U}_i}{\partial x_j}\right) = -\frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j}\left(\mu \frac{\partial \bar{U}_i}{\partial x_j} - \rho\overline{u_i u_j}\right) \tag{19}$$

(where ρ is density), which could be solved for $\bar{U}_i$ and the pressure $\bar{p}$ if only a theory for predicting the additional Reynolds stress term, $R_{ij} \equiv -\rho\overline{u_i u_j}$, were available. Classical efforts at predicting it have used its physical interpretation as the turbulent flux of the ith component of momentum in the jth direction to assume an analogy between molecular and turbulent transport mechanisms. The analogy is imperfect, however, which has led to considerable inaccuracies in mean flow prediction when this route is followed.

To see why the molecular analogy is poor, it is instructive to consider in some detail the physical properties of the Reynolds stresses. This may be most easily viewed in the context of channel flow where (19) simplifies to

$$0 = -\frac{\partial \bar{p}}{\partial x} + \frac{d}{dy}\left(\mu \frac{d\bar{U}}{dy} - \rho\overline{uv}\right). \tag{20}$$

Here, only one component of the Reynolds stress representing (minus) the flux of streamwise momentum in the y direction (perpendicular to the channel walls) acts in addition to the mean viscous shear stress. Together they comprise the total stress, $\tau \equiv \mu d\bar{U}/dy - \rho\overline{uv}$. In laminar flow, $\overline{uv} = 0$ and the solution to (20) is the well-known Poiseulle flow. In the turbulent case, (20) is not sufficient to determine $\bar{U}$ unless $\overline{uv}$ can be ascertained independently.

In the kinetic theory of nondense gases (Chapman and Cowling, 1952), the relationship $\sigma_{12} = \mu dU/dy$ for the viscous shear stress is derived through consideration of molecular momentum transport. In this case $\sigma_{12} = -\rho\langle c_1 c_2\rangle$, where $c_i = C_i - U_i$ is the molecular fluctuation velocity, C_i is the velocity of a molecule, $U_i = \langle C_i\rangle$ is the hydrodynamic fluid velocity, and $\langle\ldots\rangle$ denotes averaging over a small sensing volume containing large numbers of molecules. To a very high degree of approximation, it may be shown that

$$-\rho\langle c_1 c_2\rangle = \mu\frac{d\langle C_1\rangle}{dy} = \mu\frac{dU_1}{dy}, \tag{21}$$

where the viscosity $\mu \sim \rho\lambda_m\langle C_i C_i\rangle^{1/2}$ and λ_m is the mean free path. The derivation of (21) involves formally evaluating the effect of random molecular migrations of momentum in the presence of an inhomogeneity in the y direction of the average rectilinear particle speed. Since turbulent transport is ostensibly a similar sort of phenomenon, namely, caused by random movements of momentum within a mean field—albeit at a very much larger scale—it has been thought that a generalization of the argument leading to (21) would be applicable in this case as well.

In fact, it can be shown that three essential properties of molecular transport used in deriving (21) are not satisfied in the turbulent case. In particular, (21) incorporates a well-defined mixing time as the time between molecular collisions; it assumes to good approximation that molecules carry their momentum undisturbed over the distance λ_m before exchanging it with the surrounding molecules; finally, λ_m is exceedingly small compared to the distance of greater-than-linear variation of the bulk fluid velocity. In contrast, for the turbulent case, a useful definition of the mixing time is not self-evident; nor can it be expected that momentum is conserved, even approximately, on fluid particle paths; and the distance over which mixing occurs is more than likely to be greater than that over which the mean field varies linearly.

To get more insight into the nature of turbulent transport, it is helpful to examine how the u and v correlation underlying the Reynolds stress gets established as a fluid particle moves in the mean velocity field of a turbulent flow. In particular, consider the identity

$$\overline{u_a v_a} = \overline{u_b v_a} + \overline{v_a(\bar{U}_b - \bar{U}_a)} + \overline{v_a(U_a - U_b)}, \tag{22}$$

where a is a given, unchanging point in the flow, and b denotes the position of a particular fluid particle in a particular realization at time $t - \tau$ ($\tau > 0$), which arrives at a at time t, as illustrated in Fig. 2. The correlation $\overline{u_b v_a}$ appearing on the right-hand side of (22) is between velocity components at different times and will be zero for sufficiently large τ. The turbulent mixing time may be defined as the minimum time interval at which u_b and v_a become decorrelated; i.e., $\overline{u_b v_a} = 0$. Thus τ may be viewed conceptually as the time necessary for the correlation between u_a and v_a to be created by the physical processes represented by the last two terms on the right-hand side. The first describes displacement transport due to fluid particles carrying the average momentum of their starting point, namely, $\bar{U}_b$, to point a over the mixing time; the second accounts for the effect on transport of changes in momentum, i.e., acceleration effects, along particle paths.

The term $\overline{v_a(\bar{U}_b - \bar{U}_a)}$ is a concise mathematical statement of the physical transport mechanism that historically has been modeled through the molecular analogy using a

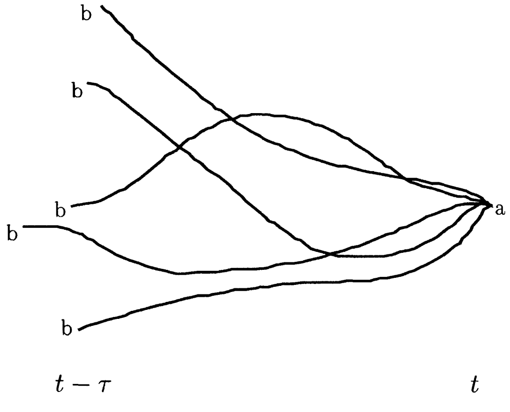

FIG. 2. Backward fluid particle paths over time interval τ between randomly located points b and fixed point a.

gradient formula. As it appears here, however, it is not limited by the gradient assumption. The latter may be deduced as an approximation if local linearity of $\bar{U}$ can be assumed. For example, in the case of a unidirectional mean flow $\bar{U}(y)$ if the Taylor series expansion

$$\bar{U}_b = \bar{U}_a - \int_{t-\tau}^{t} v(s)ds \, \frac{d\bar{U}}{dy} \tag{23}$$

is a good approximation to $\bar{U}_b$ over time τ, then it follows that

$$\overline{uv} = -T\overline{v^2}\,\frac{d\bar{U}}{dy}, \tag{24}$$

where $T \equiv \int_{t-\tau}^{t} \overline{v(0)v(s)}/\overline{v^2}$ is a Lagrangian integral time scale. In these formulas, $v(s)$ represents the Lagrangian velocity at time $s < t$ of the fluid particle in each realization that is at point a at time t, so that $v(t) = v_a$. The expression $\int_{t-\tau}^{t} v(s)ds$ in (23) is the vertical distance traveled by a fluid particle between points b and a. Clearly, (24) shows that the turbulent momentum-transport coefficient, usually called the eddy viscosity, should be given by $T\overline{v^2}$.

The properties of (22) have been examined using ensembles of fluid particle paths computed in a DNS of turbulent channel flow (Bernard and Handler, 1990; Handler *et al.*, 1992). Figure 3 shows the variation of the individual terms in (22) in the wall region. It may be noticed that the mixing term $\overline{u_b v_a} \approx 0$, indicating that the fluid particle paths were tracked at least as long as the mixing time. While displacement transport of the classical type, i.e., given by $\overline{v_a(\bar{U}_b - \bar{U}_a)}$, was found to be the dominant contributor to $\overline{uv}$, acceleration effects were not negligible. Near the wall, the latter acts to reduce Reynolds stress through deceleration of fluid particles approaching the surface, while further away from the wall it acts as an additional source of Reynolds stress. Both terms in (22) depend on physical factors occurring over a significant nonlocal region of the flow, implying that (24) is not well satisfied in this case.

A more complete understanding of the physical origins of turbulent transport requires unraveling the causes of the fluid motions leading to Reynolds stress. Considerable evidence for the dominant role of self-replicating quasistreamwise vortices in the dynamics of the wall-bounded flows now exists—as is discussed in Sec. 2.2.2. A definite connection between these and Reynolds stress has been established (Bernard *et al*, 1993) using particle paths as an intermediary. The streamwise vortices are directly responsible for the production of Reynolds stress by instigating transfer of high-speed fluid toward the wall or ejecting low-speed fluid away from the wall. Acceleration transport is linked to motions induced by those vortices in which fluid particles are accelerated as they travel over vortex cores or decelerated while traveling under them. Similar processes appear to occur in boundary-free flows, as is discussed in Sec. 2.4.3.

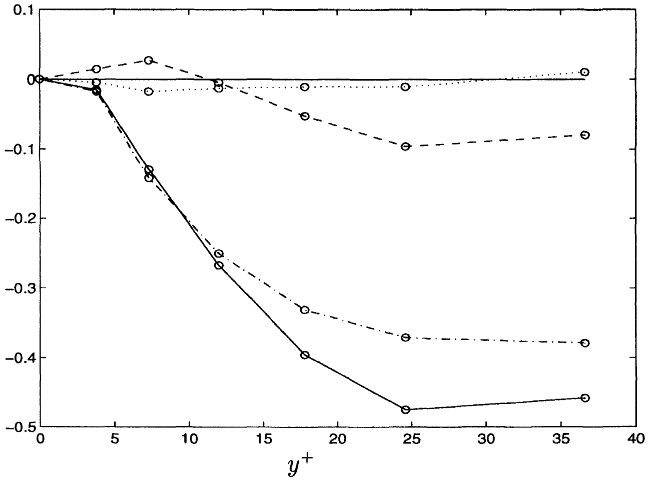

FIG. 3. Near-wall behavior of terms in Reynolds stress decomposition (22): $\overline{u_b v_a}$, · · ·; $\overline{v_a(\bar{U}_b - \bar{U}_a)}$, —·—; $\overline{v_a(U_a - U_b)}$, – – –; $\overline{uv}$, ———. Results from channel-flow DNS of Bernard *et al.* (1993) at $R_\tau = 250$.

The more the physics surrounding turbulent transport is understood, the more it is clear that its successful modeling requires taking into account nonlocal features of the flow. Chief among these is the presence of flow structures, including coherent vortices. Resolution of the self-replicating structures may be a necessary and sufficient condition for a successful prediction scheme, since the chief transport will have been taken into account; i.e., it seems likely that small-scale motions do not contribute much to the net turbulent transport. If this is the case, then LES of one sort or another may have some hope of being successful in predicting complex turbulent flows.

Not long after the development of the RANS approach, it was noted by Taylor (1915) that the closure problem could be equally well framed in terms of vorticity transport instead of momentum transport. This involves rewriting the RANS equations in such a way as to replace the Reynolds stress with the vorticity transport correlation tensor $\overline{u_i\omega_j}$. Taylor reasoned that this would be beneficial if vorticity transport was better described by a gradient law than momentum transport. The fact that vorticity is conserved on particle paths, in two-dimensional inviscid flow, suggested that this may be the case. In practice, Taylor (1932) noticed that gradient vorticity-transport laws cannot well account for vorticity transport near boundaries. In fact, it has recently been shown (Bernard, 1990) that vorticity transport is counter-gradient near boundaries and that this can be well explained by a modified form of the Lagrangian approach pursued by Taylor. In this, the effects of three-dimensional vortex stretching and reorientation are included in the transport law. This Lagrangian approach has also been put to practical use (Gorski and Bernard, 1995) in computing boundary-layer flows.

The transport issue is also faced in problems involving heat and mass transfer in turbulent flow. Here, Reynolds decomposition and averaging of the scalar equation (13) introduces the turbulent scalar flux correlation, $\overline{uc_i}$, where c denotes either temperature or concentration fluctuations of scalar contaminants. The deficiencies of gradient scalar-transport models are well known—particularly near sources. The various manifestations of turbulent transport require a nonlocal treatment to capture their complete physical origin. This is reflected in several recent approaches (Egolf, 1994; Dekker *et al.*, 1995; Bernard and Rovelstad, 1994; Bernard, 1995).

2.2 Wall-Bounded Turbulent Flows

Through numerous experiments and some recent computational work, a considerable amount has been learned about the distribution of velocity and Reynolds stress in flows near solid boundaries. This section describes some of the principal features of flows in boundary layers, channels, ducts, and pipes. Wall-bounded flows will be considered here only in their "fully developed" state, which means that their statistical properties do not change in the mean flow direction. That is to say all $\partial/\partial x$ gradients of average properties are zero. This condition is only an approximation for boundary layers that continuously develop downstream; however, in the wall layer, the mean flow is nearly parallel to the wall.

Experimental results characterizing wall-bounded flows are of two types. Earlier measurements, most of which have been confirmed or improved upon for low Reynolds numbers by DNS, were almost exclusively statistical analyses of long time series of velocity components and wall pressure fluctuations. As mentioned above, in the late 1950s and early 1960s, experimental evidence began to appear indicating that the properties of these flows were not simply a result of completely random turbulent fluctuations. Rather, it was observed that these flows had certain organized or "coherent" features that strongly influenced their statistical behavior. Much of the experimental research over the last 30 years has been an attempt to detect and characterize these coherent properties in the hope that this will lead to more physically realistic transport models.

2.2.1 Flow Regions The traditional division of wall-bounded turbulent flows is into four regions, illustrated in the sketch in Fig. 4 by Reynolds (1974). The thicknesses of the two layers nearest the wall (I and II), together denoted as the viscous layer, are exaggerated for clarity.

1. *Viscous Sublayer.* Here the mean velocity

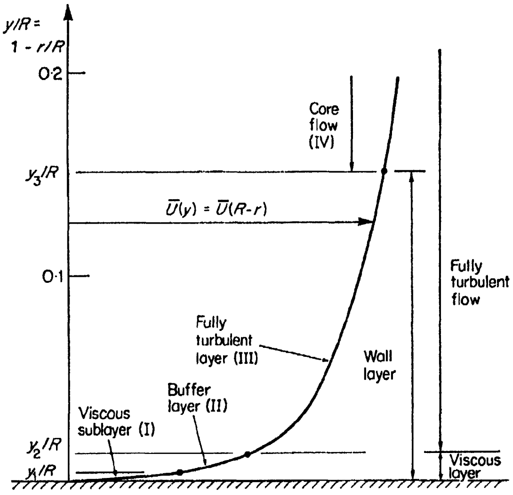

FIG. 4. Turbulent pipe (of radius R) flow velocity profile illustrating the (I) viscous sublayer, (II) buffer layer, (III) fully turbulent layer, and (IV) core-flow region. The thicknesses of layers (I) and (II) are exaggerated for clarity. From *Turbulent Flows in Engineering* by A. J. Reynolds, Copyright © 1974, John Wiley & Sons, Ltd. Reprinted by permission of John Wiley & Sons, Ltd.

varies linearly, i.e., $d\bar{U}/dy$ is constant, and the Reynolds shear stress, $-\rho\overline{uv}$, is very small as a result of the suppression of the wall-normal fluctuation, v, by the presence of the wall. The "intensity" of streamwise turbulence, $\sqrt{\overline{u^2}}/\bar{U}$, is largest in the viscous sublayer with a nearly constant value of 0.4 throughout (Alfredsson *et al.*, 1988). Thus the name "laminar sublayer," as this flow region was earlier called, is a misnomer. Velocity and length scales can be obtained from ρ, μ, and from the shear stress at the wall, $\tau_w \equiv \mu\partial\bar{U}/\partial y_{\text{wall}}$, in the form

$$u_\tau \equiv (\tau_w/\rho)^{1/2} \tag{25}$$

and

$$y_\tau \equiv \mu/(\rho\tau_w)^{1/2} = \nu/u_\tau. \tag{26}$$

For obvious reasons, u_τ is often called the "friction" velocity. If we scale the distance normal to the wall with y_τ, the viscous sublayer is usually defined as $y^+ \equiv y/y_\tau < 5$. At the outer edge of this region $d\bar{U}/dy$ begins to depart from linearity because of the increasing influence of the Reynolds stresses. In the viscous sublayer where the independent variables affecting the mean velocity variation are τ_w, μ, and y, dimensional analysis yields the linear relation

$$U^+ = y^+, \tag{27}$$

where $U^+ \equiv \bar{U}/u_\tau$. As noted by Reynolds (1974), for the pipe-flow data of Laufer (1953) at $Re_d = U_c d/\nu = 5 \times 10^5$, where U_c is the pipe centerline velocity and d its diameter, $-\rho\overline{uv}$ is approximately 10% of the wall shear stress at the edge of the viscous sublayer. For this flow the sublayer occupies only about 0.05% of the pipe radius, but the mean velocity at $y^+ = 5$ is about 18% of U_c. This clearly illustrates how large the mean velocity gradient is in this region.

2. *Buffer Layer.* The region $5 \leq y^+ \leq 30$ between the viscous sublayer and the logarithmic layer is referred to as the buffer region. Viscosity plays an asymptotically diminishing—but not negligible—role as the upper part of this region blends into region III. Thus, region II is included with region I as part of the viscous layer in Fig. 4. At $y^+ = 30$, for the $Re_d = 5 \times 10^5$ pipe-flow data of Laufer (1953), $-\rho\overline{uv}$ is almost 90% of the mean wall shear stress τ_w, and $\bar{U}$ is approximately 47% of U_c. However, the upper edge of the buffer layer is still only about 0.3% of the pipe radius. Thus, at the upper limit of the buffer layer, the mean velocity reaches almost $\frac{1}{2}$ of its maximum centerline value, and the total shear stress is dominated by the Reynolds shear stress.
3. *Logarithmic Layer.* In this layer, where the Reynolds shear stress is much greater than the viscous stress, the independent variables affecting the mean velocity distribution are τ_w, ρ, and y. Dimensional analysis yields a logarithmic mean velocity distribution, often called the "law of the wall" or "log law,"

$$U^+ = C_1 \ln y^+ + C_2, \tag{28}$$

where the constant $C_1 = 1/\kappa \approx 2.5$ (the inverse von Kármán constant) and $C_2 \approx 5.0$ (Coles and Hirst, 1968). This layer extends from $y^+ \approx 30$ to the location (depending on Reynolds number) where the mean velocity distribution no longer exhibits a logarithmic profile. Taken together, the three regions closest to the wall (I, II, and III in Fig. 4) are often called the *wall layer.* The wall layer has similar properties for all types of bounded flows, including boundary layers, channels, and pipes. The total shear stress τ, i.e., the sum of the viscous and Reynolds shear stress, varies slowly in this layer, as is seen in Fig. 6, and so it often also has been called the constant-stress layer. Recently, Panton (1996) used a matched asymptotic expansion analysis of wall flows for the inner (layers I, II, and III) and outer (layers III and IV) regions, earlier divided by Coles (1956) in this manner, where, respectively, viscous stresses and Reynolds shear stresses dominate. In this view the logarithmic region is an overlap region for which Panton has derived a Reynolds-number–dependent law for the Reynolds shear stress, scaled by the friction velocity:

$$-\frac{\overline{uv}}{u_\tau^2} = 1 - \frac{1}{\kappa y^+} - \frac{y^+}{Re_\tau}. \qquad (29)$$

Here $Re_\tau \equiv u_\tau \delta / \nu$ and δ is the boundary-layer thickness, channel half-width, or pipe radius.

4. *Core Region.* This is the outermost region of bounded flows. The physical processes occurring in this region are different for channels, ducts, and pipes compared to boundary layers. In the last it has the character of a boundary-free turbulent flow and is sometimes called the wake region, because the deficit velocity distribution, $[\bar{U}(y) - U_\infty]/u_\tau = f(y/\delta)$ (where U_∞ is the velocity in the irrotational free-stream region outside the boundary layer), is much like that of the wake of a bluff body. In the logarithmic (overlap) region (III) this velocity deficit distribution, as $y/\delta \rightarrow 0$, is given by

$$\frac{\bar{U} - U_\infty}{u_\tau} = C_1 \ln\frac{y}{\delta} + C_3. \qquad (30)$$

Here in the core or wake region IV, the "law of the wake" (Coles, 1956) applies and can be written as

$$W\left(\frac{y}{\delta}\right) = \frac{\bar{U} - U_\infty}{u_\tau} - \left(C_1 \ln\frac{y}{\delta} + C_3\right), \qquad (31)$$

with $C_3 \approx -2.7$ for a zero–pressure-gradient boundary layer (Panton, 1996). Values of C_3 can be chosen for which the function $W(y/\delta)$ fits the core-region velocity distribution of channel and pipe flows as well, in spite of the different physical processes occurring there for these flows as compared to boundary layers. The core region of a pipe is influenced by structures radially emanating from around the entire pipe circumference (Sabot and Comte-Bellot, 1976). In a high–aspect-ratio duct (wide in one cross-stream direction and narrow in the other, i.e., a channel), the core flow seems to be made up of large-scale motions emanating from opposite walls and "locking" together in the duct core region (Dean and Bradshaw, 1976).

When plotted in semilogarithmic form in Fig. 5, the mean velocity distributions in these four layers are clearly different. The Reynolds number dependence of the upper extent of the logarithmic layer and the concomitant beginning of the core layer also is quite evident.

Experimental measurements of the distribution of the Reynolds shear stress in the

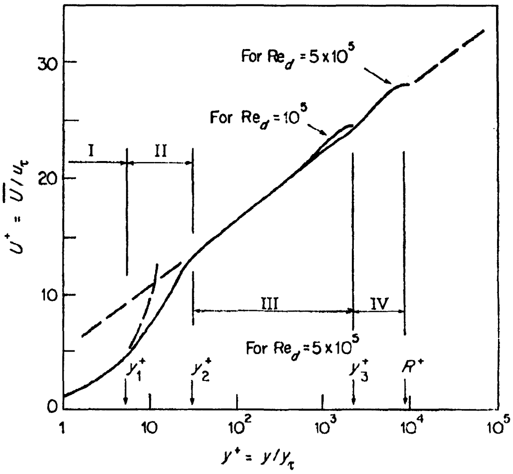

FIG. 5. Turbulent pipe-flow mean velocity distribution, normalized by wall-layer velocity and length scales, for data of Laufer (1953), which illustrates the (I) viscous sublayer, (II) buffer layer, (III) fully turbulent layer, and (IV) core-flow region. wall layer of a turbulent boundary layer at $R_\theta = 2420$, where θ is the momentum thickness, are shown in Fig. 6. These are spatially and temporally highly resolved LDV measurements of Karlsson and Johansson (1988). Compared to them in Fig. 6 are the DNS results of Spalart (1988) at $R_\theta = 300$, 600, and 1410. Also shown in the figure is the distribution of the total stress, i.e., $\mu d\bar{U}/dy - \rho\overline{uv}$. The observations made above about the varying relative proportions of the viscous and turbulent shear stresses in the different parts of the wall layer is clearly evident. Also visible is the Reynolds number dependence of the Reynolds shear-stress distribution accounted for by Eq. (29).

The Reynolds shear stress, $-\rho\overline{uv}$, is a covariance that is related to the joint probability density function (JPDF), $P(u,v)$, by

$$-\rho\overline{uv} = -\rho \iint_{-\infty}^{\infty} uvP(u,v)\,du\,dv. \qquad (32)$$

This integral represents the sum of contributions to $-\rho\overline{uv}$ from individual (u,v) pairs, weighted by how frequently they occur. The contours of $P(u,v)$ as well as of the covariance integrand, $uvP(u,v)$, shown in Fig. 7 from Ong (1992) for $y^+ = 35$, which agree well with those of Wallace and Brodkey (1977), demonstrate that "ejections" or quadrant-2 (Q2: $u < 0$, $v > 0$) events and "sweeps" or quadrant-4 (Q4: $u > 0$, $v < 0$) events are the dominant contributors to the Reynolds shear stress just above the buffer layer. In fact, nearer the wall, for $y^+ \leq 15$, Wallace *et al.* (1972) showed that Q2 (ejection) events dominate, while further from the wall Q4 (sweep) events take over as the major contributors.

2.2.2 Vortical Structures The same type of JPDF analysis considered in the previous section can be applied to the vorticity covariance given by

$$\overline{\Omega_x\Omega_y} = \iint_{-\infty}^{\infty} \Omega_x\Omega_y P(\Omega_x,\Omega_y)\,d\Omega_x\,d\Omega_y. \qquad (33)$$

Figure 8 shows $P(\Omega_x,\Omega_y)$ and the covariance integrand $\Omega_x\Omega_y P(\Omega_x,\Omega_y)$ measured by Ong (1992) at $y^+ = 35$. Clearly, the vorticity field has a preferred orientation of like-signed Ω_x and Ω_y inclined downstream at angles to the wall.

Robinson (1991) interrogated the $R_\theta = 670$ DNS database of Spalart (1988) to search for and characterize vortical structures important to the turbulence stress dynamics. Assuming that the pressure would be lower in the cores of vortices than in the surrounding fluid, Robinson (1991) detected vortical structures of the type shown in Plate 1, where two "loop"-like vortices are seen with "legs" stretched back at shallow angles with respect to the wall. Also shown are regions of high Q2 and Q4 Reynolds shear stress, ($u'v'2$ and $u'v'4$ in the plate). It is quite apparent that the turbulent stress has a strong spatial association with the vortices. The Q2 motions are primarily located on the inner side of the vortex legs and on the upstream side of the vortex "head," i.e., in regions of upwelling motion of low-speed fluid. On the other hand, the Q4 motions occur primarily on the outer side of the vortex legs where the fluid is swept down toward the surface.

In view of their importance to Reynolds stress production, a number of studies (Brooke and Hanratty, 1993; Bernard *et al.*,

1993; Miyake *et al.,* 1995) have attempted to discover the mechanisms by which quasi-streamwise vortices are able to reproduce in the near-wall turbulent-flow environment. Though not agreeing in every detail, the different approaches have made many common observations. New vortices appear as a result of the influence of pre-existing structures of sufficient size, nearness to the boundary, and intensity of rotation. They are often nested, with the uplifted downstream parts of new vortices convecting over mature vortices lying close to the wall. Parent vortices induce new structures as a result of reorientation of spanwise vorticity into the wall-normal direction followed by its shearing into the streamwise direction. Streamwise vorticity produced at the wall surface to satisfy the no-slip condition in the lateral direction may also develop into new vortices on the upwash side of parent vortices. Individual vortices interact with other vortices at different locations along their length. This limits the time scale over which any individual structure can be expected to stay as a coherent entity. Through mutual induction, there appears to be a tendency for vortices to convect away from the wall and populate the outer layers of the wall region.

2.3 Turbulent Kinetic Energy

In investigating the physics of turbulent flow, it proves to be helpful to consider the exact governing equation for second-order moments. In particular, the Reynolds stress equation has the form

$$\frac{\partial R_{ij}}{\partial t} + \bar{U}_k \frac{\partial R_{ij}}{\partial x_k} = -R_{ik}\frac{\partial \bar{U}_j}{\partial x_k} - R_{jk}\frac{\partial \bar{U}_i}{\partial x_k} + \Pi_{ij} - \epsilon_{ij} - \frac{\partial \beta_{ijk}}{\partial x_k} + \nu\nabla^2 R_{ij}, \quad (34)$$

where

$$\Pi_{ij} \equiv \overline{p\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right)}, \quad (35)$$

$$\epsilon_{ij} = 2\nu \overline{\frac{\partial U_i}{\partial x_k}\frac{\partial U_j}{\partial x_k}}, \quad (36)$$

$$\beta_{ijk} \equiv \overline{u_i u_j u_k} + \overline{p u_i}\delta_{jk} + \overline{p u_j}\delta_{ik}, \quad (37)$$

and for the purposes of the present discussion we take $R_{ij} = \overline{u_i u_j}$. The first two terms on the right-hand side of (34) represent production of Reynolds stress and the last its viscous diffusion. Equation (35) is the pressure–strain-rate correlation, (36) is the dissipation-rate correlation, and (37) forms the turbulent diffusion term. The properties of the terms of (34) have been studied by Mansour *et al.* (1988), using a channel-flow DNS.

Equation (34) yields relations for the individual normal stresses $\overline{u_i^2}$ ($i = 1, 2, 3$) or, upon contraction, an equation for the turbulent kinetic energy, k. Since $R_{ij}(\mathbf{x},t) = \mathcal{R}_{ij}(\mathbf{x},0,t)$, (34) is a special case of an even more general relation that can be derived for $\mathcal{R}_{ij}(\mathbf{x},\mathbf{r},t)$. The latter is quite complex and is not ordinarily used as an avenue toward the understanding of general flows. However, for simplified flows such as homogeneous isotropic turbulence, it has been extensively used, as is discussed in Sec. 3.1.

An understanding of the k field has intrinsic worth in the study of many turbulent phenomena such as flame propagation and sound generation. As a measure of local velocity scale, it is relevant to transport phenomena and so has been an essential aspect of many prediction schemes. Its governing dynamical equation may be put in the form

$$\rho\left(\frac{\partial k}{\partial t} + \bar{U}_j\frac{\partial k}{\partial x_j}\right) = -\rho\overline{u_i u_j}\frac{\partial \bar{U}_i}{\partial x_j} - \epsilon + \frac{\partial}{\partial x_j}\left(\nu\frac{\partial k}{\partial x_j} - \tfrac{1}{2}\overline{u_j u_i^2} - \overline{p u_j}\right), \quad (38)$$

where the first term on the right-hand side is generally positive and can be thought of as the work of the Reynolds stress in deforming the mean field to produce k. ϵ is the "isotropic" dissipation rate, i.e., the rate at which k would be dissipated in isotropic turbulence, and appears after substituting for the general dissipation rate using an identity. The last term accounts for diffusive effects, both viscous and turbulent, and causes no net increase or decrease in turbulent kinetic energy.

Physical experiments and simulations have provided some very detailed information about the k budget. Johansson and Karlsson (1989) compared the distribution in the viscous layer of the terms in Eq. (38), measured by LDV in the boundary-layer experiment at $R_\theta = 2420$ of Karlsson and Johansson (1988), with the $R_\theta = 1410$ DNS of Spalart (1988). As shown in Fig. 9, the dominant terms are production and dissipation, which are in balance outside of the viscous sublayer and buffer layer. In the lower part of the buffer layer, the production term has

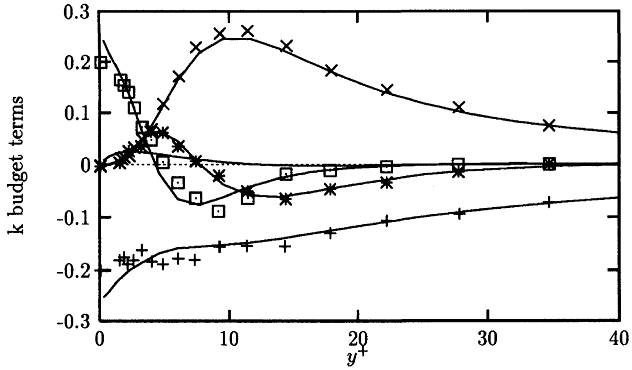

FIG. 9. Budget of turbulent kinetic energy equation terms for turbulent boundary layers. DNS results (solid lines) at $R_\theta = 1410$ courtesy of Spalart (1988) and LDV data at $R_\theta = 2420$ courtesy of Johansson and Karlsson (1989): (×) production, (+) dissipation, (*) turbulent diffusion, (□) viscous diffusion.

a maximum at about $y^+ = 10$, where it is balanced by the addition to the dissipation rate of negative viscous diffusion. The maximum dissipation rate occurs at the wall, where it is balanced by viscous diffusion, which is positive in the sublayer. Turbulent diffusion also changes signs just above the sublayer.

Further insight into the physics of the k field may be had via analysis of its spectrum, $E(\kappa,t)$. The latter, in the special case of homogeneous isotropic turbulence, satisfies

$$\frac{\partial E(\kappa,t)}{\partial t} = T(\kappa,t) - 2\nu\kappa^2 E(\kappa,t), \tag{39}$$

which may be derived from Fourier transformation of the $\mathcal{R}_{ij}(\mathbf{r},t)$ equation. Here, the last term in (39) gives the rate of dissipation of the turbulent kinetic energy at wave number κ. Summing this over wave-number amplitudes gives the total dissipation rate,

$$\epsilon(t) = 2\nu \int_0^\infty \kappa^2 E(\kappa,t) d\kappa. \tag{40}$$

Contrasting this with (12), it should be evident that wave numbers where kinetic energy is a maximum, i.e., where $E(\kappa,t)$ peaks, will be different—in fact lower—than those where dissipation is at a maximum, i.e., where $\kappa^2 E(\kappa,t)$ peaks. For large Reynolds numbers there may be a significant separation in wave numbers—equivalently length scales—between the peaks in energy and dissipation rate.

Evidently, turbulent flow requires a mechanism by which energy, which is introduced into the flow at the relatively large length scales associated with the stirring mechanism [and subsequently congregates in the region of large $E(\kappa,t)$], travels to higher wave numbers to be dissipated. The term $T(\kappa,t)$ in (39), which comes from a Fourier transform of $\mathcal{S}_{ijk}(\mathbf{r},t)$, accounts for the transfer process. It is driven physically by the stretching and folding of vortex filaments.

Among the first ideas about energy transfer between scales was that it occurs through a disequilibrium cascade in which energy primarily travels from large to small scales, with only modest amounts traveling in the reverse direction. Kolmogorov postulated that for sufficiently large Reynolds number, when dissipation and energy-containing scales are widely separated, there may be a universal structure to the small scales of the turbulence independent of the means by which energy is generated at large scales. Moreover, under these conditions, there may exist a range of scales, called the inertial range, which are at the same time not small enough for dissipation to be significant, nor so large as to be connected to the turbulence-containing eddies. Under these conditions, Kolmogorov assumed that $E(\kappa,t)$ would depend just on κ and ϵ, the latter representing the energy/second passing through this wave-number range. A dimensional argument gives $E(\kappa,t) \sim \epsilon^{2/3}\kappa^{-5/3}$. Numerous experimental evaluations of $E(\kappa)$ have confirmed the existence of this inertial range. Despite the validity of this $-\frac{5}{3}$ spectral law, the one-way cascade view of energy transfer is now widely recognized (Lesieur, 1990) to be incompatible with current understanding of the physics of the decay process. Dissipation is spatially intermittent, and the energy cascade can be viewed more accurately as a two-way street with nearly equal amounts of energy traveling in both directions, with the net transfer to smaller scales. Chorin (1994) has developed a statistical mechanical framework with which to explain the Kolmogorov spectrum in terms of such an equilibrium process (see Sec. 4.3).

The upper wave-number limit of the inertial range is that where viscosity begins to be important in causing dissipation. A length scale characterizing this, called the Kolmogorov scale, can be formulated from ν and ϵ as $\eta \sim (\nu^3/\epsilon)^{1/4}$. This has proven to be a useful parameter in establishing a minimum-resolution requirement in physical measurement techniques and in numerical simulation of turbulent flow, as well as in the scaling of turbulence properties to demonstrate their universal characteristics at high wave numbers.

2.4 Boundary-Free Turbulent Shear Flows

In contrast to the bounded flows considered previously, some of the principal properties of boundary-free turbulent shear flows are now described. The discussion is limited to steady, thin plane flows that are two dimensional in the mean, are developing as they proceed downstream from their source, and have a central plane at $y = 0$, and for which $\bar{U}(x,y) \gg \bar{V}(x,y)$ and $\partial/\partial y \gg \partial/\partial x$. Some flows in this category are a high–aspect-ratio rectangular jet, the wake of a two-dimensional bluff body—e.g., a cylinder—and a two-dimensional mixing (shear) layer. Sketches of these three boundary-free turbulent shear flows are given in Fig. 10. Axisymmetric developing free flows without swirl, such as round jets and the wake of a body of revolution, also can be treated in a similar manner to the plane flows considered here. The local length scale l in Fig. 10 is defined as the distance from the centerline at $y = 0$ to the cross-stream location where the velocity changes from its centerline value by $\frac{1}{2}U_c$. Here U_c is the mean velocity at the centerline for the jet, it is the velocity difference ($\Delta U \equiv U_h - U_e$) between the high- and low-speed sides of the mixing layer, and it is the velocity deficit at the centerline for the wake.

For such flows, the RANS equations may be approximated by

$$\bar{U}\frac{\partial \bar{U}}{\partial x} + \bar{V}\frac{\partial \bar{U}}{\partial y} \approx \frac{\partial \overline{uv}}{\partial y}. \tag{41}$$

For jets and wakes, this may be used to give the momentum flux per unit flow breadth as

$$M = \rho \int_{-\infty}^{\infty} [\bar{U}(\bar{U} - U_\infty) + \bar{v}^2 - \bar{u}^2]dy, \tag{42}$$

where U_∞ is the free-stream velocity in the case of the wake and zero for the jet with no coflow. The contribution to the momentum flux by the turbulent variances in (42) is usually small compared to that of the mean field and often can be neglected. For the plane jet, M is invariant with downstream distance, and (42) can be approximated by

$$M \approx \rho \int_{-\infty}^{\infty} \bar{U}^2 dy. \tag{43}$$

For the small-deficit plane wake, M in (42) should be interpreted as the mean momentum deficit flux per unit wake breadth and is also invariant. By contrast, for a plane mixing layer the momentum flux changes with distance downstream at the rate $V_\infty \Delta U$.

2.4.1 Similarity and Self-Preservation

Reynolds number similarity is the idea that, for sufficiently large Reynolds numbers, the structure of the turbulence no longer depends on viscosity and thus is Reynolds number independent. Self-preservation is a related idea. In this case local length and velocity scales can be found, which cause the scaled mean and other average statistical flow properties to have the same spatial distribution across the flow, independent of location in the mean flow direction. The self-preserving character of developing turbulent flows is obviously of great utility in giving experimental observations universal applicability. However, self-preservation is rigorously permitted by the equations of motion only in some restricted instances. Assuming

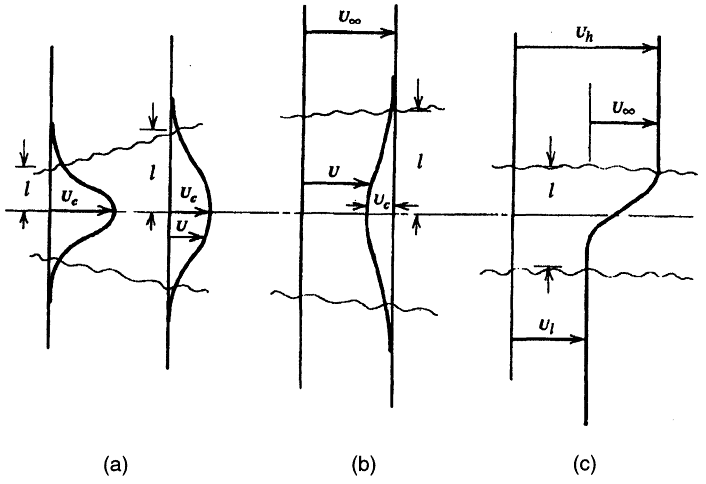

FIG. 10. Mean velocity profiles of a turbulent plane (a) jet, (b) wake, and (c) mixing layer. Note the length scale, *l*, and velocity scale, U_c. Adapted from *Incompressible Flow* by R. L. Panton Copyright © 1984. Reprinted by permission of John Wiley & Sons, Inc.

that l and U_c (ΔU for mixing layers) in Fig. 10 are the local scales that will yield self-preserving properties for plane jets, wakes, and mixing layers, then the self-preserving functional relations (Panton, 1984) for the mean velocities have the form, for a jet,

$$\frac{\bar{U}(x,y)}{\bar{U}_c(x)} = f\left(\frac{y}{l(x)}\right); \tag{44}$$

for a wake,

$$\frac{U_\infty - \bar{U}(x,y)}{\bar{U}_c(x)} = f\left(\frac{y}{l(x)}\right); \tag{45}$$

and for a mixing layer,

$$\frac{\bar{U}(x,y) - U_l}{\Delta\bar{U}(x)} = f\left(\frac{y}{l(x)}\right). \tag{46}$$

For the plane jet, substituting (44) into (43) results in

$$M = \rho U_c^2 l \int_{-\infty}^{\infty} \left[f\left(\frac{y}{l}\right)\right]^2 d\left(\frac{y}{l}\right). \tag{47}$$

The integral is a constant for self-preserving flow, as is the momentum flux M. Therefore $\rho U_c^2 l$ must also be invariant. Furthermore, assuming Reynolds number similarity, the dimensional relation

$$U_c(\rho x/M) = \text{const.} \tag{48}$$

may be derived. Taken together, (47) and (48) imply that $U_c \propto x^{-1/2}$ and $l \propto x$ for the plane jet. These relationships, based on the Reynolds-number–similarity and self-preservation assumptions, are demonstrated experimentally for the mean field of plane jets after about 5 jet widths downstream. This is where the two initial shear layers, emanating from the boundary layers on each side of the jet nozzle, have grown together to form the jet.

A similar analysis for the plane wake, with the same assumptions, gives $U_c \propto x^{-1/2}$ and $l \propto x^{1/2}$. In fact, far enough downstream, where the wake deficit is sufficiently small, plane wakes also exhibit these self-preserving characteristics. This is achieved first by the mean velocity profile, about 80 body diameters downstream in a cylinder wake, and further downstream for the turbulence intensities. Higher-order statistics require even greater distances to reach a self-preserving state.

The mean flow of mixing layers becomes self-preserving at about $Re_x = 4 \times 10^5$, at which point $U_c \sim x$ and $l \sim x$. The spreading rate of the mixing layer depends on the ratio of the freestream velocities, U_h/U_l.

2.4.2 Turbulence Spreading As the outer edges of a free turbulent shear layer is approached, many of its properties go to zero. For example, the turbulent kinetic energy, the Reynolds shear stress, and, most importantly, the vorticity all become negligible. Although the mean properties vary smoothly into the outer flow, the instantaneous turbulent/nonturbulent interface is rather sharp, as seen below in Fig. 13 for a turbulent mixing layer, and continuously changes position. Thus, the turbulence at any particular point is increasingly more intermittent, the further from the center axis it is. The outer edge region, sometimes called the "viscous superlayer," has been extensively studied by Corrsin and Kistler (1954) for a turbulent boundary layer whose core region has wakelike characteristics. The viscous superlayer is a highly sheared layer with thickness of the order of the Kolmogorov scale. A possible mechanism determining the rate at which the irrotational flow outside the turbulent layer is "entrained," i.e., made turbulent, is the engulfing of the irrotational fluid by layers of rotational fluid and subsequent viscous diffusion of vorticity, which is amplified by the straining action of these layers.

2.4.3 Some Characteristics of Mixing Layers The self-preserving length scale commonly used for mixing layers is the momentum thickness

$$\theta = \int_{-\infty}^{\infty} \frac{\bar{U} - U_l}{U_h - U_l}\left[1 - \frac{\bar{U} - U_l}{U_h - U_l}\right]dy, \tag{49}$$

which is proportional to the length scale l in Fig. 10. The self-preserving character of mixing layers, formed from two boundary layers with different free-stream velocities, U_h and U_l, meeting at the exit plane of a splitter plate, is shown in Fig. 11. The mean velocity distributions of an experimental mixing layer of Bell and Mehta (1992) at three streamwise locations and for R_θ up to 6000 are com-

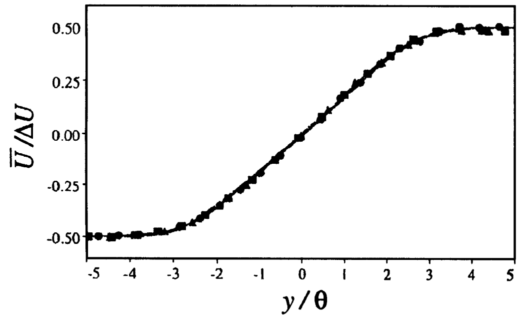

FIG. 11. Comparison of the mean velocity profiles of turbulent mixing layers, in their self-preserving regions, from the temporally developing DNS of Rogers and Moser (1994) at τ = 105.2, 116.7, 128.6, 141.0, and 150.8 and from the experiment of Bell and Mehta (1992): (■) x = 108.1 cm, (●) x = 128.4 cm, and (▲) x = 189.4 cm. The curves for the various values of τ are indistinguishable at the scale of the figure. Adapted from "Direct Simulation of a Self-Similar Turbulent Mixing Layer," by M. M. Rogers and R. D. Moser in *Physics of Fluids* **6**, Copyright © 1994, American Institute of Physics. Reprinted by permission of the American Institute of Physics.

pared with the temporally growing DNS mixing layer of Rogers and Moser (1994) at five different times in the self-preserving period of the simulation, with R_θ ranging from 800 to 2420. The Reynolds shear stress distribution shown in Fig. 12 for these two comparison flows also displays self-preserving characteristics. Brown and Roshko (1974) observed that coherent spanwise vortices with diameters of the order of the mixing layer width are a striking, persistent feature of mixing layers and appear to play a dominant role in their dynamics. They, and later Konrad (1976), also observed that, superimposed on the large spanwise roller vortices and in the "braid" region in between them, streamwise streaks occur, which Bernal and Roshko (1986) later demonstrated were due to vortices with axes oriented primarily in the streamwise direction. An instantaneous schlieren photograph of both the spanwise rollers and the streamwise streaks (Bernal and Roshko, 1986) is shown in Fig. 13. The spanwise rollers and the interspersed braid regions are also seen in Fig. 14, where contours of constant spanwise vorticity Ω_z are plotted from the temporally growing mixing-layer DNS of Rogers and Moser (1994). Views of this DNS flow in the cross-stream plane for cuts through a roller (indicated by the line marked B in Fig. 14) and through the braid (marked A) are shown in Fig. 15 for times (a) before self-preservation is reached and (b) during self-preservation. In these cross-stream views, contours of streamwise vorticity Ω_x and contours of a passive scalar for which Sc = 1 (in the high-speed free stream) are shown. Clearly, the flow in the self-preservation region is more disorganized than at the earlier time. Rogers and Moser (1994) note that they only observed distinct streamwise vortices and the "pairing" of spanwise rollers at the earlier times before the self-preserving state is achieved. Others have shown earlier (e.g., Hussain, 1986), as seen in Fig. 16, that Reynolds stress and kinetic energy production are concentrated primarily in the braid regions.

3. THEORY OF IDEALIZED TURBULENT FLOWS

3.1 Isotropic and Homogeneous Turbulence

A fundamental aspect of turbulent flow is the way in which energy decays from an arbitrary initial state in the absence of new turbulence produced by the presence of a mean shear. By assuming the turbulence to be homogeneous and isotropic, the decay problem is reduced to its simplest form. In this case, (38) becomes

$$dk/dt = -\epsilon, \tag{50}$$

which makes clear the essential role of the dissipation rate ϵ in determining the history of the kinetic energy field during the decay process. Further analysis of (50) depends on having information available about ϵ. This, in fact, can be usefully obtained from the exact ϵ equation, which is formally derivable from the Navier–Stokes equation:

$$\frac{d\epsilon}{dt} = \frac{7}{3\sqrt{15}} S_k R_t^{1/2} \frac{\epsilon^2}{k} - \frac{7}{15} G \frac{\epsilon^2}{k}. \tag{51}$$

The first term on the right-hand side of (51) represents the effect of vortex stretching in augmenting ϵ, while the second accounts for its destruction. Here, $R_t \equiv k^2/\nu\epsilon$ is the turbulence Reynolds number, $S_k \equiv -\overline{(\partial u/\partial x)^3}/[\overline{(\partial u/\partial x)^2}]^{3/2}$ is the skewness factor of $\partial u/\partial x$, and $G \equiv \overline{u^2}\ \overline{(\partial^2 u/\partial x^2)^2}/[\overline{(\partial u/\partial x)^2}]^2$ is the "palinstrophy" coefficient (see Lesieur, 1990, for a discussion of this terminology). A measure of the local intensity of the turbulent vorticity field is the turbulent enstrophy $\zeta \equiv \overline{\omega_i^2}$. In view of the isotropic identity $\zeta = \epsilon/\nu$, it is clear that there is a close connection between dissipation regions and those of high vorticity fluctuations. In fact, after division by ν, (51) may be written as the enstrophy equation.

Generally, S_k and G are time dependent, and so the system of equations formed by (50) and (51) is not closed. Further progress in the analysis of the isotropic decay problem can be had if additional information deriving from the two-point statistics is brought to bear on the situation. In particular, the isotropy condition introduces great simplification in the forms of $\mathcal{R}_{ij}$ and $\mathcal{S}_{ijk}$ so that they each, in fact, depend on just a single scalar function. In the case of $\mathcal{R}_{ij}$ it may be shown that

$$\mathcal{R}_{ij}(\mathbf{r},t) = \overline{u^2}(t)\left[\left(f(r,t) + \frac{r}{2}\frac{\partial f(r,t)}{\partial r}\right)\delta_{ij} - \frac{r}{2}\frac{\partial f(r,t)}{\partial r}\frac{r_i r_j}{r^2}\right], \tag{52}$$

where the longitudinal correlation coefficient

$f(r,t)$ was defined earlier. A similar result for $\mathcal{S}_{ijk}(\mathbf{r},t)$ shows that it depends on just the triple longitudinal correlation coefficient $K(r,t) \equiv -\mathcal{S}_{111}(r\mathbf{e}_1,t)/(\overline{u^2})^{3/2}$. If it is assumed that the turbulent flow maintains a structural self-similarity during the decay (von Kármán and Howarth, 1938), i.e., one in which $f(r,t)$ and $K(r,t)$ satisfy

$$f(r,t) = f(r/l(t)) \tag{53}$$

and

$$K(r,t) = K(r/l(t)), \tag{54}$$

where $l(t)$ is an appropriate length scale, then it may be shown that S_k and G are constants and $l(t) \sim \lambda(t)$. In this case (50) and (51) form a closed system so that they may be solved for the decay of $k(t)$ and $\epsilon(t)$ from an arbitrary initial state. These solutions can be expected to be germane to the general decay problem—where exact self-preservation is not present—since solutions to (50) and (51) are stable to perturbations of S_k and G; i.e., the solutions will not be qualitatively different if S_k and G show some time dependence.

Speziale and Bernard (1992) have extensively analyzed the self-similar decay solutions including interpreting their relationship to the general decay problem and to physical experiments. It was found that they admit two fixed-point solutions. One has $R_t = 0$, is approached at large times whenever $7G/15 < 2$, and is associated with the final period of decay. This corresponds to weak turbulence where $R_t \to 0$, $k \sim t^{-5/2}$, and f has the Gaussian form

$$f(r/\lambda) = \exp(-r^2/2\lambda^2), \tag{55}$$

as was first predicted and verified experimentally by Batchelor and Townsend (1948). It may be shown (Sedov, 1944; Bernard, 1985) via analysis of the separability properties of the exact dynamical equation for $f(r/\lambda)$ and $K(r/\lambda)$ (known as the von Kármán–Howarth equation), that (55) is compatible with a vanishingly small, but nonetheless finite, influence of vortex stretching.

A second fixed point of the decay is $R_t = [(7G/15 - 2)/(7S_k/3\sqrt{15})]^2$. It is approached rapidly for large initial values of R_t whenever $7G/15 > 2$ and is the unique high–Reynolds-number fully self-preserving decay law. For this, $k \sim t^{-1}$ is reached as an asymptotic state after the stretching and dissipation terms in (51) come into balance, typically after several eddy turnover times. Until this happens, decay with $k \sim t^{-\alpha}$, $1 \le \alpha \le 1.4$, is predicted. The smaller the initial R_t is, the longer it takes until t^{-1} decay is reached. This may explain the propensity of experiments to show $t^{-\alpha}$ decay with $\alpha \approx 1.25$ on average. The few experiments that have been performed at high R_t do indicate a t^{-1} decay.

A single self-similar solution cannot be maintained throughout the decay process. After the initial transient, in which R_t approaches a constant and the t^{-1} decay law is reached, a further change must eventually occur in which R_t decays to zero and the t^{-1} decay shifts to the final-period $t^{-5/2}$ solution. Whatever the initial form of f is, it must change over to (55) in due course.

3.2 Homogeneous Shear Flow

The ways in which the decay process described in the previous section is modified by the presence of mean shear—which acts to produce turbulence—is of considerable theoretical and practical interest. The essence of this phenomenon may be most easily examined in the case of an initially homogeneous isotropic turbulence subjected to a uniform mean shearing, say $S \equiv d\bar{U}/dy > 0$. In this case, (50) is modified by the addition of a single production term,

$$\frac{dk}{dt} = -\overline{uv}\frac{d\bar{U}}{dy} - \epsilon, \tag{56}$$

which is positive since $\overline{uv} < 0$.

A number of experimental and theoretical studies have attempted to predict the short- and long-term behavior of k and ϵ subjected to homogeneous shear. Generally, these have found exponential growth at approximately the same rate for k and ϵ over the dimensionless times that have been examined ($St < 30$). It is not certain what occurs at larger times, but two principal scenarios have been put forward. Townsend (1956) hypothesized that, given enough time, a production-equals-dissipation equilibrium would result in which terms on the right-hand sides of (56) and (51) achieve balance and k and ϵ attain constant values. An alternative viewpoint is that the exponential growth in k and ϵ, observed for relatively short times, continues unabated for long times as well.

The latter point of view is consistent with standard modeling assumptions that have been applied to the ϵ equation. In this, a scaling argument is used to conclude that the vortex-stretching term in (51) must be subsumed by the dissipation term. The resulting equations give exponential growth in k and ϵ. Note that, after substitution for R_t in (51) corresponding to the two equilibrium states discussed in the previous section, it is found that either $d\epsilon/dt = -(7G/15)\epsilon^2/k$ or $d\epsilon/dt = -2\epsilon^2/k$. In either case there is domination of vortex stretching by dissipation. Before equilibrium is reached, however, vortex stretching does make a contribution.

Unlike the decay case, in homogeneous shear flow, R_t increases with time, significantly affecting the relative behavior of the terms in the ϵ equation. The production-equals-dissipation equilibrium results if it is assumed merely that there is some residual effect of vortex stretching at high Reynolds numbers (Bernard and Speziale, 1992). The slight enhancement of dissipation that results is just enough to raise ϵ to the point that it slows and stops the growth in k and then consequently itself also. Numerical calculations show that this occurs at times that are generally beyond those seen thus far in physical experiments or computations.

Some indication that the production-equals-dissipation scenario is the more physical of the two may be found by considering the behavior of the enstrophy equation in isotropic decay in the limit of zero viscosity (Lesieur, 1990). For very small ν, i.e., high R_t, the vortex-stretching term in (51) will be unchecked by dissipation and the enstrophy will increase dramatically in consequence of nearly inviscid vortex stretching. Only later, after R_t drops precipitously because of the rise in ζ (i.e., ϵ) and the fall of k, does vortex stretching lose its dominance, i.e., when the t^{-1} equilibrium is reached. Turbulence models that limit the right-hand side of (51) to being purely dissipative miss the initial rise in vorticity; moreover, in the $\nu \rightarrow 0$ limit they erroneously predict constant enstrophy as the long-time solution, a physical impossibility. Keeping a net vortex stretching is equivalent to predicting enstrophy blowup in the $\nu \rightarrow 0$ limit, a result that is generally compatible with numerical solutions to the inviscid Euler equations (Pumir and Siggia, 1992). Whether or not this happens in finite or infinite time depends on the behavior of S_k as $\nu \rightarrow 0$; such information is not yet available.

4. TURBULENCE MODELING AND THEORY

4.1 Closure Schemes

Turbulence modeling is the name given to the various strategies that have been developed for obtaining closure to the average equations of turbulent flow. The simplest approaches model R_{ij} appearing in the RANS equation (19)—most often using a molecular analogy—or else model the vorticity transport correlation in the rotational form of the RANS equation. In second-order closures, the unknown terms in the R_{ij} equation (34) are modeled. Some alternative approaches, based mainly on the two-pont correlation equation, are considered in the next section.

Constituitive models for R_{ij} most commonly incorporate gradient transport in the general form

$$\overline{u_i u_j} = \tfrac{2}{3}k\delta_{ij} - \nu_t\left(\frac{\partial \overline{U}_i}{\partial x_j} + \frac{\partial \overline{U}_j}{\partial x_i}\right), \tag{57}$$

where $\nu_t > 0$ is termed the "eddy viscosity." Equation (57) is specially designed to be consistent with a contraction of indices, since $\partial \overline{U}_i/\partial x_i = 0$ for incompressible flows. It can also be thought of as the lowest-order term in a functional expansion of the Reynolds stress in terms of mean velocity differences (Speziale, 1991).

For unidirectional flows, such as in a channel, (57) takes the form

$$\overline{uv} = -\nu_t \frac{d\overline{U}}{dy}. \tag{58}$$

There is a wide variety of approaches to the selection of ν_t. For example, in the mixing-length model (Prandtl, 1925), the molecular transport analogy is invoked to justify the expression $\nu_t = l_m^2|d\overline{U}/dy|$, where l_m is a mixing length. In the k–ϵ closure (Launder and Spalding, 1974), dimensional reasoning gives $\nu_t = C_\mu k^2/\epsilon$, where C_μ is a constant, and additional model equations must be solved for k and ϵ independently of (19). For flow situations where (58) is invalid—e.g., because $\nu_t < 0$ or infinite—none of the various expressions for ν_t has meaning. The general experience with eddy viscosity models is that among the class of flows where (57) cannot be excluded *a priori,* no one model is suitable for every case. Among the important flows where (57) is inadequate are those with streamline curvature, body forces, and nonsteady mean velocity. Its implied isotropy of the normal stresses prevents (57) from reproducing secondary flows, such as can appear in noncircular ducts. Some of these fundamental limitations can be alleviated by forming nonlinear generalizations of (57) that include quadratic terms in the functional expansion (Speziale, 1987). While in some instances they improve upon linear models, they still fail to capture important curvature and relaxation effects.

At the outset, modeling of the R_{ij} equation (34) has the advantage that the convective and viscous diffusion terms are computed exactly. The modeling effort thus needs to focus just on the higher-order correlations Π_{ij}, ϵ_{ij}, and β_{ijk}. While the general outlines of a physical interpretation of these terms can be given, they are largely opaque to physical explanation in terms of classifiable events in turbulent flow. Modeling efforts have focussed instead on using such dynamical restrictions as frame invariance under the extended Galilean group, material frame invariance in the limit of two-dimensional turbulence, realizability (the condition that velocity variances such as $\overline{u_i^2}$ are predicted to be always positive), and consistency with rapid distortion theory to guide the development of functional forms (Speziale, 1991). The resulting closures are better able to include anisotropy and relaxation effects than lower-order closures, and, unlike the latter, they are able to distinguish between the presence of plane shear, plane strains, and rotating plane shear.

4.2 Statistical Closures

The modeling techniques discussed in the previous section are limited in the range of physical ideas about turbulence that they are able to incorporate in forming closure. Consequently, a number of other methodologies have been devised that provide an opportunity to encompass alternative physical ideas. Several of such theories depend on making hypotheses about the statistical properties of the velocity field as viewed from Fourier space. Others utilize probabilistic expansions of the velocity field. Such methods are often too mathematically complex to be useful for predicting general flows, though they can offer insights into the analysis of relatively simple flows, such as those discussed in Sec. 3. In recent years, renormalization-group methods have been brought to bear on the closure problem as well. Many of the details of these methodologies may be conveniently viewed in the monographs by Leslie (1973), Lesieur (1990), and McComb (1990).

At a given point in homogeneous, isotropic turbulence, experimental measurements show that the velocity components tend to be Gaussian random variables. The multiple-point statistics, however, are not Gaussian; i.e., the velocity field is not a Gaussian random field. If it is assumed that the departure from Gaussianity is not too severe, then there are a number of closely related techniques that can be used to generate approximate closures. These proceed in spectral space by essentially closing the hierarchy of Fourier transformed equations for $\mathcal{R}_{ij}$, $\mathcal{S}_{ijk}$, and so on.

An early idea in this direction was to close the system at the level of third-order moments—which have fourth-order moments as unknowns—by relating the fourth-order correlations to products of second-order moments using the properties of Gaussian random fields. Since the velocity field is not Gaussian, this "quasinormal" hypothesis cannot be exactly true, but it may have some partial validity. It was subsequently found that the solution to the closed system generates negative energy, on account of unwarranted growth in the third-order moments. Further hypotheses are needed to force their saturation, and thereby ensure realizability. A successful approach of this sort is to use "eddy damping" in coordination with a "Markovianization" assumption. The resulting closure is referred to as EDQNM. This has the virtue of being applicable to high–Reynolds-number flows and is much less expensive to use than DNS. Its mathematical complexity primarily limits its use to unbounded flows.

In the direct interaction approximation (DIA), and its close relatives (Kraichnan, 1958, 1959; Leslie, 1973), the velocity field is subjected to a probabilistic expansion about the Gaussian state. Fourier transformations of the Navier–Stokes equation for turbulence in a three-dimensional box driven by a homogeneous isotropic stirring force leads to a hierarchy of coupled equations for the Fourier coefficients of the velocity field. An equation is also generated for the response tensor associated with an infinitesimal perturbation force. Various statistical approximations are made to develop a fully realizable closed system of equations for the ensemble average of the response tensor and quadratic products of the velocity modes. As originally constituted, DIA does not produce the inertial-range spectrum, but later variants, in particular the Lagrangian history DIA, do so.

The RNG method, as developed by Yakhot and Orszag (1986), starts with a similar correspondence principle as used in DIA to the effect that the Navier–Stokes equation with the correct forcing can be made to reproduce an inertial-range spectrum. The forcing function is chosen to be analogous to that in equilibrium thermal systems. The velocity field is written as the sum of long- and short-wavelength modes. A dynamical equation for the former is derived from the space-time Fourier transform of the forced Navier–Stokes equation, by repeatedly using it to eliminate the high–wave-number part of the velocity field. The equation is then averaged over high–wave-number strips, leaving an equation for the long-wavelength modes. A zero–wave-number limit is taken, the variables are rescaled, and the procedure is repeated. In the asymptotic limit, a turbulence closure or LES scheme can be extracted.

4.3 Thermodynamics of Vortex Systems

Beginning with the important work of Onsager (1949) in two dimensions, there has been much interest in explaining some of the important properties of turbulence, such as the Kolmogorov inertial-range spectrum, in terms of the statistical mechanics of vortex systems. In recent years (e.g., Montgomery and Joyce, 1974; Miller, 1991; Robert, 1990) understanding of the 2D case has achieved a high degree of development, and attention has turned increasingly toward examining the situation in three dimensions. One of the principal goals is to describe the statistical and fractal properties of stretching, folding, and interacting vortical structures whose combined effect is to create the $-\frac{5}{3}$ inertial-range law. Chorin (1994) has provided a three-dimensional thermodynamics of vortex systems that fits within the framework of modern statistical mechanics. He demonstrates that vortex systems are distinguished by having negative temperatures and that turbulence evolves toward an equilibrium at the infinite-temperature limit. Using percolation theory and polymer statistics to develop a statistical description of vortex stretching, he shows how the $-\frac{5}{3}$ exponent appears as a critical exponent. This represents a distinct shift from earlier viewpoints, e.g., summarized by McComb (1990), in which turbulence in the Kolmogorov range is believed to be a strongly coupled nonequilibrium statistical system.

A second primary objective of a statistical mechanical formulation of turbulence, whether through vortex systems or otherwise, is to set up machinery for a renormalization procedure. As cited previously in regard to RNG, this is a methodology for systematically reducing the complexity of a physical system by absorbing the effect of small scales into computable larger-scale motions. The end result of renormalization is providing a formalism for large-eddy simulation techniques as discussed in Sec. 4.5. For vortex systems, renormalization can be applied by removing small hairpin vortices from the calculation (Chorin, 1993) or through rescaling of vortex rings (Chorin and Hald, 1995). Such methods can form the basis for efficient implementations of vortex methods for simulating turbulent flow (Bernard, 1996).

4.4 Direct Numerical Simulations

Numerical simulations of turbulent fluid flow are possible using the standard techniques of computational fluid dynamics (CFD), so long as adequate grid resolution is used to capture motions at the scale of the inertial range. The first successful simulations were of pressure-driven turbulent flow between two plane walls, i.e., channel flow. These used spectral methods, which fit in well with the use of periodic boundary conditions in the streamwise and spanwise directions. For successful simulation of turbulence, the computational domain must be at least as large as the distance over which significant correlation occurs in the velocity field. This presumably allows for a fair representation of the dynamical behavior of the principal vortical structures in the flow. Acceptable domain size for a channel-flow simulation is $L_x \approx 4\pi h$, $L_z \approx 2\pi h$, where h is the channel height. A minimal mesh that satisfies these requirements for Reynolds numbers just in the turbulent regime, i.e., $\leq$10 000, is on the order of 64^3 or 250 000 points.

The necessary grid density for turbulent-flow simulation goes up rapidly with Reynolds number, as may be seen from the following considerations. Assume that the smallest mesh spacing should be the Kolmogorov scale, $\eta \sim (\nu^3/\epsilon)^{1/4}$, and that the mesh must cover a region of the size of the scale of energy-containing eddies. The latter scale may be taken as $l_e = k^{3/2}/\epsilon = k^{1/2}T$, where the eddy-turnover time $T \sim k/\epsilon \sim k/(dk/dt)$ measures the time over which some appreciable decay might take place. The ratio $l_e/\eta = R_t^{3/4}$ (where $R_t = k^2/\nu\epsilon$ is the turbulence Reynolds number) is proportional to the number of grid points that are needed in each coordinate direction. For three dimensions, the required mesh must therefore have $R_t^{9/4}$ points. Furthermore, the minimal number of time steps of the calculation is $\sim R_t^{3/4}$, which is determined as the ratio of T to the maximum permissible time step in a numerical algorithm, $\sim \eta/k^{1/2}$. Thus, on the order of R_t^3 operations are necessary in performing a DNS, which is well beyond the capability of the current generation of computers once $R_t \sim 10^5$. The outlook is not good that high–Reynolds-number flows can be treated by such schemes any time in the foreseeable future.

4.5 Large-Eddy Simulations

Direct numerical simulation is not practical for most turbulent engineering flows by reason of the wide range of scales in need of resolution. Clearly, it is necessary to devise a means for limiting the range of computable scales—but not one so drastic as to put the entire range of physics into the transport correlations, such as occurs in Reynolds averaging. The resolution of these conflicting approaches is the large-eddy simulation (LES) technique that attempts to compute the energy-containing scales while modeling the rest. A variety of schemes for carrying out LES have been devised, though many issues remain to be resolved before it can be considered a generally applicable flow-prediction tool for engineering design.

The primary point of departure in formulating the LES approach has traditionally been through a filtering operation applied to the Navier–Stokes equations. A filtered velocity is defined via

$$\langle U\rangle(\mathbf{x},t) = \int_{R^3} G(\mathbf{x}|\mathbf{x}')U(\mathbf{x}',t)d\mathbf{x}', \tag{59}$$

where $G(\mathbf{x}|\mathbf{x}')$ is any one of a variety of filter functions. These can be functions of small spatial support or global functions that effectively filter high–wave-number modes from the velocity field. After applying the filtering operation to the Navier–Stokes equations, there results an equation for the resolvable fields $\langle U\rangle$ that is formally equivalent to the RANS equation, with the exception that the Reynolds stress is replaced by the subgrid stress tensor $\tau_{ij} = \langle U_iU_j\rangle - \langle U_i\rangle\langle U_j\rangle$. The latter ostensibly represents the effect of small-scale motions on the large. Unlike the Reynolds stress tensor, however, it lacks a clear-cut physical interpretation in terms of momentum flux. Subgrid models have tended to be reminiscent of (57) in that they assume

$$\tau_{ij} = \tfrac{2}{3}\tau_{kk}\delta_{ij} - \nu_t\left(\frac{\partial\langle U_i\rangle}{\partial x_j} + \frac{\partial\langle U_j\rangle}{\partial x_i}\right). \tag{60}$$

The most widely used subgrid model is that due to Smagorinsky (1963), in which

$$\nu_t = (C_S\Delta)^2|\langle S\rangle|, \tag{61}$$

where C_S is the Smagorinsky constant, Δ is the grid spacing of the numerical mesh, $|\langle S\rangle| \equiv (2\langle S\rangle_{ij}\langle S\rangle_{ij})^{1/2}$, and $\langle S\rangle_{ij} = (\partial\langle U_i\rangle/\partial x_j + \partial\langle U_j\rangle/\partial x_i)/2$. A motivation for (61) is that it is the outcome of assuming local equilibrium between molecular dissipation of small-scale turbulent energy and its production out of the resolved field. Such an equilibrium has more of a global character than a local one, however, since there are spatially intermittent regions of "backscatter" in which energy flows from small to large scales.

In an effort to correct for the purely dissipative form of the Smagorinsky model, there has been great interest in devising models that can adjust to local conditions in the flow, thereby producing backscatter when and if necessary. Such models are referred to as dynamic models. The approach of Germano *et al.* (1991) uses an extra coarse-grained filtering to sample the energy content of the smallest resolved scales as a means of adapting the coefficient C_S to local conditions.

Large-eddy simulations have been and continue to be applied to a range of flows at Reynolds numbers and complexity somewhat greater than are obtainable with DNS. A number of issues remain to be resolved before grid-based LES can be extended to engineering flows. One major problem is finding subgrid representations of the near-wall physics that permit a reduced grid coverage adjacent to boundaries. Finally, it should be noted that radically different formulations of LES are also possible, as discussed in Sec. 4.3. It remains to find out which of these methods is the best route to take for predicting turbulent flows.

5. SUMMARY

Driven by the wide range of technological problems requiring reliable prediction of turbulent forces, energies, and transport rates, the study of turbulence continues to be a priority among fluid dynamicists. A long history of experimental study has produced much valuable insight into many aspects of bounded and unbounded turbulent flows. In recent years this has been complemented by numerical schemes yielding detailed realizations of turbulent flow at modest Reynolds numbers in relatively uncomplicated geometries. Turbulence modeling can offer some benefit in predicting special classes of flows, though to obtain more accurate predictions, or treat flows in general complex configurations, approaches that are more closely aligned with the flow physics are required. Large-eddy simulations, in a variety of forms, attempt to balance the advantages of numerical simulations with the economies of small-scale modeling. Such methods are well poised to capitalize on recent advances in understanding the statistical equilibrium of vortical structures in the inertial range scales, and may offer the best long-range prospect for solving general turbulent-flow problems.

GLOSSARY

Anemometry: The measurement of velocity in fluids.

Aspect Ratio: The ratio of breadth to height when used to describe the geometry of a wind tunnel or channel in experimental fluid dynamics.

Backscatter: The flow of energy from small to large turbulent length scales or, equivalently, from high to low wave numbers.

Boundary Layer: A thin layer of fluid adjacent to boundaries where the mean velocity and/or temperature change rapidly with distance normal to the surface.

Braid Region: The region in boundary-free turbulent flows between two consecutive large spanwise-oriented vortices. In a frame of reference moving with the mean flow, a stagnation point occurs in this region, indicating a location of high compressive and extensional strain.

Buffer Layer: A thin layer near a solid surface in bounded flow, between the layer adjacent to the surface where the mean velocity varies linearly and the logarithmic layer.

Circulation: The line integral of the tangential component of the velocity vector around a closed circuit in a fluid. By the Stokes and divergence theorems, the circulation is also the integral of the normal vorticity component over an arbitrary surface whose boundary is the circuit. The circulation is the measure of the strength of a vortex tube.

Closure: A solvable system of equations formed from the averaged fluid-dynamics transport equations.

Computational Fluid Dynamics (CFD): Numerical methods for solving the time- and space-dependent equations describing fluid motion.

Core Region: The region above the logarithmic layer in bounded turbulent flows.

Correlation: The averaged product of two or more fluctuating flow variables at different times and/or spatial locations. When this product is normalized with respect to the standard deviations of the variables, it is called the correlation coefficient. In part it is a measure of the phase coincidence of the time series of the variables.

Diffusion: The movement of transportable properties such as heat (internal energy), momentum, species concentration, and vorticity through a fluid. Molecular diffusion occurs down gradients of the property. Turbulent diffusion is generally much greater and can be counter-gradient.

Direct Numerical Simulations (DNS): Numerical solutions of the Navier–Stokes equations for turbulent flow in which all the essential scales are resolved by a sufficiently fine computational grid.

Drag: The resistance to motion of a solid body in relative motion to a fluid caused by unbalanced viscous stresses and pressures acting on the body surface.

Eddy Turnover Time: A time scale over which some significant energy loss might occur in a turbulent flow.

Eddy Viscosity: Turbulent momentum-transport rate formulated in analogy to the molecular viscosity.

Energy Density: The kinetic energy contained in spherical shells of radius κ and thickness $d\kappa$, where $\kappa = |\mathbf{k}|$ is the magnitude of the wave-number vector.

Enstrophy: The average of the sum of the squares of the vorticity vector components.

Entrainment: The inclusion of surrounding nonturbulent fluid into a region of turbulent fluid.

Flux: The transport of a fluid or flow property across a surface either in the fluid or at its boundary.

Friction Velocity: A velocity scale defined in terms of the mean shear stress at the solid surface of a boundary layer. It is commonly used for scaling flow phenomena occurring near a solid surface.

Homogeneous Turbulence: Turbulent flow whose statistical properties are independent of spatial position.

Instability: The capacity of a fluid flow to become disordered in response to a small disturbance.

Integral Scales: A measure of the largest length or time scales in a turbulent flow. They are determined by integrating autocorrelation functions or two-point space or time correlation functions, respectively.

Irrotational Flow: Regions of a flow in which the curl of the velocity vector field is zero, i.e., where the vorticity is zero.

Isotropic Turbulence: Turbulent flow whose statistical properties have no preferred direction.

Kolmogorov Scale: A length scale of turbulence, named for the Russian mathematician Kolmogorov, characterizing dissipation of turbulent kinetic energy into heat.

Laminar Flow: Fluid flow lacking the disordered motions characteristic of turbulence. It may be thought of as the orderly motion of layers (laminae) of fluid moving relative to one another.

Large-Eddy Simulations (LES): A numerical method in which turbulent flow fields are computed by solving the filtered Navier–Stokes equations of fluid motion on a coarse grid. The large, energy-containing motions are computed while the more universal turbulent motions, of a size smaller than the grid resolution, are modeled.

Lift: The net fluid force on a solid body acting in the direction opposite to that of the force of gravity.

Logarithmic Layer: The flow layer in a bounded turbulent flow in which the mean velocity varies logarithmically with distance normal to the bounding surface.

Mixing Time: The time interval over which velocity fluctuations along fluid particle paths become decorrelated.

Momentum Thickness: A characteristic length scale of fluid motions measuring the momentum deficit in wake and boundary-layer flows.

Passive Scalar: A scalar property of a fluid having no influence on the velocity field.

RANS: The Reynolds averaged Navier–Stokes equations.

Reynolds Number: A nondimensional number, named for the British engineer and scientist Osborne Reynolds, defined as the ratio of inertial to viscous forces acting in a flow. Its magnitude characterizes the transition from laminar to turbulent flow and different regimes within fully turbulent flow.

Reynolds Stress: The correlation between products of pairs of fluctuating velocity components. It may be interpreted physically as an average momentum flux.

Schmidt Number: A nondimensional number formed by the ratio of the molecular viscosity to the mass concentration diffusivity. It measures the relative rates of momentum or vorticity diffusion to mass diffusion.

Solenoidal Vector Field: A divergence-free vector field.

Taylor Microscale: A turbulence-length scale, formulated by the British meteorologist and fluid dynamicist G. I. Taylor, that characterizes small-scale dissipative phenomena. It is defined in terms of a parabolic fit to two-point spatial correlation functions at their origin.

Turbulence Decay: The tendency for turbulent kinetic energy—in the absence of a production mechanism—to diminish in time through its dissipation into heat.

Turbulence Modeling: Procedures for deriving closure to the turbulent transport equations by approximating higher-order unclosed correlations (see **Closure**).

Turbulence Structures: Turbulent motions whose spatial and temporal features have recurring aspects that can be detected and characterized. These are frequently also called "coherent structures." Vortices are the most common turbulence structures.

Turbulent Kinetic Energy: Half the sum of the average variances of the turbulent velocity fluctuations.

Turbulent Transport: The net movement of fluid and flow properties such as heat, momentum, species concentration, and vorticity through a fluid by means of turbulent fluctuations (see **Diffusion**).

Viscous Sublayer: The very thin layer next to solid surfaces in bounded turbulent flows in which the mean velocity varies linearly. The relative magnitude of the turbulent fluctuation amplitudes to the mean velocity is greatest in this region.

Vortex Lines: Lines in a flow that are everywhere tangent to the vorticity vector field.

Vortex Strength: The circulation of a circuit enclosing a vortex tube. It is invariant along the tube.

Vortex Tube: A bundle of contiguous vortex lines, tubular in shape, passing through a closed circuit in a flow.

Vorticity: Formally the curl of the velocity vector, it is the measure of the rotative motion of fluid particles. It is a defining property of turbulence in that flow regions without vorticity are not turbulent.

22.1
Introduction

Ultrafast spectroscopy denotes the investigation of very fast processes with electromagnetic radiation at an extremely high time resolution. It covers the pico- and femtosecond timescale and has meanwhile reached the attosecond regime. The high impact of the field results from the fact that changes in all common forms of matter are related to the motion and rearrangement of nuclei and electrons. If we assume that an atom with a mass of 10 amu has a kinetic energy of 1 eV, then the atom needs about 2×10^{-14} seconds = 20 femtoseconds to transverse a distance of 1 Å. This shows that the femtosecond timescale is the natural scale of atomic motions and elementary processes in matter. This is also reflected by the time periods of vibrations in molecules and of phonons in condensed systems, which are in the range of 10–1000 femtoseconds.

The pump-probe technique is the most direct realization of ultrafast spectroscopy. An ultrashort light pulse, the pump pulse, excites the system under investigation and starts the process of interest (see Figure 22.2). A second ultrashort pulse, the probe pulse, arrives with a certain delay at the sample and makes a snapshot of the current stage of the process. To characterize the complete evolution of the process, the experiment has to be repeated with varying delay times. Using ultrashort light pulses instead of fast detectors and electronics results in an about 10^5 higher time resolution. To understand the observed dynamics, a description of an intrinsic nonstationary situation has to be given, usually on a quantum mechanical level, at least for a part of the system. The key elements that have to be considered are couplings between subsystems and superpositions of eigenstates and their evolution.

The development of this field started about 40 years ago when picosecond laser pulses became available. They were immediately applied to study photoinduced molecular processes, energy redistribution between vibrations, and vibrational coherences (Eisenthal, 1975; Laubereau and Kaiser, 1978; Zewail, 2000). The development of mode-locked dye lasers and in particular of the much more reliable Ti : sapphire lasers resulted in pulses with durations down to a few femtoseconds. As these systems were available, people started

Encyclopedia of Applied Spectroscopy. Edited by David L. Andrews.

ISBN: 978-3-527-40773-6

to investigate basic photochemical processes on the subpicosecond timescale like dissociation of small molecules (Rosker, Dantus and Zewail, 1988; Rose, Rosker and Zewail, 1989; Zewail, 2000), electronic relaxation (Elsaesser and Kaiser, 1991), electron (Barbara, Walker and Smith, 1992) and proton transfer (Elsaesser and Kaiser, 1986) as well as isomerization reactions (Åberg *et al.*, 1994). These investigations promoted the understanding of molecular processes to a completely new level and were recognized by the award of the Nobel Prize in Chemistry to Ahmed Zewail in 1999 (Zewail, 2000). Owing to the development of new nonlinear conversion schemes (Riedle *et al.*, 2000) and the refinement of detection techniques, it is now possible to investigate almost every system with a time resolution down to 20 femtoseconds or even less and research dealing with such different topics like isolated molecules, solid-state physics, or biological systems make extensive use of ultrafast spectroscopy. Accordingly, almost every technique known from steady-state spectroscopy has meanwhile been transferred into the time domain. Broadband pulses provide, in addition, the unique possibility to construct very complex pulse shapes by manipulating the amplitude and phase of the frequency components in Fourier space. Using such appropriately designed electromagnetic fields for excitation allows to influence and control processes (Brixner and Gerber, 2003). By making attosecond pulses available, the time resolution was recently again dramatically improved (Corkum and Krausz, 2007). Those pulses are generated by recolliding electrons after an ultrashort photoionization event and the shortest pulse length reported so far is only 0.13 femtoseconds. Another current development is the implementation of femtosecond X-ray (Bargheer *et al.*, 2006) and electron diffraction techniques (Siwick *et al.*, 2003), which can measure the change of structures and might open the way to make a direct movie of ultrafast processes with subatomic spatial resolution.

Owing to the vastness of the field, it is not possible to give a comprehensive overview. We only describe a few selective examples to give an impression of the possibilities that the technique provides as well as the concepts that are important for theoretical modeling. Accordingly, we also restrict ourselves to weak field phenomena and have to exclude the fascinating area of high-intensity physics. The remainder of the article is organized as follows. Section 22.2 introduces the basic theoretical concepts used to describe ultrafast processes and experiments. In Section 22.3, some of the essential experimental tools and methods are sketched. In Section 22.4, different applications are described with a focus on molecular processes.

22.2
Principles and Theoretical Concepts

22.2.1
Potential Energy Surfaces

The quantum dynamics of a molecular system characterized by electronic coordinates $\mathbf{r}$ and nuclear coordinates $\mathbf{R}$ is determined by the time-dependent Schrödinger equation

$$i\hbar\frac{\partial}{\partial t}\Psi(\mathbf{r},\mathbf{R};t) = \hat{H}(t)\Psi(\mathbf{r},\mathbf{R};t) \quad (22.1)$$

where the Hamilton operator consists of a molecular part and an interaction term accounting for the coupling to the radiation field, $\mathbf{E}(t)$, here taken in dipole approximation ($\mathbf{d}$: dipole moment vector) :

$$\hat{H}(t) = \hat{H}_{\text{mol}} + \hat{V}_{\text{mol-field}}\,(t) \\ = \hat{T} + \hat{H}_{\text{el}} - \hat{\mathbf{d}} \cdot \mathbf{E}(t) \qquad (22.2)$$

Here, we introduced the nuclear kinetic energy, $\hat{T}$, and the electronic Hamiltonian, $\hat{H}_{\text{el}}$, which also contains the nuclear–nuclear repulsion. Using the Born–Oppenheimer separation of electronic and nuclear motions, the molecular wave function is written as

$$\Psi(\mathbf{r}, \mathbf{R}; t) = \sum_a \varphi_a(\mathbf{r}, \mathbf{R}) \psi_a(\mathbf{R}; t) \qquad (22.3)$$

where we introduced the adiabatic electronic states $\varphi_a(\mathbf{r}, \mathbf{R})$ and the nuclear wave packet on a given electronic state $\psi_a(\mathbf{R}; t)$. The latter is obtained from the set of coupled equations (May and Kühn, 2004)

$$i\hbar \frac{\partial}{\partial t} \psi_a(\mathbf{R}; t) \\ = \left(\hat{T} + \hat{V}_a(\mathbf{R}) - \hat{\mathbf{d}}_a(\mathbf{R}) \cdot \mathbf{E}(t) \right) \psi_a(\mathbf{R}; t) \\ + \sum_{b \neq a} \left(\hat{T}_{\text{ab}} - \hat{\mathbf{d}}_{\text{ab}}(\mathbf{R}) \cdot \mathbf{E}(t) \right) \\ \times \psi_b(\mathbf{R}; t) \qquad (22.4)$$

The first term describes the nuclear motion on the so-called potential energy hypersurface (PES) $V_a(\mathbf{R})$. This motion can be triggered, for example, by the coupling of an infrared (IR) laser field to the coordinate-dependent dipole operator of the considered electronic state. The laser field also triggers transitions between different electronic states via the transition dipole operator whose dependence on the nuclear coordinates is often neglected (Condon approximation), that is, $\hat{\mathbf{d}}_{\text{ab}}(\mathbf{R}) \approx \mathbf{d}_{\text{ab}}$. Transitions between adiabatic electronic states can also be caused by nonvanishing matrix elements of the nuclear kinetic energy. Such nonadiabatic transitions can become particularly important in situations where PESs of different electronic states come energetically close to each other. Nonadiabatic processes are at the heart of photochemistry. They cause internal conversion (IC) transforming electronic energy into vibrational energy, which comes along with a considerable shortening of the excited state lifetimes. Their description still provides a challenge to theory (Domcke, Yarkony and Köppel, 2004).

If the electronic states are well separated from each other, the transition probability follows the energy gap law, which results from the dependence of the Franck–Condon factors on the change of the vibrational quanta. On the other hand, nonadiabatic processes can be extremely efficient if a conical intersection is involved (Domcke and Stock, 1997; Domcke, Yarkony and Köppel, 2004). In this case, two electronic states are degenerate along a hyperline in the multidimensional space spanned by the nuclear coordinates. Of particular interest is the dynamics in the branching space, which is spanned by the coupling mode and the tuning mode. The nonadiabatic electronic coupling varies along the former and the energy gap between the corresponding so called diabatic states varies along the latter. This branching space is orthogonal to the hyperline of the intersection, while the shape of the adiabatic PESs in this space looks like a double cone (Figure 22.1). A conical intersection can be regarded as the extension of an avoided crossing into

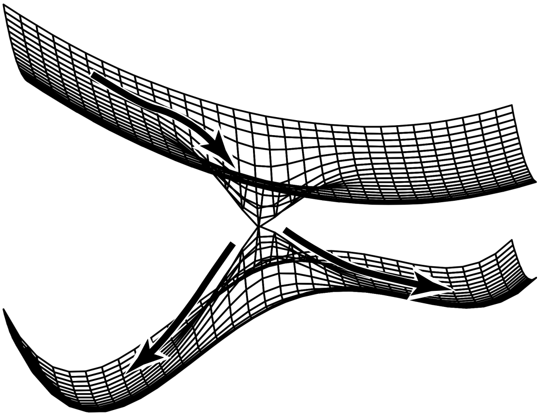

Fig. 22.1 Two PESs connected by a conical intersection. The relaxation pathway splits at the intersection and two minima corresponding to two different species are populated.

two dimensions. Owing to the double cone topology, a branching of the relaxation pathway at the intersection is quite likely. In this case, a part of the population usually reaches a minimum of the ground-state PES that differs from the original one and that is associated with a photoproduct. The rest of the population returns to the original minimum and completes the IC path. The speed of the process is given by the accessibility of the conical intersection, which depends on its energetic location and on whether the evolution of the excited-state population involves also coordinates that lead to the intersection. The quantum yield of a photoreaction depends on the dynamics at the intersection itself and how the wave packet propagates on the lower part of the double cone.

22.2.2
Wave Packets

As a consequence of the interaction with the laser field, the nuclear wave function will no longer describe a stationary molecular eigenstate on the considered PES, $\chi_{a,\xi}$ (**R**). Instead one has a coherent superposition (with coefficients $c_{a,\xi}(t)$) of such eigenstates called a *molecular wave packet*:

$$\psi_a(\mathbf{R};t) = \sum_{\xi} c_{a,\xi}\,(t)\;\chi_{a,\xi}\,(\mathbf{R}) \qquad (22.5)$$

Wave packets have been known since the early days of quantum mechanics. However, their observation in real time had to await the development of ultrafast spectroscopies during the last decades. In ultrafast spectroscopy, the molecule interacts with a sequence of N laser fields, that is,

$$\mathbf{E}(\mathbf{r};t) = \sum_{p=1}^{N} \mathbf{e}_p E_p(t-t_p) e^{-i(\omega_p t - \mathbf{k}_p\cdot\mathbf{r})} + \text{c.c.} \qquad (22.6)$$

Here, $\mathbf{e}_p$, ω_p, and $\mathbf{k}_p$ are polarization vector, carrier frequency, and wave vector, respectively, of the pth field. The pulse envelope, $E_p(t-t_p)$, is usually assumed to be of Gaussian shape centered at t_p.

In pump-probe spectroscopy, for instance, a first pump-pulse may excite a vibrational wave packet from the electronic ground to some excited

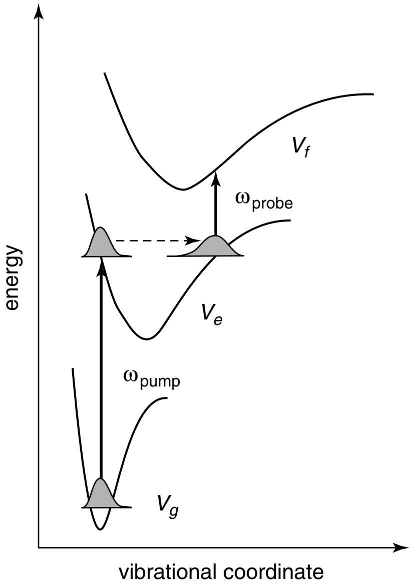

Fig. 22.2 Pump-probe spectroscopy of wave-packet dynamics along a vibrational coordinate. The pump-pulse with frequency ω_{pump} promotes the electronic ground-state (V_g) wave packet to the excited-state PES V_e, where it is probed by a time-delayed pulse with frequency ω_{probe} via a transition to a higher excited-state PES V_f.

state (see Figure 22.2). Owing to the different electronic structure, the nuclei are displaced from equilibrium and the wave packet no longer corresponds to a stationary state and propagates, that is, the bond is elongated. The ongoing dynamics can be interrogated by a time-delayed second pulse probing, for example, the transition to another electronic state from where fluorescence can be observed. The signal will reflect the oscillatory motion and dispersion of the wave packet in the intermediate state as well as concurring processes like photodissociation or nonadiabatic transitions to other electronic states.

Wave-packet dynamics as a modern research area has been initiated by Jortner and Berry's prediction of molecular quantum beats as a means for characterizing intramolecular radiationless transitions due to the breakdown of the Born–Oppenheimer approximation (Jortner and Berry, 1968). The development of numerical methods such as the split-operator approach and the utilization of fast-Fourier transforms for the calculation of the action of the kinetic energy operator onto the wave packet allowed for the efficient propagation of wave packets on general potentials in the early 1980s (Kosloff and Kosloff, 1982; Feit, Fleck and Steiger, 1982) marks a theoretical breakthrough, which enabled simulation of reactive processes at least for one-dimensional situations.

Straightforward extensions of these propagation methods face the limit of exponential scaling with the number of coupled degrees of freedom. This restriction is somewhat relaxed in the multiconfiguration time-dependent Hartree (MCTDH) method whose development has been a milestone toward the simulation of ultrafast multidimensional wave-packet dynamics (Meyer, Manthe and Cederbaum, 1990). Here, the wave packet for a D-dimensional system is expanded as follows:

$$\psi(\mathbf{R};t) = \sum_{j_1..j_D} A_{j_1..j_D}(t)\, \chi_{j_1}^{(1)}(R_1;t) \times \chi_{j_2}^{(2)}(R_2;t)\ \ldots\ \chi_{j_D}^{(D)}(R_D;t) \tag{22.7}$$

The use of a time-dependent basis set facilitates a flexible representation of the moving wave packet such that a considerably smaller number of basis functions is required as compared to the case of a fixed basis. Using this approach, the quantum dynamics of some tens of coordinates can be treated numerically exact; for special systems some thousand degrees of freedom are possible. Still, the propagation of the wave packet requires the knowledge of the complete PES including possible nonadiabatic couplings. Since its determination for complex systems is not feasible, methods that are based on classical trajectories with electronic structure theory-based forces determined on the fly have been developed. Quantum effects such as nonadiabatic transitions can be built into these simulations using the surface hopping method or semiclassical approaches (Stock and Thoss, 2005).

Despite the recent success of these all-atom simulations of complex systems at finite temperature the dynamics are more rigorously described by statistical methods such as the Liouville–von Neumann equation for the density operator $\hat{\rho}$. This facilitates, for instance, a reduced description of a relevant subsystem in interaction with a heat bath (May and Kühn, 2004). As a consequence of this, interaction energy and phase relaxation occurs, captured by the diagonal and off-diagonal elements of the reduced density matrix expressed in terms of the states of the relevant system {a}. The related damped wave-packet dynamics can be described in the simplest case of a Bloch model by

$$\frac{\partial \rho_{\mathrm{ab}}}{\partial t} = -i(\omega_{\mathrm{ab}} - i\gamma_{\mathrm{ab}})\rho_{\mathrm{ab}} - \delta_{\mathrm{ab}} \sum_c \Gamma_{\mathrm{ac}} \rho_{\mathrm{cc}} + i\mathbf{E}(t) \cdot \sum_c (\mathbf{d}_{\mathrm{ac}} \rho_{\mathrm{cb}} - \rho_{\mathrm{ac}} \mathbf{d}_{\mathrm{cb}}) \tag{22.8}$$

Here, ω_{ab} denotes the frequencies of transitions that are subject to dephasing with the rate γ_{ab}. The second term on the right-hand side describes the population redistribution with rates Γ_{ab} and the final term is due to the interaction with the laser field.

22.2.3
Theoretical Nonlinear Spectroscopy

22.2.3.1 Response Function Formalism

The different nonlinear spectroscopic techniques depend on the time delay between the pulses as well as on the phase-matching direction $\mathbf{k}_s$ for the detection of the macroscopic polarization field, which is defined as the expectation value of the dipole operator (n_{mol} : volume density of molecules in sample):

$$\mathbf{P}(\mathbf{r};t) = n_{\mathrm{mol}} \langle \hat{\mathbf{d}}(\mathbf{r};t) \rangle \tag{22.9}$$

The response function formalism is based on an expansion of the polarization in powers of the electric field strengths ("tr" denotes the trace operation)

$$\mathbf{P}(\mathbf{r};t) = \sum_n \mathbf{P}^{(n)}(\mathbf{r};t) = n_{\mathrm{mol}} \sum_n \mathrm{tr}\left[\mathbf{d}\hat{\rho}^{(n)}(\mathbf{r};t)\right] \tag{22.10}$$

Thus the nth order polarization is determined by a perturbation expansion of the density operator with respect to $\hat{V}_{\text{mol-field}}(t)$. This leads to

$$\mathbf{P}^{(n)}(\mathbf{r};t) = n_{\text{mol}} \int_0^\infty dt_n \ldots \int_0^\infty dt_1 \times S^{(n)}(t_n, \ldots, t_1)\mathbf{E}(\mathbf{r}; t - t_n) \times \ldots \times \mathbf{E}(\mathbf{r}; t - t_n - \ldots - t_1) \tag{22.11}$$

where the material properties are completely described by the response functions $S^{(n)}$, which are given by nth order correlation functions of the molecular dipole operator (Mukamel, 1995). For instance, the first-order response function that contains the information about linear spectroscopy is given by

$$S^{(1)}(t_1) = \frac{i}{\hbar}\theta(t_1)\,\text{tr}\,([\hat{\mathbf{d}}(t_1), \hat{\mathbf{d}}(0)]\hat{\rho}_{\text{eq}}) \tag{22.12}$$

where $[\hat{A}, \hat{B}]$ denotes the commutator and $\hat{\rho}_{\text{eq}}$ is the equilibrium density operator. For the case of an electronic two-level system coupled to intra- and intermolecular degrees of freedom Eq. (2.12) becomes (ω_{eg} is the transition frequency between states g and e, d_{eg} the transition dipole matrix element, and the expectation value is taken with respect to the ground state density)

$$S^{(1)}(t_1) = \frac{i}{\hbar}\theta(t_1)\left|d_{\text{eg}}\right|^2 \times \left(\exp\left[-i\langle\omega_{\text{eg}}\rangle t_1 - g(t_1)\right] - \text{c.c.}\right) \tag{22.13}$$

with the line shape function

$$g(t) = \frac{1}{\hbar^2}\int_0^t dt' \int_0^{t'} dt'' \langle\delta\omega_{\text{eg}}(t'')\delta\omega_{\text{eg}}(0)\rangle \tag{22.14}$$

Here, it has been assumed that the fluctuation of the transition frequency due to the interaction of the two-level system with its surroundings, $\omega_{\text{eg}}(t) = \langle\omega_{\text{eg}}\rangle + \delta\omega_{\text{eg}}(t)$, obey Gaussian statistics. In this formulation, the line shape function is the central quantity. It also enters the nonlinear response functions and is the starting point for simulations. Apart from models such as the multimode Brownian oscillator (Mukamel, 1995), the correlation functions can also be obtained from classical molecular dynamics simulations.

Comparing Eqs (22.6) and (22.11), we notice that the polarization can be written as

$$\mathbf{P}^{(n)}(\mathbf{r}, t) = \sum_L \mathbf{P}_L^{(n)}(t)e^{-i(\Omega_L t - \mathbf{K}_L\cdot\mathbf{r})} \tag{22.15}$$

Here, $L = \{l_1, l_2, \ldots, l_n\}$ comprises the numbers indicating possible combinations of fields for a given order n, $\Omega_L = \sum_p l_p\omega_p$, and $\mathbf{K}_L = \sum_p l_p\mathbf{k}_p$. In principle, a self-consistent solution of Schrödinger and Maxwell equations is required since the polarization enters as a source term into the latter. However, for optically thin samples, changes of incident fields in the medium can be neglected. Expanding the signal field into a Fourier series analogous to Eq. (22.15), one finds that the Fourier component along a certain direction $\mathbf{k}_s$ is proportional to the respective polarization term in Eq. (22.15) with wave vector selectivity introduced by the phase-matching condition, $\mathbf{k}_s \approx \mathbf{K}_L$. As an example, consider a third-order pump-probe experiment with $\mathbf{k}_1 = \mathbf{k}_2 = \mathbf{k}_{\text{pump}}$ and $\mathbf{k}_3 = \mathbf{k}_{\text{probe}}$. If the signal is detected in phase-matched probe direction, one has only terms with $L = \{\pm 1, \mp 1, 1\}$. The transient absorption signal can be calculated in slowly varying envelope approximation via

$$S(\omega_{\text{probe}}) = \frac{4\pi\,\omega_{\text{probe}}}{cn(\omega_{\text{probe}})} \times \frac{\operatorname{Im}\int dt\, E^*_{\text{probe}}(t) P_L^{(3)}(t)}{\int dt \left|E_{\text{probe}}(t)\right|^2} \tag{22.16}$$

where n is the index of refraction and we have skipped the vector character (Mukamel, 1995).

22.2.3.2 Nonperturbative Methods

In more complex situations that neither can be mapped onto the Brownian oscillator Hamiltonian nor can a diagonalization be performed, calculation of the multitime response functions becomes too tedious and a direct propagation approach is used (Domcke and Stock, 1997). This has also the advantage that it is, in principle, nonperturbative, that is, strong field effects can be considered. The idea can be illustrated for a pump-probe experiment with two incident pulses. To arbitrary order in the two fields, the polarization can be written as

$$\mathbf{P}(\mathbf{r}, t) = \sum_{n_1,n_2=-\infty}^{+\infty} \mathbf{P}_{n_1,n_2}(t) e^{i(n_1\mathbf{k}_{\text{pump}}+n_2\mathbf{k}_{\text{probe}})\cdot\mathbf{r}} \tag{22.17}$$

Defining the phases $\mathbf{k}_{\text{pump}}\mathbf{r} = \varphi_{\text{pump}}$ and $\mathbf{k}_{\text{probe}}\mathbf{r} = \varphi_{\text{probe}}$, the Schrödinger equation is solved using the time-dependent Hamiltonian where the wave vector dependence in the fields (22.6) is replaced by these phases. Calculating the polarization from Eq. (22.9), a certain component of the polarization can be extracted by inverting Eq. (22.17). For instance, $\mathbf{P}_{0,1}(t)$, contains the polarization component for the $\mathbf{k}_{\text{probe}}$ direction in any order with respect to the fields.

In combination with efficient propagation methods such as MCTDH, this direct approach is an important step toward first-principle quantum simulations of ultrafast spectroscopy (see, e.g., study of ultrafast electron transfer (Wang and Thoss, 2008)).

22.3
Experimental Methods

Figure 22.3 shows a typical layout of an ultrafast spectroscopic experiment. A mode locking oscillator generates ultrashort laser pulses that are subsequently amplified and transferred to other spectral regions by nonlinear optical processes. At some point of the setup, the laser beam is split into two arms to obtain a pump and a probe pulse, which are perfectly synchronized to each other. The pump pulse excites the sample while the interaction of the probe pulse is used to measure pump-induced coherences and population changes in the sample. Typically, a motorized delay line is incorporated in the path of the pump beam. By changing the pump delay, the time between the arrival of the pump and the probe pulses at the sample is systematically varied. The temporal evolution of a system after photo excitation is then reconstructed from the single point measurements taken at different delays. In the following, we shortly describe the components and techniques applied in such experiments.

22.3.1
Generation of Ultrashort Pulses

Ti : sapphire and fiber oscillators are commonly used to generate ultrashort

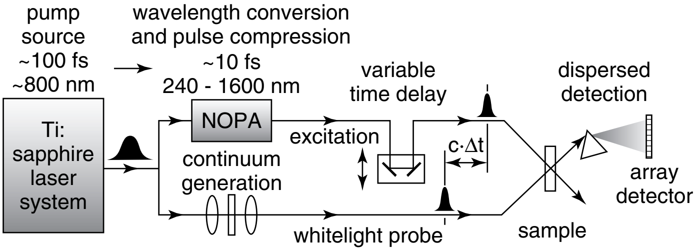

Fig. 22.3 Scheme of an ultrafast pump-probe experiment.

laser pulses at high repetition rates. Their output is directly used in applications that need only low energy pulses in a restricted wavelength range. Their layouts are shown in Figure 22.4. In these resonators, locking of longitudinal cavity modes and the formation of pulses occur since the pulses experience a higher gain or lower losses compared to less intense continuous-wave radiation. In the case of the Ti : sapphire oscillator, the intensity-dependent Kerr lens in the sapphire crystal causes for pulses a better spatial overlap with the tightly focused pump beam resulting in a higher gain (Spence, Kean and Sibbett, 1991). In the fiber oscillator, intensity-dependent birefringence of the fiber leads, in combination with appropriately aligned polarization tuning elements for pulses, to a higher transmission through the polarizer insulator (Tamura *et al.*, 1993). To generate short pulses, the total group delay dispersion of the resonator must be set to zero. In the Ti : sapphire oscillator, a prism sequence or chirped mirrors compensate for the dispersion of the other elements. The output pulses have a center wavelength of about 800 nm, energies of several nanojoules and can be as short as a few femtoseconds. In the fiber oscillator, dispersion compensation results from the combination of sections of a standard fiber that exhibits negative dispersion with an Erbium-doped fiber, which is the gain medium and has positive dispersion. The output is in the spectral region around 1550 nm and is usually frequency doubled if it serves as seed of an amplifier system.

To achieve pulse energies in the millijoules region, the oscillator output is amplified, typically with a regenerative amplifier operating at a repetition rate of 1 kHz (see Figure 22.5) (Backus *et al.*, 1998). Using a thin film polarizer (TFP), the seed pulse is coupled into the resonator of the amplifier. If a suitable voltage step is applied to the Pockels cell, the polarization of the pulse changes and it is captured in the resonator where it makes several round trips. A Ti : sapphire crystal pumped by a pulsed and frequency-doubled YLF or YAG laser serves as gain medium. When the inversion of the crystal is depleted, the pulse is released from the resonator by a second voltage change at the Pockels cell. The seed pulses are stretched to about hundred picoseconds by a grating stretcher before they enter the resonator. Otherwise, the high intensities of the amplified pulses would lead to nonlinear distortions of the pulse shape and to damage of the optical elements within the resonator. After the amplifier, a grating compressor removes the chirp introduced by the stretcher and the

dispersion of the resonator resulting in pulse duration down to a few tens of femtoseconds.

Many different schemes have been successfully implemented to access other wavelength regions and to shorten the pulse duration further. Here, we restrict ourselves to an approach that is notably versatile and is being extensively applied in spectroscopic experiments. Its central element is the optical parametric amplification of a white light contiuum (Riedle *et al.*, 2000; Cerullo and De Silvestri, 2003), see Figure 22.6. Pulses from a Ti : sapphire amplifier system with a pulse length in the order of 100 femtoseconds are typically used as input. A small fraction in the order of 2 μJ is split off and tightly focused into a sapphire substrate where self-focusing and self-phase modulation lead to the generation of a white light continuum. The remainder of the input beam is frequency doubled and serves as pump light for the parametric amplifier. The nonlinear medium of the amplifier is a $\beta - \mathrm{B_aB_2O_4}$ (BBO) crystal cut for type I phase matching. The white light and the pump beam cross each other at a small angle of about 3° in the nonlinear crystal. Choosing the appropriate nonlinear geometry results in the remarkable situation where the phase-matching condition becomes, to first order, independent of the seed wavelength (Riedle *et al.*, 2000). Then a very broad amplification bandwidth is

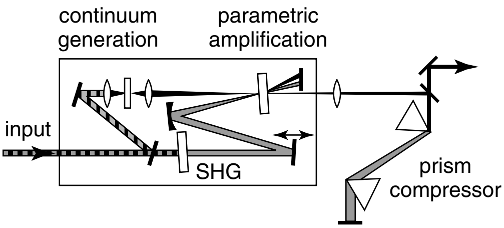

Fig. 22.6 Layout of a noncollinearly phase-matched optical parametric amplifier (NOPA) (Riedle *et al.*, 2000).

possible even with a thick crystal and a high gain for broadband pulses and pulse energies up to several 10 μJ can be achieved.

The dispersion of the amplified pulses is controlled with a prism compressor resulting in pulse durations down to 10 femtoseconds (see Figure 22.6). Using more sophisticated compression schemes, pulse durations as short as 5 femtoseconds have been demonstrated (Cerullo and De Silvestri, 2003). Since the white light has some chirp, the output of the noncollinearly phase-matched optical parametric amplifier (NOPA) can be easily tuned over the whole visible region and even far into the near infrared (NIR) by slightly changing the path length of the pump beam and thereby shifting its temporal overlap with the white light. The NOPA pulses can be efficiently frequency doubled extending the accessible wavelength range also far into the ultraviolet (UV).

22.3.2
Probing with Linear Techniques

Meanwhile, many different techniques are available to probe the pump pulse-induced changes of a system and their evolution with time. In this paragraph, techniques that are linear in the energy of the probe pulse are considered. The most straightforward one is perhaps the transient absorption spectroscopy (see Figure 22.3). A probe pulse transverses the sample in the same region as the pump and its energy loss due to absorption within the sample is measured. Very often, a white light continuum generated in a sapphire or a CaF_2-substrate is used as probe since the white light covers the complete spectral region from the NIR to the near UV and only very low pulse energies are necessary for probing (Kovalenko *et al.*, 1999). After the sample, the probe beam is dispersed by an imaging spectrograph and transmission changes over a broad spectral range are measured simultaneously with an array detector. An interesting feature of the technique is that absorption changes in the sample can be extracted in absolute numbers using Eq. (22.18).

$$\frac{Sig(\lambda)}{Sig_0(\lambda)} = \frac{T(\lambda)}{T_0(\lambda)} = e^{-n_{\mathrm{ex}}\cdot(\sigma(\lambda)-\sigma_0(\lambda))\cdot d} \tag{22.18}$$

$Sig(\lambda)$ is the dispersed probe signal measured with pump pulses hitting the sample and $Sig_0(\lambda)$ the signal when the pump beam is blocked. $T(\lambda)$ and $T_0(\lambda)$ stand for the corresponding sample transmissions. n_{ex} is the number density of excited particles, $\sigma(\lambda)$ is the time-dependent absorption cross section of the excited particle, $\sigma_0(\lambda)$ is its absorption cross section in the original state, and d is the sample thickness. The signal $S(\omega_{\mathrm{probe}})$ introduced in Section 2.3.1 is directly linked to these quantities by Eq. (22.19) and the experimental results can be compared to simulations by means of Eq. (22.16).

$$S(\omega_{\text{probe}} = 2\pi c/\lambda) = \frac{n_{\text{ex}}}{n_{\text{mol}}} \cdot (\sigma_0(\lambda) - \sigma(\lambda)) \tag{22.19}$$

Here, n_{mol} is the number density of the particles.

In Figure 22.7, the transient spectrum after excitation of a perylene bisimide dye is compared to the steady-state absorption and fluorescence spectrum (Schlosser and Lochbrunner, 2006). The depicted change of the optical density $\Delta OD = -\log(T/T_0)$ clearly shows the three contributions to the signal: (i) the bleach of the electronic ground state due to the excitation, (ii) stimulated emission from the electronically excited state to the ground state, and (iii) the excited state absorption caused by electronic transitions from the excited state to higher lying states. The bands contributing to the transient absorption in the visible and UV reflect the electronic state of a system.

Changes in vibrational structure and population show up as variations in the band shapes. However, those can be more specifically measured using an infrared pulse as probe pulse (Elsaesser and Kaiser, 1991). Another possibility is to measure the Raman signal associated with the probe pulse (Laubereau and Kaiser, 1978) or to perform stimulated Raman measurements by applying an additional picosecond pulse for pumping the Raman transition and by recording the stimulated emission at the Raman frequencies with the femtosecond probe pulse (Kukura, McCamant and Mathies, 2007).

Usually, several contributions of the transient absorption overlap spectrally. Then it is useful to look at the time-dependent emission. In most cases, this is done by fluorescence up-conversion (Yoshihara, Tominaga and Nagasawa, 1995; Schanz *et al.*, 2001).

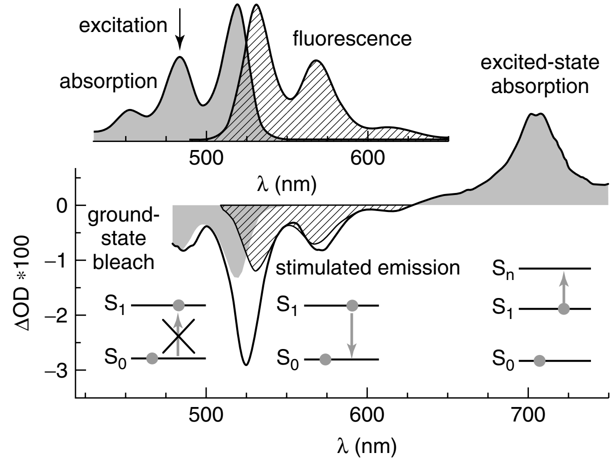

Fig. 22.7 Steady-state absorption and fluorescence spectrum of a perylene bisimide dye dissolved in chloroform and the transient absorption spectrum measured 5 picoseconds after optical excitation at 480 nm.

The spontaneous emission of the excited sample is imaged onto a nonlinear crystal. There, it is spatially overlaid with the probe pulsethat functions as a gate pulse in this case. The fraction of the emission that overlaps temporally with the gate pulse is subject to sum-frequency mixing and is transferred to shorter wavelengths. The strength and the spectrum of the sum frequency signal are measured with a spectrograph in dependence on the arrival time of the gate pulse at the crystal. The evolution of the emission spectrum is then directly reproduced by the time-dependent sum frequency signal.

For experiments in the gas phase or in a molecular beam, a very sensitive probe process is necessary due to the low sample densities. In this case, ionization techniques are used since ions and electrons can be detected with a very high efficiency (Stolow, Bragg and Neumark, 2004). One observable is the time-dependent mass spectrum, which reveals changes in the ionization probability and fragmentation pattern. Another one is the time-dependent photoelectron spectrum. It reflects the shape of the absorption bands associated with transitions from the populated electronic states to ionic states. Meanwhile powerful imaging and coincidence techniques were developed. They allow to assign each observed photoelectron to specific particles and to extract, besides the kinetic energy, the angular distribution, which is sensitive to the orbital from which the electron is emitted.

22.3.3
Probing Coherences

The probe schemes described above are not suitable to investigate electronic coherences. This is the domain of four-wave mixing (FWM) processes and interferometric techniques. In addition, nonlinear techniques of higher order have been applied. However, their discussion is beyond the scope of this article.

The most common realizations of ultrafast FWM spectroscopy are photon echo and two-dimensional spectroscopy. Three pulses are focused from somewhat different directions onto a common spot of the sample (see Figure 22.8) (Weiner, De Silvestri and Ippen, 1985). The first pulse induces a coherence between the ground and the excited state. The second pulse interacts with the coherence and creates a population in the excited-state the coherence or removes depending on the relative phase. A spatially modulated excited-state population results and constitutes a grating with the grating vector $\mathbf{k}_1 - \mathbf{k}_2$. The third pulse is diffracted by this grating and as signal a photon

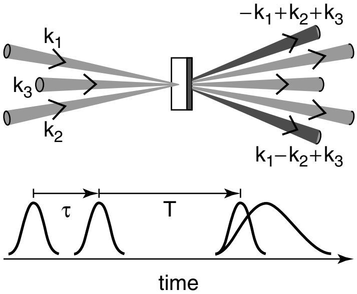

Fig. 22.8 Geometry and time diagram of a photon echo experiment.

echo with the wavevector $\mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3$ is generated. The time τ between the first and second pulse is often called *coherence time* since the signal strength depends on the coherence decay during this time interval. The time T between the second and the third pulse is named *population time* since during this interval the evolution of the populations is relevant. The role of the first and the second pulse can be exchanged and a second echo is emitted in the direction of the wavevector $-\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3$. Its dependence on the coherence time is mirrored compared to the former echo signal. In transient grating experiments, the first two pulses are simultaneously applied, that is, the coherence time is set to zero and not varied, and only the dependence on the population time is measured. Photon echo studies focus on the coherence time and deal predominantly with dephasing phenomena.

In photon echo experiments, usually the three applied pulses are identical. However, the arrangement can also be used for coherent Raman scattering. In the anti-Stokes configuration, the center frequency of the second pulse is shifted to lower frequencies with respect to the first pulse (Schmitt *et al.*, 1998). If the difference frequency fits to a vibrational mode, the vibrational resonance leads to a strongly increased diffracted signal at frequencies on the anti-Stokes side of the third pulse.

To extend the photon echo measurement to two-dimensional spectroscopy, a fourth laser pulse acting as local oscillator is interferometrically superimposed on the photon echo (Jonas, 2003). The resulting heterodyne signal is spectrally resolved and the coherence time τ is scanned keeping the population time T fixed. For each echo wavelength, the time-dependent signal is Fourier transformed. The result is a two-dimensional complex valued plot of the echo signal in dependence of the excitation and the signal frequencies. It shows which photon energies in the excitation contribute to the echo signal at a certain wavelength and if coherence transfer between excitation and echo generation occurs. The same approach using IR pulses is applied to investigate couplings between vibrational modes (Hamm, Helbing and Bredenbeck, 2008).

Wave-packet interference is another approach to look at the evolution of excitation-induced coherences. The sample is excited by two phase-locked collinear propagating pump pulses usually generated by means of a Michelson interferometer (Scherer *et al.*, 1991). The first pulse generates a wave packet that should at least partially return to the Franck–Condon region when the second pulse hits the sample. Then the degree of coherence between excited and ground state and the relative phase with respect to the field of the second pulse determine whether constructive, destructive, or incoherent superposition occurs. The corresponding signature is the appearance of interference fringes in scans of the delay between the excitation pulses.

22.3.4
Pulse Shaping

Ultrashort laser pulses constitute a broad band of phase-locked frequency components. If one has access to each of these components and one can tune its amplitude and phase, then it is possible to

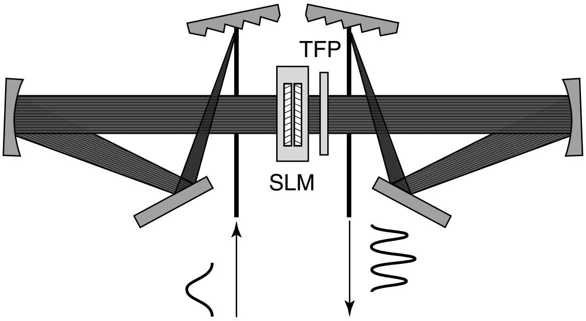

Fig. 22.9 Setup of a pulse shaper. SLM denotes a spatial light modulator containing two liquid crystal arrays and TFP a thin film polarizer.

generate completely arbitrary waveforms and pulse shapes. Only the carrier frequency would be similar and the shortest possible features are given by the original band width. Figure 22.9 shows a popular 4*f*-setup, which allows manipulating with high resolution amplitude and phase of the spectral components of a pulse. (Weiner, 2000). The incoming pulse is spectrally dispersed by a grating. A cylindrical mirror or lens placed in a distance to the grating equal to its focal length *f* collimates the beam and then focuses each spectral component on its own spot. The focal plane represents now a Fourier plane of the pulse. A modulator, typically a liquid crystal mask, consisting of two layers is placed in this plane. The birefringence of each mask pixel is separately controlled via applied voltages and thereby the phase shift of the transmitted light and, in combination with a TFP, also its amplitude. The spectral components are recombined via a second cylindrical lens or mirror and a second grating. The pulse spectrum is now composed of independent tunable components that can be as many as there are modulator pixels.

Pulse-shaping techniques opened the way to new experimental approaches that use optimized laser pulses to drive and control photoinduced processes. Usually they are implemented by means of a feedback loop. Using a shaperpulses with different shapes are applied to excite the system under investigation. The results of the excitations are analyzed and compared to each other. The pulse shapes giving the best results are selected, in different ways modified, and again applied. The procedure is repeated until no more significant improvement is observed. Meanwhile, many light-driven processes have been controlled in this way (Brixner and Gerber, 2003). This includes nonlinear frequency conversion, high harmonic generation, molecular processes, and imaging. In case several pathways interfere with each other, coherences in the system are relevant for the result. If the phase properties of the light pulse influence the relative phases between the pathways, the resulting interference is very sensitive on the pulse and coherent control of the process can be achieved (Rabitz *et al.*, 2000).

22.4
Applications

22.4.1
Wave-Packet Dynamics in Small Molecules

22.4.1.1 Vibrational Wave Packets

Small molecules in the gas phase provide good test cases for the concepts of nonstationary quantum mechanics. The time evolution of one-dimensional wave packets was, for example, studied in Na_2 (Baumert *et al.*, 1991). A 70-femtosecond-long laser pulse at 627 nm excites Na_2-molecules in a supersonic beam. A duplicate of the pulse is used to ionize the molecule via two-photon absorption at varying delay times (see Figure 22.10).

The $Na_2{}^+$-ion signal detected with a time of flight mass spectrometer shows a strongly oscillating time dependence, which is a clear signature of a wave-packet propagation in a bound potential. The spectrum of the excitation pulse overlaps with several vibrational levels of the $A^1\Sigma$ state and creates a coherent superposition of the vibronic states with the vibrational numbers $v' = 10–14$. The ionization probability is at the inner turning point of the $A^1\Sigma$ potential higher than at the one outer due to resonances with higher electronic states. Each recurrence of the wave packet at the inner turning point results in a transient rise of the $Na_2{}^+$ signal. The time delay between subsequent ionization maxima is 306 femtoseconds, which matches very well with the vibrational period that is given by the energetic separation of 109 cm^{-1} between the vibrational states. The long lifetime of the oscillations indicates that the wave packet broadens only slowly due to the quite moderate anharmonicity of the $A^1\Sigma$ potential at the involved vibrational levels.

22.4.1.2 Reactive Wave-Packet Dynamics

Couplings between electronic states and associated reaction channels strongly modify the wave-packet dynamics. The

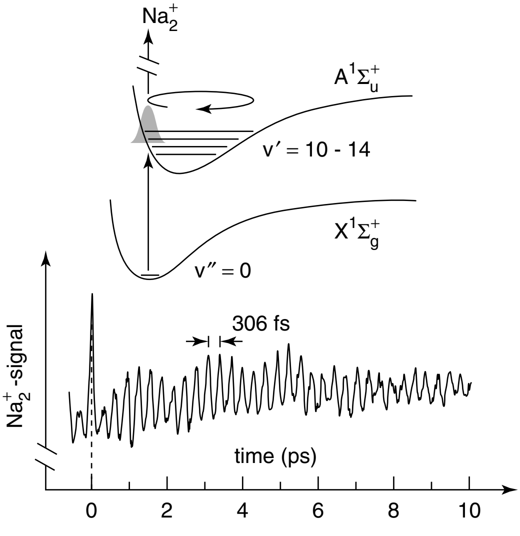

Fig. 22.10 Generation of a wave packet in Na_2 and oscillations in the ion signal due to the wave-packet propagation. (Adapted from Baumert, *et al.*, 1991.)

observed dynamics can then be used to analyze the reaction mechanisms. A one-dimensional example is the photodissociation of NaI (Zewail, 2000; Rose, Rosker and Zewail, 1989). A pump pulse at 307 nm launches in the first electronically excited state a wave packet, which then propagates toward the outer turning point (Figure 22.11). Thereby, it passes through an avoided crossing resulting from the diabatic covalent and the diabatic ionic PES. According to the Landau–Zener mechanism, the wave packet splits into two with one staying in the upper state while the other propagates along the lower covalent PES resulting in the formation of atomic iodide and sodium. The former is reflected by the binding ionic PES, returns to the Franck–Condon region, and is again reflected there. In this way, the wave-packet splitting is repeated several times until the excited state of NaI is depopulated.

With laser-induced fluorescence, the population of atomic sodium and electronically excited NaI can be followed in time (Zewail, 2000; Rose, Rosker and Zewail, 1989). At a probe wavelength of 589 nm, the resonance fluorescence of atomic sodium is dominant and one observes steplike increases of the sodium population every time the wave packet splits at the avoided crossing. In case the probe wavelength is off resonant the fluorescence of NaI dominates. The data shows recurrences of the wave packet which decay exponentially due to the losses at the avoided crossing.

If a laser pulse prepares a wave packet on a repulsive PES, the wave packet propagates in a ballistic fashion. The motion of its center of gravity follows almost purely classical dynamics and is given by the inertia of the involved nuclei and the slope of the PES. Accordingly, the dissociation products appear with some delay after the optical excitation. In addition, the wave packet exhibits broadening as a result of its wave nature. All these features have been demonstrated, for example, in the case of the photodissociation of ICN into I and CN (Rosker, Dantus and Zewail, 1988).

22.4.1.3 Influence of the Environment

In a dense environment, the wave-packet dynamics is strongly influenced by the interaction of the excited molecule with adjacent atoms or molecules. Several effects can occur (Gühr *et al.*, 2007). The forces exerted by the environment change the molecular PESs

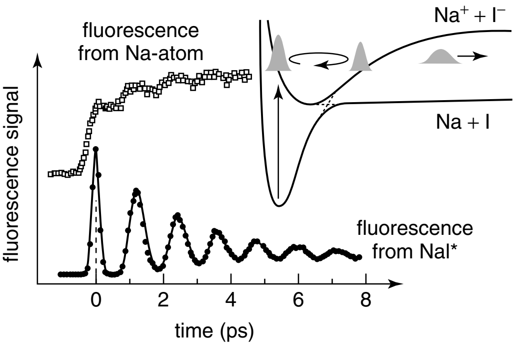

Fig. 22.11 Time-resolved observation of the photodissociation of NaI and the corresponding potential energy diagram (Zewail, 2000; Rose, Rosker and Zewail, 1989). The resonance fluorescence of the Na-atoms (squares) shows a stepwise buildup and the NaI-fluorescence a decay strongly modulated by the recurrences of the wave packet launched by the pump pulse in the electronically excited state of NaI. (Adapted from Zewail, 2000.)

and thereby the vibrational frequencies. The dynamics on originally purely repulsive PESs can even exhibit wave-packet recurrences due to reflections from adjacent particles. Moreover, energy is dissipated into the environment. Wave-packet oscillations are thereby efficiently damped and the population is collected at the potential minimum on a timescale in the order of 10 picoseconds. Fluctuations and inhomogeneities of the environment cause a dephasing of the coherent superposition generated by the optical excitation even if no energy exchange takes place. The decay of coherence-induced signal oscillations is therefore much faster than in the case of isolated molecules. On the other hand, it is possible to generate, in a matrix, coherently excited phonons with a short pulse excitation of an embedded chromophore.

22.4.2
Dynamics of Polyatomic Molecules

Larger molecules have usually several or many degrees of freedom that are involved in the dynamics, and the manifold of contributing states is very dense. This has two major consequences. First, the couplings between the intramolecular degrees of freedom have a strong impact. They cause energy redistribution between vibrational modes and often efficient radiationless electronic transitions. Secondly, the wave functions have a complex structure and observables are averages over population distributions as long as the temperature is not extremely low. Wave-packet signatures are therefore typically much less pronounced as in the case of small molecules. Quite often the dynamics is then described as a single or a series of transformations between states or configurations and the speed of the transformations is characterized by means of rates.

22.4.2.1 Vibrational Energy Redistribution and Cooling

Anharmonicities of the PES cause couplings between the vibrational modes of a molecule and thereby intramolecular vibrational energy redistribution (IVR). Energy transfer was measured for a number of molecules by IR pump and Raman probe spectroscopy (Laubereau and Kaiser, 1978; Hartl and Zinth, 2000). Transfer times in the range of 1 picosecond to almost 10 picoseconds were observed. This indicates that after several picoseconds, the energy is distributed over all vibrational modes and the molecule can be regarded as its own heat bath with an internal temperature.

Large molecules are often investigated in condensed phase. The interaction with the environment then causes an energy flow from the excited molecule to the environment and cooling of the molecule. This process was characterized by Raman measurements as well as via the shape of transient absorption spectra (Elsaesser and Kaiser, 1991; Schwarzer *et al.*, 2002). The intramolecular temperature decays exponentially to the temperature of the environment and the corresponding cooling times vary with the solvent and solute from slightly less than 10 picoseconds up to 40 picoseconds.

22.4.2.2 Solvation

The change of electronic states is usually accompanied by a change of the charge distribution in the molecule and of the static dipole moment. The environment reacts by adjusting its polarization so that the free enthalpy is again minimized. In solution, two contributions to the solvent polarization have to be considered. One is the electronic polarizability, which reacts instantaneous on changes of the charge distribution of the solute and is characterized by the index of refraction n. The second contribution results from the orientation and arrangement of the solvent molecules in the solvation shell around the solute. The energies associated with the two contributions $E_{\text{solv, elec}}$ and $E_{\text{solv, nuc}}$ are given by Eqs (22.20) and (22.21).

$$E_{\text{solv, elec}} = \frac{\mu^2}{4\pi\ \varepsilon_0\ a^3} \cdot \frac{n^2-1}{2n^2+1} \tag{22.20}$$

$$E_{\text{solv, nuc}} = \frac{\mu^2}{4\pi\ \varepsilon_0\ a^3} \cdot \left(\frac{\varepsilon-1}{2\varepsilon+1} - \frac{n^2-1}{2n^2+1}\right) \tag{22.21}$$

μ is the static dipole moment of the solute, a is its Onsager radius, ε is the static dielectric constant of the solvent, and ε_0 is the dielectric constant of vacuum. To adjust the second contribution, the nuclei of the solvent have to move. This includes vibrational motions, librations, and changes in the arrangement of the solvent molecules in the solvation shell. Accordingly, this response occurs on several timescales. Its evolution can be monitored by measuring the time-dependent shift of the emission spectrum after optical excitation of a chromophore that exhibits a reasonable strong change of the electric dipole moment like, for example, coumarin 153 (Horng *et al.*, 1995). The solvation dynamics is characterized by multiple exponential components with time constants in the range of a few hundred femtoseconds to several ten picoseconds. Smaller solvent molecules react faster and solvents, which form networks like the hydrogen-bonded networks of alcohols, exhibit slow response components associated with the rearrangement of the network. For certain solvents and a sufficient time resolution provided, the response can also exhibit oscillatory contributions caused by coherently excited motions of the solvent molecules (Pérez-Lustres *et al.*, 2005). It was also shown that the time dependence of the solvent response can be reconstructed from the frequency-dependent dielectric constant.

22.4.2.3 Electronic Dynamics: Internal Conversion, Conical Intersections, and Photochemistry

Most molecules exhibit excited-state lifetimes that are much shorter than the radiative lifetimes. Owing to the many nuclear degrees of freedom, nonadiabatic processes are likely to occur resulting in efficient IC and in photochemical products.

A key issue to understand molecular dynamics and photochemical processes is to locate conical intersections and to identify the involved coordinates. In an interplay of experimental (Fuß *et al.*, 1998) and theoretical work (Bernardi, Olivucci and Robb, 1996), several structural motifs were identified, which facilitate conical intersections. One important motif is, for example, a kink between a double and an adjacent single bond. It can lead to an energetic degeneracy between the electronic ground state and the first doubly excited singlet state. The molecular backbone is strongly twisted at this geometry and after the passage through the intersection, the twist motion can continue to a complete cis–trans isomerization. The rotation around the double bond is accompanied by a twist motion around the adjacent single bond. This can result in a Hula-twist isomerization where the two moieties on both sides of the double bond perform a bending motion instead of a rotation by 180° relative to each other. This allows for cis–trans isomerizations even in environments with low flexibility like proteins or organic matrices.

22.4.2.4 Coherent Wave-Packet Dynamics

Ultrashort excitation pulses generate, also in larger molecules, a coherent superposition of vibronic states. The wave packet launched by the pulse oscillates in those vibrational modes that contribute to the superposition. In time-resolved experiments with sufficient resolution, this results in oscillatory shifts of the bands contributing to the transient spectra and oscillations in kinetic traces measured at fixed probe wavelengths (see Figure 22.12). The frequencies of the oscillations are the frequencies of the contributing vibrations. Compared to small molecules, usually more

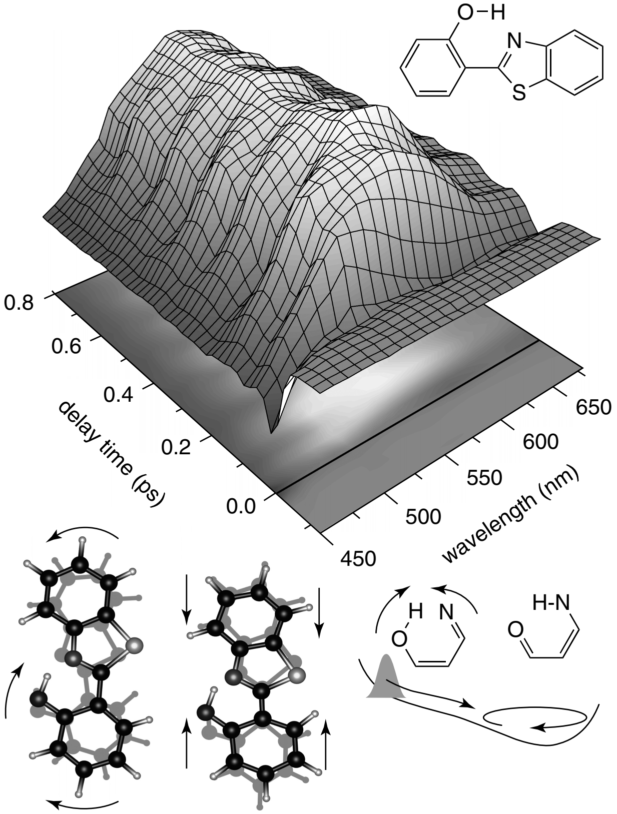

Fig. 22.12 Time-resolved transmission change after optical excitation of 2-(2′-hydroxyphenyl)benzothiazole. The excitation induces an intramolecular proton transfer, which proceeds as a ballistic wave-packet motion and excites coherently the depicted vibrational modes. (Lochbrunner, Wurzer and Riedle, 2003.)

vibrational modes and shorter damping times are observed due to the larger number of degrees of freedom.

A superposition of vibrational levels can be directly generated by the optical excitation. This is possible for Raman active modes and the superposition can then be reconstructed from the resonance Raman cross sections and the pulse spectrum (Takeuchi and Tahara, 2000). The optical excitation launches a wave packet not only in the electronically excited state but also very often in the electronic ground state via stimulated impulsive Raman scattering (SIRS). During the excitation process, population is pumped into the electronically excited state. The slope of the excited-state PES accelerates the corresponding wave packet along the Raman active modes. The ongoing interaction with the pulse can stimulate a part of the wave packet back into the electronic ground state where it oscillates in the Raman modes according to the gained momentum.

A coherent excitation of a vibrational mode can also result from the dynamics of a wave packet when the Franck–Condon region is already left and is not always caused by a direct optical excitation. For example, in azulene and in [2,2′-bipyridyl]-3,3′-diol, the coherent excitation of vibrational modes is observed that are optically inactive due to their symmetry (Wurzer *et al.*, 1999; Stock *et al.*, 2008). Accordingly, the analysis of oscillations reveals which coordinates contribute also beyond the Franck–Condon region to the path of the wave packet – information that can hardly be obtained by other methods.

The analysis of the coherent wave-packet motion is particularly valuable to reveal the mechanisms of photo reactions. Two examples are given here to demonstrate this approach. In the case of 2-(2′-hydroxyphenyl)benzothiazole, an excited-state intramolecular proton transfer takes place after optical excitation of the S_1-state. Femtosecond absorption experiments find that the proton transfer results in a coherent excitation of vibrational modes, which modulate the distance between the hydrogen donor and acceptor atom (Figure 22.12) (Lochbrunner, Wurzer and Riedle, 2003). This shows that prior to the transfer the donor–acceptor distance is shortened by a deformation of the molecular backbone until the hydrogen atom can be bound to the acceptor atom without the need for extra energy. Thereby the whole process can proceed along a barrierless and adiabatic pathway. The general notion is that if a process proceeds as a wave-packet motion, momentum is gained along coordinates that contribute strongly to the reaction path. After the process, the momentum results in oscillations in the associated normal modes of the product. This ringing of the product can be analyzed by time-resolved experiments and reveals which coordinates contribute to the reaction path.

In the case of the photodissociation of the metal hexacarbonyl compound $Cr(CO)_6$, oscillatory signal contributions with a low frequency of 95 cm^{-1} and with a higher frequency of about 400 cm^{-1} are observed in time-resolved, mass-selective dissociation experiments (Trushin *et al.*, 2008). The oscillatory component with the higher frequency is observed from the beginning of the dissociation process and results from a dominant optical excitation of the totally symmetric Cr-C stretch vibration. However, the low-frequency component is only observed in measurements that monitor the return of the wave packet at the electronic ground state. The frequency points to the coherent excitation of a totally symmetric C-Cr-C bending vibration. The results indicate that the electronic relaxation proceeds through a conical intersection between the S_1 and the S_0 state, which has a trigonal–bipyramidal geometry since after such an intersection the PES must have a slope along the C-Cr-C bending coordinate, resulting in an acceleration of the wave packet along this coordinate. This example demonstrates that the analysis of coherent wave-packet oscillations can give valuable information on the location of conical intersections.

22.4.2.5 Photoinduced Electron Transfer

The fundamental process of electron transfer can take place on timescales ranging from very slow for media in a glassy state to ultrafast for photoinduced reactions (Barbara, Meyer and Ratner, 1996). The charge transfer between a donor (D) and an acceptor (A) is strongly coupled to its environments. This necessitates a reorganization of intra- or intermolecular vibrational coordinates as well as of the polarization state of the solvent. Both effects can be described in a model where the potential or free energy is plotted along a reaction coordinate resulting, for example, in a double minimum potential, where D and A configurations are separated by a barrier. Possible transfer mechanisms encompass the limits of thermal activation and nuclear tunneling. Ultrafast photoinduced electron transfer occurs on timescales where the nonequilibrium effects with respect to the surroundings are important and the concepts underlying, for example, transition state theory break down. This might relate to the solvent which typically involves two timescales, that is, femtosecond inertial and picosecond diffusional motion. Measured intramolecular electron transfer times in $\mathrm{Ru}^{(\mathrm{II})}-\mathrm{Ru}^{(\mathrm{III})}$ mixed valence compounds in water yielded 80 femtoseconds, which is comparable to the inertial motion, but much faster than the diffusional one (Barbara, Meyer and Ratner, 1996). Furthermore, oscillatory components in the pump-probe signal have been demonstrated. They are a consequence of a coherent vibrational wave-packet motion, which is impulsively excited upon the Franck–Condon transition $\mathrm{D}-\mathrm{A} \rightarrow \mathrm{D}^{+}-\mathrm{A}^{-}$ (see also simulation in Wang and Thoss, 2008). Other examples are intermolecular D–A complexes in solution which have been studied, for example, by fluorescence up-conversion (Rubtsov and Yoshihara, 1999). Figure 22.13 shows data giving clear evidence for wave-packet motion, which has been assigned to an out-of-plane intramolecular vibration of the acceptor.

Owing to its technological importance, ultrafast heterogeneous electron transfer has attracted considerable attention. In particular, electron injection from a photoexcited adsorbed chromophore into a semiconductor is studied as a model for the primary process occurring in dye-sensitized electrochemical solar cells (Frischkorn *et al.*, 2007; Prezdho, Duncant and Prezhdo, 2008). In the case of perylene as dye and TiO_2 as semiconductor, injection times as short as 10 femtoseconds were observed. This fast dynamics results from the fact that the electron is transferred to a continuum of acceptor states in the conduction band of TiO_2. The insertion of bridge-anchor groups between the surface and the chromophore results in a slow down of the transfer rate, which is very sensitive to

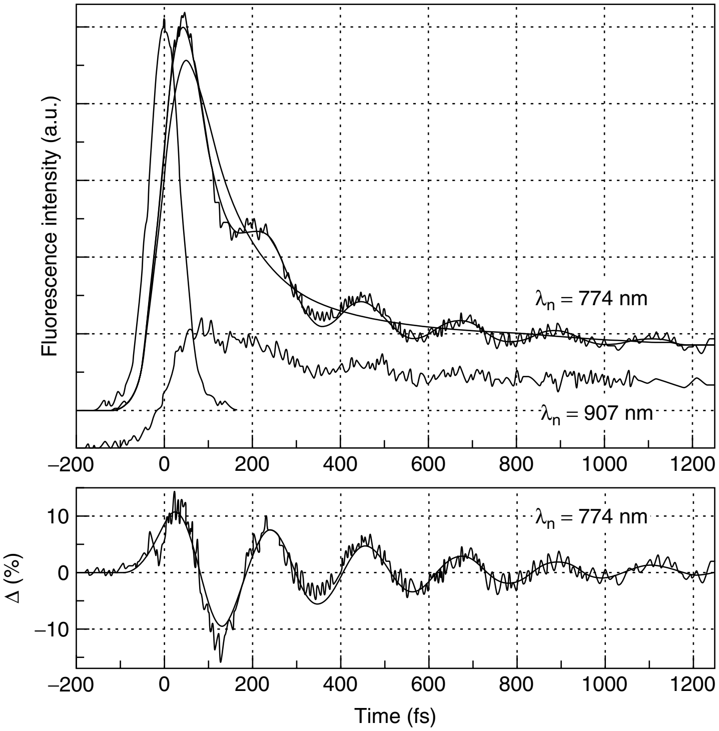

Fig. 22.13 Fluorescence decay of the hexamethylbenzene-tetracyanoethylene D–A complex in CCl_4 excited in the blue and red side of the time-integrated fluorescence spectrum. The oscillatory part ($\nu_{osc} = 155\ cm^{-1}$) is shown separately in the lower panel. The upper panel also contains the instrument response function (85 femtoseconds FWHM) as well as result of a biexponential plus oscillatory function fit. (Reprinted from (Rubtsov and Yoshihara, 1999), with permission from the ACS.)

the group type. If the group consists of conjugated bonds, it acts like a wire and only a moderate decrease of the rate is observed. If saturated bonds interrupt the transfer pathway, they induce a tunneling barrier and suppress the transfer strongly.

22.4.3
Clusters and Liquids

22.4.3.1 **Atomic Clusters**

Clusters are interesting objects since they allow to study how material properties change by going from the isolated atom or molecule to the condensed phase. They are generated in supersonic expansions of atomic or molecular gases. Typically, an inert gas is used as carrier to achieve low temperatures. Depending on the parameters of the expansion, clusters of various sizes between a few atoms or molecules up to many thousands of them can be generated (Hertel and Radloff, 2006). To measure the dynamics and evolution of electronically excited clusters, mass-selective ion and photoelectron spectroscopy are used in combination with the pump-probe technique (Stolow, Bragg and Neumark, 2004).

Atomic metal cluster anions are investigated to understand the transition from a single atom to a metal. They show very fast electronic relaxation processes even if the cluster contains only a few atoms (Dermota, Zhong and Castleman, 2004). The fast dynamics results from inelastic electron scattering, which is very similar as in the solid state although somewhat slower. The dynamics at stronger excitation intensities is governed by the finite size of the cluster. Multiphoton absorption results in multiple ionization and above a certain threshold in a Coulomb explosion of the cluster driven by the positive excess charges (Dermota, Zhong and Castleman, 2004). In the cluster a plasmon can be excited, that is, a collective oscillation of electrons. Its frequency depends on the density of quasi-free electrons and shifts to lower frequencies as the cluster expands during the Coulomb explosion (Fennel *et al.*, 2007). At some time, the plasmon frequency becomes resonant with the optical frequency of the exciting laser pulse if the pulse duration is sufficiently long. In this case, dramatically enhanced absorption occurs heating the cluster further up and resulting in extremely fast nonthermal electrons due to various acceleration processes.

In a supersonic expansion, molecules can form clusters that are typically stabilized by intermolecular hydrogen and van-der-Waals bonds. Optical excitation and photoionization of such clusters result often in complex fragmentation patterns and time dependences, and the interpretation relays on a careful analysis of the experimental findings. Ammonia clusters are a typical example (Hertel and Radloff, 2006). Nevertheless, it was possible to show for the ammonia dimer $(NH_3)_2$ that, after excitation to the $\tilde{A}$ state but prior to dissociation, a hydrogen transfer in the electronically excited state can occur leading to the $NH_4{-}NH_2$ complex. Interestingly, fast hydrogen transfer can also occur in mixed clusters containing one solute and a few solvent molecules like NH_3 or H_2O. For example, transfer in the electronically excited state from the solute to the solvent was observed on the subpicosecond timescale for indole ammonia and methanol water clusters. Such clusters give interesting insights into solvation processes since one can regard them as nanodroplets. The following two examples indicate that, in many cases, quite moderate cluster sizes result already in efficient solvation. The spectral and dynamical signatures of a solvated electron in water are almost fully developed when the cluster exceeds a size of about only 25 water molecules (Hertel and Radloff, 2006). In the case of the photodissociation of $I_2{}^-$ with NIR photons, it was shown that one solvation shell of CO_2 or OCS results in complete caging and recombination of the $I_2{}^-$ molecule (Sanov and Lineberger, 2004). Time-resolved experiments reveal that in the case of a full solvation shell the iodine atoms are directly reflected by the shell, whereas in the case of a partial solvation shell the weaker forces lead to a slowdown of the dynamics. If the excitation is performed with near-UV photons a higher lying dissociative state of $I_2{}^-$ with the spin-orbit excited $I^- + I^*(^2P_{1/2})$ asymptote is populated. Then, quenching of the spin-orbit excitation is necessary for recombination. This is only possible if the environment strongly disturbs the electronic structure of the $I_2{}^-$ anion. Therefore, the recombination yield and the dynamics depend strongly on the structure of the solvation shell and do not vary monotonically with the cluster size. However, almost complete caging is observed for about two solvation shells.

22.4.3.2 Water and Hydrogen-Bonded Networks

Disordered hydrogen-bonded networks are showing structural fluctuations on a broad range of timescales and have been targeted by ultrafast infrared spectroscopy (Nibbering *et al.*, 2007). Owing to its relevance, for example, for aqueous solvation, water has attracted most attention, although there are some efforts devoted, for example, to alcohols such as solvated methanol-OD oligomers (Asbury *et al.*, 2003). Due to technical limitations (high optical density of OH stretching fundamental transition in H_2O), most studies focused on isotopically diluted samples, that is, OH in HOD/D_2O or OD in HOD/H_2O. Upon excitation of the OH stretching vibration, one observes an ultrafast vibrational energy relaxation (~0.7 picoseconds), which has been assigned to be due to a Fermi resonance coupling with the HOD bending overtone vibration. Since the efficiency of this relaxation pathway depends on the proper resonance, it is not only influenced by the composition of the system but also on the fluctuation of the transition frequencies. These fluctuations are described by the correlation function of the energy gap, for example, for the OH stretch fundamental $\langle\delta\omega_{\mathrm{OH}}(t)\delta\omega_{\mathrm{OH}}(0)\rangle$, which determines the line shape function and therefore the nonlinear response (cf Eq. (22.14)). Three-pulse photon echo peak shift measurements on HOD/D_2O revealed a correlation function, which shows signatures of an underdamped motion (170 femtoseconds) related to the hydrogen-bond and a 1.2-picosecond decay assigned to be due to structural reorganization of the network (Fecko *et al.*, 2003). The subpicosecond dynamics of neat liquid water itself has been studied only recently (Cowan *et al.*, 2005). Here, one finds that correlations decay on a timescale of about 50 femtoseconds. This ultrafast loss of memory of the initially excited configuration was ascribed to the anharmonic coupling to librational motions in the hydrogen-bonded network.

The dynamics of an excess proton in water is another important issue that has been addressed by ultrafast IR spectroscopy (Woutersen and Bakker, 2006). Essentially there are two limiting structures the Eigen ($H_9O_4^+$) and the Zundel ($H_5O_2^+$) cations, which are related to proton migration. They can be distinguished by the absorption of the terminal OH stretching vibrations. Exciting the Eigen-like structure and probing for the Zundel-like one, it was found that the interconversion between these structures is faster than 100 femtoseconds.

22.4.4
Biological Systems

At first glance, stepping from molecules in solution to chromophores in biosystems seems to provide merely a different type of environment. However, biological systems are designed to fulfill a certain task, which is often made possible only by the concerted interplay of highly specific interactions. Although the biologically relevant response time to some external stimulus is in the range of microseconds or longer, the individual steps involving, for example, barrier crossings, can be substantially faster. These elementary steps and their importance for the structure–function relationship are in the focus of ultrafast spectroscopy.

22.4.4.1 **Primary Steps of Photosynthesis**

The conversion of sunlight into a transmembrane potential, which drives biochemical reactions in higher plants and certain bacteria builds on the ultrafast primary steps of excitation energy and electron transfer in pigment–protein complexes. Here, a variety of structures realize the same highly efficient cascade of energy funneling and charge separation. Purple bacteria such as *Rhodobacter (Rb.) sphaeroides* and *Rhodopseudomonas (Rps.) acidophila* have been the first organisms for which high-resolution X-ray structures became available. Here, light harvesting is performed by two types of ring-shaped antenna complexes. The peripheral antenna (LH2) consists of two pools of Bacteriochlorophyll a molecules, which are fixed by the protein scaffold. The closely packed B850 ring (16–18 pigments with 9 Å distance) gives rise to absorption around 850 nm, while a second absorption band around 800 nm originates from the B800 ring of 8–9 pigments being well separated (21 Å). These two pigment pools show an ultrafast dynamics, which can be described in terms of Frenkel exciton theory (Renger, May and Kühn, 2001). It has been extensively studied by various spectroscopic methods (Grondelle and Novoderezhkin, 2006; Sundström, 2008) leading to the following picture (time constants for 77 K): Excitation energy transfer among the B800 molecules takes place on timescales from 0.4 to 2 picoseconds, the transfer to the B850 pool covers the range from 0.4 to 1.1 picoseconds, while the intra-B850 transfer shows timescales of 150 femtoseconds and faster. This fast dynamics localizing the excitation energy in the red part of the spectrum is only possible due to the coupling between the electronic excitations to vibrations of the pigment and the protein, which causes energy dissipation (Renger, May and Kühn, 2001). The core antenna (LH1) receives the excitation energy from LH2 within about 5 picoseconds. Its structure is similar to that of the B850 ring, but it hosts the reaction center that traps the excitation energy within 30–40 picoseconds. The mechanism of the subsequent charge separation in the reaction center involves the initially excited special pair (P) of two strongly coupled bacteriochlorophyll molecules, a monomeric bacteriochlorophyll (B), a bacteriopheophytin (H), and a quinone (Q). Much effort had been focused on the role of B in the electron transfer chain, but by now there is clear evidence that at ambient temperatures the state P^+B^- forms within 3 picoseconds, suggesting a stepwise transfer mechanism. This intermediate decays within 0.9 picoseconds to give P^+H^- and after further 200 picoseconds P^+Q^- (Zinth and Wachtveitl, 2005) (see Figure 22.14).

Ultrafast two-dimensional spectroscopy in the visible range has been applied to the Fenna–Matthews–Olson light harvesting complex of sulfur bacteria to unravel the coupling patterns between its seven pigments, which are not arranged in some regular order (Brixner *et al.*, 2005).

22.4.4.2 **Rhodopsins**

Rhodopsins are photoreceptors where the absorption of a photon leads to a

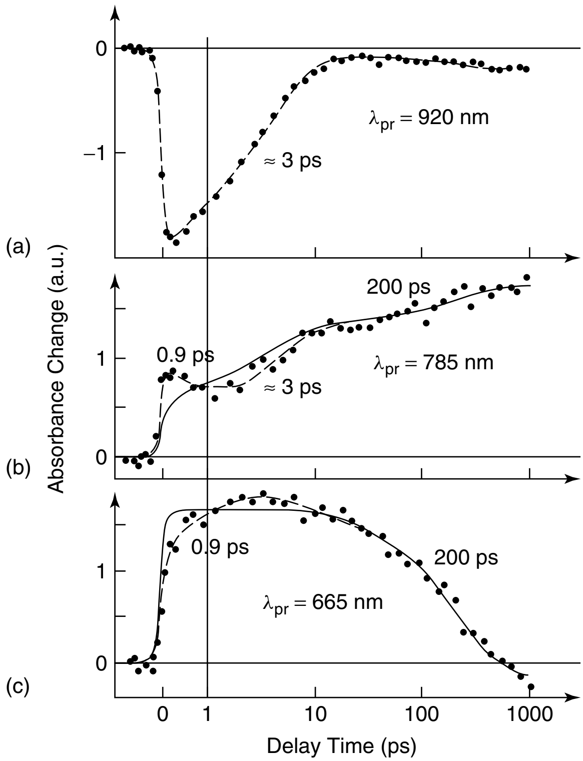

Fig. 22.14 Transient absorption of the reaction center of Rb. sphaeroides. At 920 nm, the signal is dominated by the decay of the primary donor (P*), at 785 and 665 nm the 0.9-picosecond component gives evidence for the P^+B^- to P^+H^- transfer. The 200-picosecond component corresponds to the electron transfer to the quinone. The solid and dashed lines represent fits with and without, respectively, the 0.9-picosecond component. Note that the axis is linear until 1 picosecond. (Reprinted from (Zinth and Wachtveitl, 2005), with permission from Wiley-VCH Verlag GmbH & Co. KgaA.)

conformational change, which as the result of a signaling cascade, eventually triggers some biological response. In rhodopsins, one has an 11-cis to all-trans conformational change in the retinal chromophore, which is key for the process of primary vision. In unicellular organisms, on the other hand, bacteriorhodopsin provides the means for ion transport across a membrane. The cis–trans isomerization of retinal has been one of the early targets of ultrafast spectroscopy (Sundström, 2008), see Figure 22.15. In fact, the formation of the primary photoproduct, bathorhodopsin, via an S_1-S_0 conical intersection occurs with high efficiency on a timescale of about 200 femtoseconds (Schoenlein *et al.*, 1991). The nature of the reaction coordinate has long been disputed. Here, valuable insight about the evolution on the excited S_1 state

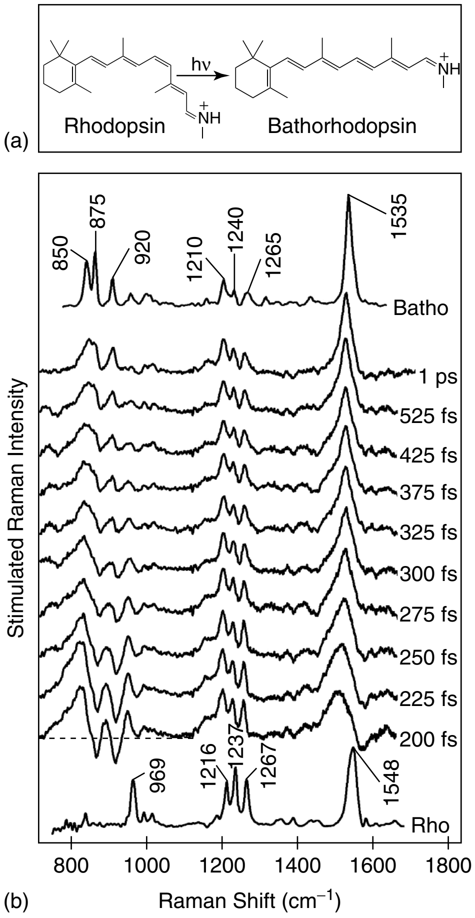

Fig. 22.15 (a) Photoinduced 11-cis to all-trans isomerization of the retinal chromophore of rhodopsin. (b) Characterization of this process after S_1-S_0 transition by means of time-resolved femtosecond-stimulated Raman spectra; lower and uppermost curve show resonance Raman spectra of ground-state rhodopsin and bathorhodopsin, respectively. (From (Kukura *et al.*, 2005), reprinted with permission from the AAAS.)

surface toward the conical intersection comes from on-the-fly adiabatic molecular dynamics simulations (Frutos *et al.*, 2007). It has been found that the retinal up to about 60 femtoseconds after excitation deforms to prepare for an asynchronous crankshaft type motion, which leads to the conical intersection after about 110 femtoseconds. The coherent evolution of the vibrations after the S_1-S_0 transition has been followed by femtosecond-stimulated Raman experiments as shown in Figure 22.15 (Kukura *et al.*, 2005). These data allow conclusions to be derived on the redistribution of the excess energy and the motions involved in forming the photoproduct. Dispersive features indicate changes in vibrational frequency along the reaction coordinate, which are particularly pronounced for the hydrogen out-of-plane motions observed around 800–900 cm^{-1}.

22.4.4.3 **Peptide Dynamics**

The function of peptides and proteins is largely determined by their three-dimensional structure. The latter is not static but fluctuates on rather different timescales, related to the intrinsic length scales. The fastest fluctuations in the picosecond and femtosecond range are not accessible to the well-established structure determination methods of nuclear magnetic resonance spectroscopy. However, they are likely to be of importance, for example, for energy transport or in the process of opening reaction channels leading to conformational changes. The most prominent signature in the IR spectrum of peptides is the amide I vibration (C=O stretch) of the peptide unit, which absorbs around 1620 cm^{-1}. Amide I modes on different peptide units are coupled leading to a delocalization of this vibration and therefore contain information on the secondary structure of the peptide and its fluctuations. This information, however, is congested in the linear IR spectrum. Two-dimensional (20) IR spectroscopy can be used to unravel this information by spreading the spectrum into a second dimension. For peptides, this was first demonstrated by Hochstrasser and coworker (Hamm, Lam and Hochstrasser, 1998). They used a dynamic hole-burning approach where a narrow band laser excites the sample and a broadband laser probes the spectral changes. If the dispersed signal is plotted as a function of the frequency of the pump laser, one obtains a 2D signal, which on the diagonal contains information on the amide I eigenstates, disentangling homogeneous (antidiagonal) and inhomogeneous (diagonal) contributions to the line width. Furthermore, in the off-diagonal part of the spectrum, cross peaks appear, which are related to the coupling of the considered transitions. The localized nature of the individual amide I vibrations and the sensitivity of the coupling strengths on the backbone structure allow for a simulation of these spectra in terms of vibrational Frenkel excitons (Mukamel and Abramavicius, 2004). The above-mentioned paper triggered host of investigations of the equilibrium conformational dynamics of various peptides in solution using different 2D IR spectroscopies (Woutersen and Hamm, 2002). More recently, the focus has been extended to membrane bound peptides (Mukherjee *et al.*, 2006).

One might ask whether this scheme can be applied to proteins containing hundreds of local amide I modes. It turns out that the 2D IR spectrum is rather sensitive to the structural motif as illustrated in Figure 22.16 (Ganim *et al.*, 2008). This gives direct access to the observation of large conformational changes, that is, protein folding and unfolding. In order to trigger these changes, the temperature-jump method has been used (Ganim *et al.*, 2008). An ultrafast alternative is the use of photoswitches built into the peptide structure. Photoexcitation of azobenzene, for instance, leads to a reversible cis–trans isomerization, which is capable of triggering a conformational change, for example, of small cyclic peptides (Hamm, Helbing and Bredenbeck, 2008).

22.4.4.4 **DNA**

The UV photochemistry and photophysics of nucleic acid bases has been studied extensively in gas and solution phase with the prospect that it contains the key for the understanding of DNA photoprotection and UV-damage (Crespo-Hernández *et al.*, 2004). Singlet excitation of DNA bases gives rise to a rapid radiationless deactivation,

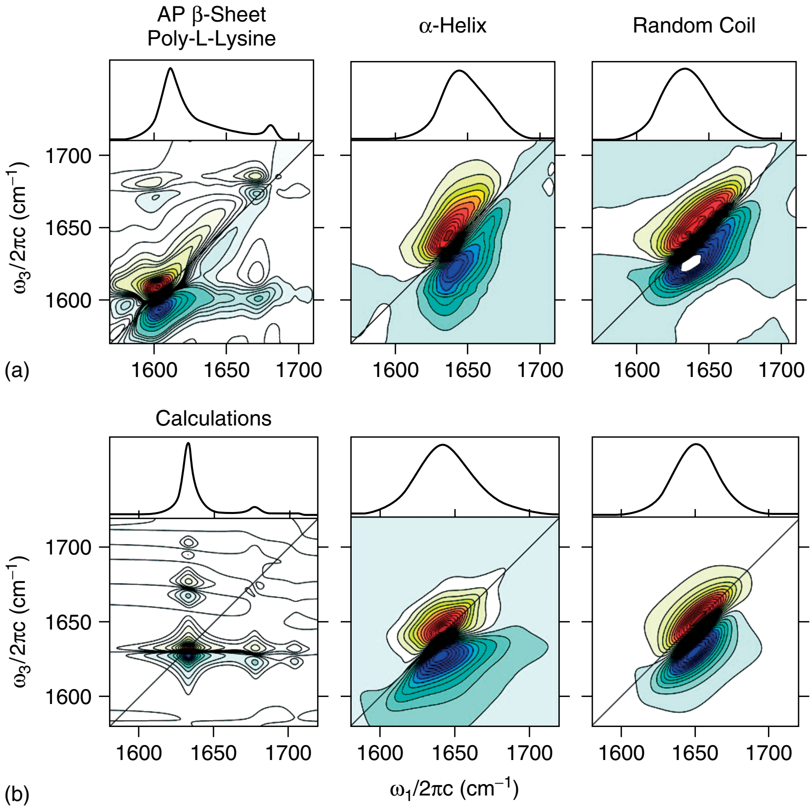

Fig. 22.16 Sensitivity of the 2D IR spectrum in the amide I region with respect to the secondary structure of poly(L-lysine) (panel (a) measured spectra, (b) model calculation). The upper/lower panels show the 2D IR spectra. The antiparallel (AP) β-sheet has two diagonal peaks as well as off-diagonal ones due to coupling pattern of amide I vibrations. These peaks merge into a single one for the α-helix and random coil, which can only be distinguished in the 2D IR spectrum. Notice that along ω_1 one has overlapping induced absorption and stimulated emission leading to an asymmetry with respect to the diagonal. (Reprinted from (Ganim *et al.*, 2008), with permission from the ACS.)

which necessitates the use of femtosecond methods for unraveling the coupled electron-vibrational dynamics. Quantum chemical calculations predict the relevant singlet manifold of the bases to be comprised of $\pi\pi^*$ and $n\pi^*$ excitations, where the former are carrying most of the oscillator strength. Time-resolved photoelectron spectroscopy of a supersonic jet expansion of adenine has been utilized to identify a 50-femtosecond $\pi\pi^*$ to $n\pi^*$ decay followed by a 750-femtosecond internal conversion into the electronic ground state for excitation well above the $\pi\pi^*$ origin (Ullrich *et al.*, 2004).

Upon base pairing new relaxation pathways become possible. For isolated base pairs, evidence for a deactivation along a reaction coordinate involving the hydrogen-bonded proton motion has been found. This leads to the stabilization of a charge transfer state, which converts into the S_0 ground state (Schultz *et al.*, 2004). Upon base stacking, the situation changes and the formation of an excimer has been observed. For double strands of adenine–thymine oligomers, the excimer formation is as fast as 400 femtoseconds and the excimer state decays within 50 picoseconds (Crespo-Hernández, Cohen and Kohler, 2005).

Base pairing does have a great impact on the vibrational dynamics in the electronic ground state. The formation of hydrogen bonds leads to substantial anharmonicities of the PES. For adenine–uracil pairs in deuterochloroform solution, pump-probe IR spectroscopy revealed a decrease of the lifetime of the hydrogen-bonded NH-stretching vibration by a factor of 3 as compared to monomeric uracil (Woutersen and Cristalli, 2004). DNA oligomers are investigated in the presence of water. For the IR spectrum, this gives rise to a broad absorption around 3000–3600 cm^{-1}, masking the fundamental transitions of the hydrogen-bonded NH and NH_2 stretching modes. Using two-color IR pump-probe spectroscopy, the symmetric NH_2 stretching band of adenine–thymine oligomers could be assigned by virtue of its anharmonic coupling to the NH_2 bending and carbonyl stretching modes in the fingerprint range (Heyne, Krishnan and Kühn, 2008). The anharmonic couplings related to base pair stacking and secondary structure of guanine–cytosine oligomers have been studied with the help of two-dimensional IR spectroscopy in the carbonyl stretching region (amide I modes) (Krummel and Zanni, 2006).

22.4.5
Solid State and Surfaces

22.4.5.1 Semiconductors

Ultrafast spectroscopy is applied to semiconductors and semiconductor nanostructures like single and multiple quantum wells to study many-body dynamics (Chemla and Shah, 2001; Axt and Kuhn, 2004). Pump probe and, in particular, FWM experiments are powerful methods to investigate coherences, correlations, and quantum kinetics in these systems. Deviations from the uncoupled quasi-particle picture are found to be quite strong and for many aspects the theory has to be extended beyond the mean-field level. The following examples illustrate these findings.

Early experiments on GaAs found already surprisingly efficient exciton–exciton scattering at mean exciton separations of more than 100 nm (Schultheis, Kuhl and Honold, 1986). Exciton scattering by free carriers was found to be even 10 times stronger. This demonstrates that in dense matter Coulomb forces lead even for formally neutral quasi-particles like excitons to strong interaction with other quasi-particles. In this respect, it is interesting to note that the formation of quasi-particles is not instantaneous. Femtosecond experiments on GaAs with terahertz-probe pulses found that Coulomb screening of free carriers takes several tens of femtoseconds (Huber *et al.*, 2001). This indicates that in the case of fast collisions screening is less efficient as for slow dynamics. The strong Coulomb interaction between the charge carriers leads, in general, to an ultrafast relaxation and equilibration

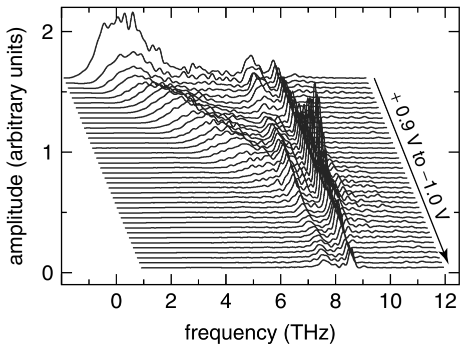

Fig. 22.17 Fourier transformations of time-resolved reflectivity measurements on a III-V semiconductor superlattice. The measurements were performed with different bias voltages as indicated at the right. (Reprinted from (Först *et al.*, 2007), with permission from Wiley-VCH Verlag GmbH & Co. KgaA.)

(Först *et al.*, 2007). However, for efficient recombination of electrons and holes, disorder and traps are necessary.

The analysis of quantum beats in time traces reveals information about carrier-phonon coupling. Time-resolved reflectivity experiments on III–V semiconductor superlattices showed, for example, that the coupling between optical phonons and Bloch oscillations can be efficiently tuned by an applied bias voltage (Först *et al.*, 2007) (Figure 22.17). The bias voltage changes the Bloch frequency linearly. If it is in resonance with an optical phonon, a strong increase of the phonon signal is observed. The largest signal is found for frequencies slightly below the frequency of the uncoupled phonon at 8.8 THz. This was interpreted as an indication that the dephasing rate of the Bloch oscillations increases by resonantly enhanced electron–phonon scattering. FWM experiments on GaAs quantum wells found clear evidence for two processes contributing to the dephasing of excitons (Carter, Chen and Cundiff, 2007): migration of the excitons and the interaction with acoustic phonons. The second contribution is identified on the basis of oscillatory features in time-dependent peak shifts of photon echo signals, which have a frequency in the expected range.

Ultrafast spectroscopy has also revealed strong evidence for biexcitons giving insight in Coulomb-induced correlations between electron hole pairs (Chemla and Shah, 2001; Axt and Kuhn, 2004). In several experiments, quantum beats with a frequency corresponding to the binding energy of biexcitons have been observed. Biexcitonic signatures might also be identified by means of their Stark shift, which is a red shift, if the excitation is just below the biexciton resonance contrary to mean-field contributions, which are blue-shifted (Axt and Kuhn, 2004).

22.4.5.2 Polymers and Organic Materials

Polymers and organic materials are very interesting for photonic applications like solar cells and organic light-emitting diodes (OLEDs). Ultrafast spectroscopy has contributed substantially to understand the exciton dynamics and the photoinduced charge generation in these materials (Lanzani *et al.*, 2005). The degree of disorder is much higher than in the case of semiconductors and the varying electronic structure of different molecular moieties has a strong impact on the dynamics (Scheblykin *et al.*, 2007). Electron hole pairs created by an optical excitation form Frenkel excitons, which are more or less localized on molecular chromophores and migrate by hopping processes through the material. Femtosecond absorption measurements show that after optical excitation, energy transfer on two timescales takes place. Within the first picoseconds, a red shift of the emission is observed indicating a relaxation toward the lowest state in the spatial vicinity of the excited chromophore. Thereafter, energy transfer occurs via thermally activated hopping. The transfer mechanism is of Förster type in both cases (Scheblykin *et al.*, 2007). Exciton migration becomes more efficient if the homogeneity of the site energies is improved. This was, for example, demonstrated for a polymer matrix highly doped with dye molecules, which interact only weakly with their environment but which can facilitate exciton migration by Förster energy transfer (Schlosser and Lochbrunner, 2006). Ultrashort pump pulses lead typically to exciton densities, which are high enough that bimolecular processes and exciton–exciton annihilation become important. If two excitons approach each other until they occupy two adjacent sites, they can interact and one of them is then usually annihilated (Scheblykin *et al.*, 2007). The associated time dependence of the exciton population can be analyzed to characterize the exciton mobility.

Photogeneration of charges in polymers is intensively investigated by ultrafast spectroscopy. The application of an external electric field increases the probability for the appearance of free charges (Kersting *et al.*, 1994). This allows to identify of the features and signatures of the generation process. The results show that primarily excitons are optically generated, which can then dissociate into free charges. The efficiency depends critically on the binding energy of the Frenkel excitons. In polymers with a significant binding energy charge pair generation occurs only if dissociation sites with an appropriate electronic structure are available, a sufficiently strong external field is applied, or the excitation brings a large amount of excess energy into the system. In the latter case, charge generation is restricted to a time window in the order of 100 femtoseconds limited by vibrational energy redistribution (Scheblykin *et al.*, 2007). For organic solar cells, the charge generation due to the interaction with electron acceptors like fullerenes is of particular importance. Experiments applying photoconductivity as probe process showed that the charge generation depends sensitively on the electron donating polymer (Müller *et al.*, 2005). In the case of methyl substituted poly(*p*-phenylene), coulombically bound polaron pairs are formed at the polymer fullerene interface. They show a high recombination probability resulting in a low photocurrent yield. In contrast, with poly(2-methoxy,5-(3,7-dimethyloctyloxy)-1,4-phenylenevinylene as donor free carriers are generated within 500 femtoseconds leading to a high yield.

J-aggregates of dye molecules show photoinduced dynamics, again determined by Frenkel excitons. Time-resolved absorption experiments found a clear signature for the transition from the one-exciton to a two-exciton state (van Burgel, Wiersma and Duppen, 1995). They also showed that efficient exciton–exciton annihilation can occur due to the mobility of the excitons. Calculations indicate that transient spectra should also exhibit features due to coherences between several exciton states (Heijs, Dijkstra and Knoester., 2007).

22.4.5.3 Surfaces

In the field of surface science, ultrafast spectroscopy plays an increasing role in order to understand the relevance of electronic surface states, the interaction with adsorbates, and the evolution of catalytic processes (Güdde, Berthold and Höfer, 2006). For most pump-probe techniques, the bulk contribution would lead to an overwhelming background signal. However, meanwhile several techniques have been developed, which are particularly sensitive to the surface. In the case of two-photon photoemission (2PPE), the kinetic energy of photoelectrons generated by the probe pulse is measured. Only electrons from the surface have a significant kinetic energy since photoelectrons from the bulk are subject to inelastic scattering before they reach the surface (Güdde, Berthold and Höfer, 2006). Other probe techniques rely on nonlinear second-order mixing processes like second harmonic generation (SHG) and sum frequency generation (SFG) (Bonn, Kleyn and Kroes, 2002). These processes are only possible if the medium exhibits no inversion symmetry. While for most materials this condition is not fulfilled in the bulk, it is an intrinsic property of surfaces and interfaces. Then the signal results only from the surface or the interface.

Image potential states are typical for metal surfaces. An electron is bound to the surface by attractive Coulomb forces resulting from the image charge in the metal. For well-ordered crystals, the electron can freely move parallel to the surface. However, the wavefunction extends into the bulk and couples strongly to the bulk states. This leads to ultrashort lifetimes in the range of 10–60 femtoseconds (Güdde, Berthold and Höfer, 2006) (Figure 22.18). If rare-gas adlayers are adsorbed on surfaces of metal crystals like copper or ruthenium, the lifetime increases strongly. The rare-gas layer can influence the lifetime in two ways. It pushes the wavefunction of the image potential state out off the bulk reducing the coupling to the conduction band (Figure 22.18). In addition, the state can be shifted in energy resulting in a larger energetic separation from the relevant bands of the bulk.

The chemistry on surfaces is characterized by a sequence of steps including adsorption of reactants, frequently dissociation, rearrangement, bonding, and desorption of products. Ultrafast spectroscopy provides new insight into the mechanisms of these processes (Bonn, Kleyn and Kroes, 2001). In addition, the laser pulse excitation of surfaces with adsorbates can also lead to new reaction pathways. Pump pulses can influence the dynamics in several ways. They can promote reactions if they are directly absorbed by the reactants. They can also be absorbed by the substrate and energy is subsequently transferred to the reactants by hot electrons or phonons. Electron-mediated processes are only possible within a short time window of about ~1 picosecond due to the strong electron–phonon coupling that cools the electrons efficiently whereas cooling of the phonon bath occurs on a timescale of ~50 picoseconds. The relevance of electron-mediated processes was demonstrated for the recombination of hydrogen atoms adsorbed on an Ru(100) surface (Frischkorn *et al.*, 2007). After the absorption of ultrashort laser pulses, hot electrons from the substrate cause a strong excitation in coordinates associated with the motion of

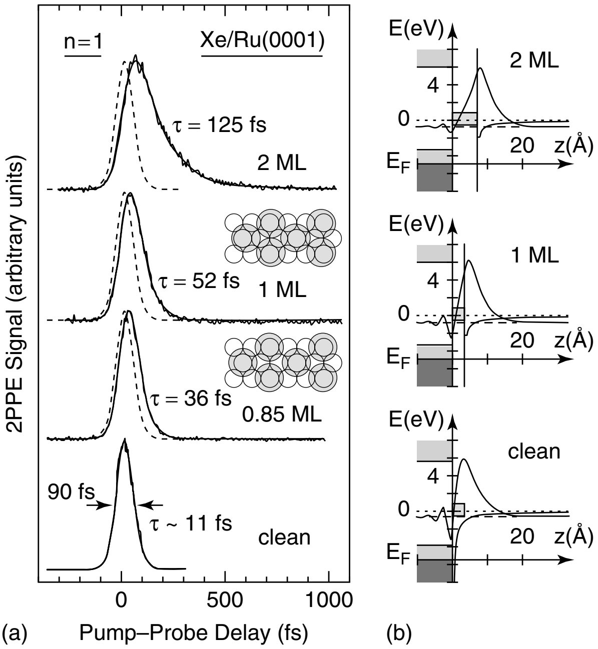

Fig. 22.18 (a) 2PPE lifetime (τ) measurements of the lowest image potential state of ruthenium(0001) for the clean surface (lowest panel and dashed curves) and with Xe coverages up to two monolayers (MLs). (Reprinted from (Güdde, Berthold and Höfer, 2006), with permission from the ACS.)

H-atoms parallel to the surface. This allows the formation of H–H complexes with some excess energy. Redistribution of the energy causes the excitation of vibrational motions perpendicular to the surface and finally desorption of H_2. Electron-mediated energy transfer was also found for the desorption of CO_2 from an Ru(0001) surface covered with CO and atomic oxygen (Bonn, Kleyn and Kroes, 2001).

22.4.6
Laser Control

Traditional chemistry controls reactions using a statistical approach, that is, changing equilibria via modifying external conditions. Ultrafast lasers open the possibility for controlling the wave-packet dynamics involved in elementary reaction steps. The field emerged in the 1980s triggered by the suggestion of two-photon pump-dump control of branching reactions (Tannor and Rice, 1985). Here, it is assumed that there are two exit channels on the electronic ground-state PES, $AB + C \leftarrow ABC \rightarrow A + BC$. Upon electronic excitation, the wave packet samples the available configurations on the excited-state potential and if dumped back onto the ground state, in the right moment, one can preferentially populate either of the two exit channels. A next breakthrough in terms of theoretical modeling has been the development of optimal control theory by Rabitz *et al.* (Peirce, Dahleh and Rabitz, 1988), where the problem of finding the proper field for populating a certain target is solved by means of functional optimization. Predicting laser fields, either by optimal control or by optimization of parameterized field forms and achieving control by tuning laser parameters in the laboratory, is known as open loop control. There are many examples for experimental realization of open loop control in atoms and diatomic molecules (Wollenhaupt, Engel and Baumert, 2005), but also in more complex systems such as the selective ground-state bondbreaking of diazomethane by chirped pulses (Windhorn *et al.*, 2003), the population of high vibrational states of the CO group in carboxyhemoglobin (Ventalon *et al.*, 2004), or the control of fragmentation products in the Coulomb explosion of silver clusters (Döppner *et al.*, 2005).

From the experimental point of view it would, however, be desirable to define the target and then let the molecule decide what kind of field is required. The appropriate approach is optimized feedback closed loop control and has been suggested by Rabitz *et al.* (Judson and Rabitz, 1992). Here, the laser pulse is iteratively optimized using a pulse shaper by incorporating the feedback from the experiment, that is, the reaction yield. For molecular reactions, the first successful demonstration has been by the group of Gerber in 1998 (see Figure 22.19) (Assion *et al.*, 1998).

Meanwhile, there are a number of applications (Brixner and Gerber, 2003) even to complex biological systems (Wohlleben *et al.*, 2005). From the theoretical point of view, this approach represents a serious challenge since even for simpler systems such as polyatomics no first-principle simulation is feasible. In certain cases, however, insight can be gained from appropriately chosen reduced model systems (Daniel *et al.*, 2003).

Using shaped laser pulses to control wave-packet dynamics is a rapidly developing field holding potential in different areas. Some examples include coherently

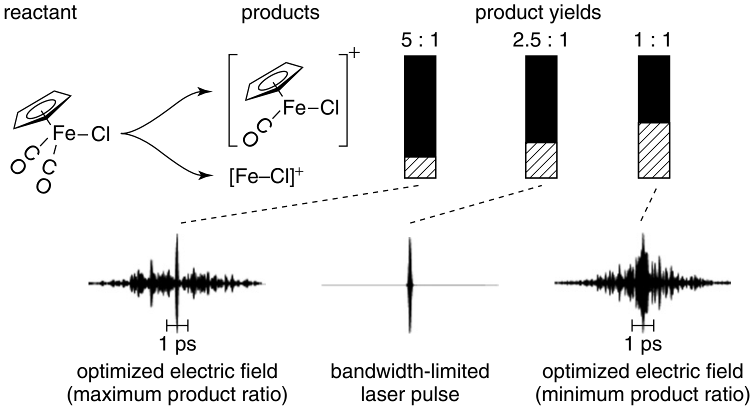

Fig. 22.19 Coherent feedback control of the $[CpFe(CO)Cl]^+/[FeCl]^+$ branching ratio. (Reprinted from (Brixner and Gerber, 2003), with permission from Wiley-VCH Verlag GmbH & Co. KgaA.)

controlled laser microscopy employing the coherent anti-Stokes Raman effect with a single pulse (Dudovich, Oron and Silberberg, 2002), the use of coherent control theory to perform logic operations with vibrational qubits in quantum information (de Vivie-Riedle and Troppmann, 2007), or even the manipulation of certain features in nonlinear optical spectra (Abramavicius and Mukamel, 2004).

22.4.7
New Frontiers

22.4.7.1 Generation of High Harmonics and Attosecond Pulses

If ultrashort high energy pulses interact with matter, coherent deep ultraviolet (XUV) and soft X-ray radiation is generated. In a typical experiment, 50–5-femtosecond short laser pulses with a center wavelength of 800 nm are focused into a gas jet of noble gas atoms or small molecules. After the jet XUV radiation, propagating collinear with the NIR-beam can be observed (Kapteyn *et al.*, 2007). A capillary filled with gas can be used instead of a jet. A schematic spectrum of the generated radiation is shown in Figure 22.20. It consists of many odd harmonics of the fundamental (Agostini and DiMauro, 2004; Pfeifer, Spielmann and Gerber, 2006). Under suitable conditions, harmonics with order numbers up to 100 can be observed and the shortest available wavelengths are only a few nanometers. In the low-frequency region, the intensity decreases with the order until the order number reaches a plateau region in which the intensity shows only a weak dependence on the order. At high frequencies when the photon energy is $\approx 3.2 \cdot U_P + I_P$, the plateau region ends and a “cutoff” region follows in which the intensity decays rapidly with the order number. I_P is the ionization potential of the medium and U_P the ponderomotive energy associated with the pulse field strength E_0 and the angular frequency ω of the fundamental via $U_P = e_0^2\, E_0^2/(4\, m_e\, \omega^2)$.

The appearance of this radiation is explained by the following three-step model (Corkum and Krausz, 2007). In the case of very intense laser pulses, the electric field strength, approaches for the valence electrons, the strength of the binding Coulomb potential. When the laser field adopts its maximal strength during an optical cycle, the tunneling probability becomes quite large and a significant fraction of the electrons is set free. Those electrons are subsequently accelerated by the laser field. Since the field reverses its direction in the next half cycle, the electrons are driven back to the atom or molecule. When they

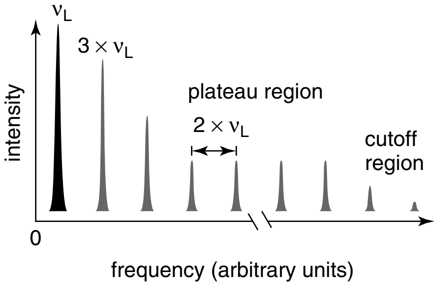

Fig. 22.20 Schematic spectrum of high harmonics generated by an ultrashort laser pulse with the center frequency ν_L. (Adapted from Agostini and DiMauro, 2004.)

return, they have a kinetic energy of about 50–1000 eV. Inelastic scattering and recombination of the electrons occur with high probability and transfer their kinetic energy into electromagnetic radiation. The recombination events themselves and the thereby emitted XUV pulses are extremely short, that is, in the order of 100 as. Since these events take place every half optical cycle, a train of attosecond pulses is generated and the spectrum consists of odd harmonics. In the maximum of the driving pulse, the recolliding electrons have the highest kinetic energy and lead to the contributions with the shortest wavelengths. In the case of a very short driving pulse, only a single attosecond pulse contributes to the highest frequencies. A single attosecond pulse can then be isolated from the train by selecting only the short wavelength contributions with an appropriate band pass filter. This approach led to isolated attosecond pulses with durations down to 130 as (Sansone *et al.*, 2006).

22.4.7.2 **Application of High Harmonics and Attosecond Pulses**

High harmonic generation is a promising technique for coherent radiation in the XUV and soft X-ray region. For example, in time-resolved photoelectron spectroscopy, such probe pulses provide access to high lying core electrons and their chemical shifts. Several techniques like quasi-phase matching and pulse shaping are applied to increase the high harmonic yield (Pfeifer, Spielmann and Gerber, 2006; Kapteyn *et al.*, 2007).

Attosecond time resolution is of particular interest for extremely fast electronic processes, like the decay of atomic core excitations. Such processes can be expected if no rearrangements or motions of nuclei are involved. Several experiments have been carried out using an attosecond pulse for excitation and the field of the associated NIR pulse for probing (Kling and Vrakking, 2008). The XUV attosecond pulse results in photoemission of valence as well as core-level electrons. The NIR field accelerates the photoelectrons and changes the photoelectron spectrum. This effect depends sensitively on the strength of the NIR field at the moment of the electron release and thereby on the phase of the NIR carrier wave at the time of the attosecond excitation. Accordingly, this "streaking" technique provides a time resolution comparable to the attosecond pulse length. Even more interesting, the ejection time of secondary photoelectrons, which result from relaxation processes like, Auger decays, can be precisely determined (Corkum and Krausz, 2007). In a similar way, tunnel ionization induced by the NIR field can be used as probe process with a time resolution much below the optical period.

Another approach uses the high harmonic spectrum to investigate the dynamics in small molecules during the generation process (Itatani *et al.*, 2004). After the tunnel ionization, the remaining ion is usually in a nonstationary configuration and its wavefunction evolves while the photoelectron first propagates away and then returns to the core. Since the whole process is coherent, the interference between the wavefunctions of the returning electron and the core has a strong impact on the emission of the XUV light (Kling and Vrakking, 2008). The characterization of the XUV spectrum, in dependence on the molecular orientation, can therefore provide a tomographic picture of the electronic wavefunction and its evolution.

22.4.7.3 Carrier Envelope Phase and Frequency Comb

In the case of very short laser pulses and nonlinear interactions, the carrier envelope phase (CEP), that is, the relative phase between the pulse envelope and the carrier wave becomes important. For a linearly polarized Gaussian pulse, a CEP of 0 indicates that the maximum of the envelope coincides with a field maximum of the carrier wave whereas a CEP of $\pm\pi/2$ indicates a zero crossing of the field at the maximum of the envelope (see Figure 22.21). The maximal field strength is therefore slightly higher in the former case than in the latter.

In a femtosecond oscillator, the phase delay and the group delay of a roundtrip are somewhat different and subsequent pulses exhibit different CEPs. In the ideal case of constant phase and group delay per roundtrip the shift of the CEP between the pulses is always the same. The spectrum of such a pulse train consists of equally spaced frequency components with a spacing given by the repetition rate of the oscillator (see Figure 22.21). Extrapolating this frequency comb toward lower frequencies results in a lowest component, which deviates from zero by the carrier envelope offset frequency (f_{CEO}) given by the CEP shift per pulse (Hänsch, 2006). f_{CEO} can be measured with a 1 f to 2 f interferometer (see Figure 22.21). This requires a pulse spectrum with reasonably strong components separated by an octave from each other. If the width of the pulse spectrum is insufficient, it can be broadened by self-phase modulation in a microstructured fiber. The low-frequency components are frequency-doubled with a nonlinear crystal and the SHG signal is overlaid with the high-frequency components on a fast photodetector. The interference between the frequency-doubled low-frequency components and the high-frequency components results in a beat signal with the carrier envelope offset frequency f_{CEO}. This radiofrequency as well as the pulse repetition rate f_{Rep} can be accurately measured and compared to high-precision standards like a cesium atomic clock. The frequency of a comb mode with the integer mode number m is strictly linked to these two frequencies by

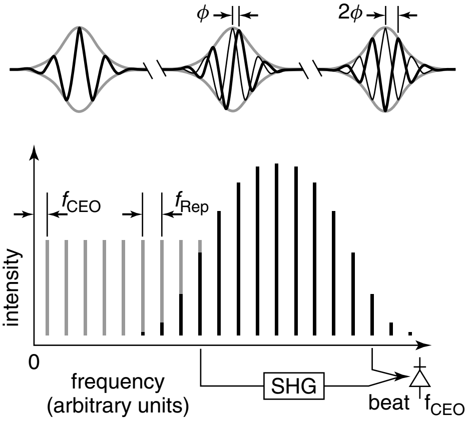

Fig. 22.21 A train of femtosecond pulses as it is generated by an oscillator. They differ only in their CEP ϕ. The lower panel shows the spectrum of the pulse train (black sticks). The gray sticks indicate an extrapolation of the observed frequencies toward zero. (Adapted from Hänsch, 2006.)

the relation $f_m = m \cdot f_{\text{Rep}} + f_{\text{CEO}}$. Accordingly, the frequency of each comb mode is known with an extremely high accuracy and can be used for high-precision spectroscopy. For this elegant approach, Theodor W. Hänsch was awarded the Nobel price in Physics in 2005 (Hänsch, 2006). The technique was, for example, applied to measure the 1S–2S transition frequency of the hydrogen atom with an accuracy of 1.4 parts in 10^{14} (Fischer *et al.*, 2004). Such experiments are highly relevant to test fundamental physical laws. The frequency comb allows also implementing atomic clocks based on optical transitions. They have the potential for a much higher accuracy than clocks operating at radiofrequencies and measurements with the same level of accuracy can be performed in much shorter times due to the high optical frequencies.

It is also possible to stabilize and control the f_{CEO} by this technique and thereby to generate pulses with deterministic CEP and electric field (Baltuška *et al.*, 2003). Adjusting the CEP to 0 or π results in the maximal field strength (see Figure 22.21), which is particularly useful in the case of nonlinear interactions of few cycle pulses. A prominent example is the generation of single attosecond pulses. In this case, the high-frequency components of the high harmonic spectrum are only generated during the central and strongest cycle of the electric field. Selecting these spectral components with a filter results in a single attosecond pulse (see above) (Sansone *et al.*, 2006).

22.4.7.4 **Time-Resolved X-Ray and Electron Diffraction**

One central vision in ultrafast spectroscopy is to follow, in real time, the structural and geometric changes during an ultrafast process. Ultimately, this should lead to a movie with femtosecond time resolution. Since structure and function are strongly related to each other, a much deeper understanding of the relevant mechanisms is expected for most processes.

To measure time-resolved structural changes, X-ray and electron diffraction are applied. X-ray diffraction itself is an extremely well established technique and the generation of short X-ray pulses has made large progress. Since the interaction of X-ray photons with matter is comparably weak and accordingly the diffraction efficiency low, a high X-ray flux is needed to observe a diffraction pattern. In several experiments, laser-driven plasmas have been used as X-ray sources (Bargheer *et al.*, 2006). An energetic laser pulse is focused onto a metal target like, for example, a copper tape. The high peak intensity in the order of 10^{17} W cm^{-2} results in a plasma with very energetic electrons. They penetrate into the metal and generate incoherent Bremsstrahlung and characteristic line emission, for example, K_α radiation. From this X-ray radiation, only the fraction that propagates toward the sample is used as probe beam. An optical pump pulse excites the sample and the X-ray diffraction pattern is recorded with a charge coupled device (CCD) camera in dependence on the delay time between the excitation and the X-ray pulse. Mostly, crystalline samples have been investigated so far since they provide the highest diffraction efficiencies. In this way, it was already possible to observe nonthermal melting, the dynamics of optical phonons, and the propagation of acoustic sound and shock waves. In the future, accelerator-based sources like the free electron laser will provide much higher X-ray fluxes (Pfeifer, Spielmann and Gerbr, 2006). This will make ultrafast X-ray diffraction applicable to a much wider class of samples and problems.

As an alternative to X-rays, electrons can be used as probe in ultrafast diffraction experiments (Zewail, 2006; Siwick *et al.*, 2003). If their kinetic energy is in the order of 30 keV, their de Broglie wavelength matches internuclear distances in the solid phase and results in diffraction patterns containing rich information. Since electrons interact very strongly with matter, their diffraction efficiency is several orders of magnitude higher than that of X-rays and quite low fluxes are needed to obtain a good signal-to-noise ratio. Owing to the Coulomb repulsion between the electrons, space charge effects are usually quite severe and electron pulses spread strongly in space and time when they consist of thousand or more electrons. This makes the experiments challenging and the available time resolution is about few hundred femtoseconds (Baum *et al.*, 2007). The electron pulses are generated by irradiating a photocathode with femtosecond laser pulses. The photoemitted electrons are accelerated by a high voltage to the appropriate kinetic energy. The sample is placed as near as possible to the exit of the acceleration section since short propagation distances minimize space charge effects. A femtosecond pump pulse initiates the dynamics in the sample and a CCD camera records the diffraction pattern behind it. In the case of dense matter the sample has to be extremely thin. Otherwise it cannot be penetrated by the electrons. If this is not possible, a grazing incidence geometry is used and the diffraction pattern is measured in reflection. Meanwhile, a number of pioneering experiments have been carried out and demonstrate that, for example, melting processes (Siwick *et al.*, 2003), phase transitions (Baum *et al.*, 2007), and structural changes during chemical reactions (Zewail, 2006) can be studied in detail.

Glossary

Nonadiabatic Transition: The transition between two adiabatic electronic states triggered by the motion of the nuclei.

Pump-Probe Technique: A pump pulse initiates a process and a probe pulse measures the associated transient changes of observables.

Response Function: The function that describes the material response to the applied external fields.

Wave Packet: The superposition of quantum mechanical states that does not correspond to an eigenstate of the Hamiltonian.

INTRODUCTION

The field of ultrasonic biophysics is very broad, encompassing a large range of frequencies and many different biological systems. The modern use of ultrasound started several decades ago in the form of sonar for military applications. Since then it has developed to the point where it is used very extensively in industry, bioengineering, and medicine. Its original applications in medicine were for therapy, where the energy absorbed from ultrasound waves was used to heat a variety of tissues and structures lying below the body surface. Ultrasound could penetrate and deposit heat within these tissues, whereas insufficient heat could be conducted from surface sources. Improved instrumentation and techniques available after World War II led to the development of ultrasound systems for medical imaging. Over the past 35 years ultrasound has developed into an indispensable clinical diagnostic tool. Currently, ultrasound is used to image most parts of the body, and more than half of all pregnant women in the United States are examined with ultrasound. This widespread utilization has resulted from ultrasound's proven clinical utility for imaging soft tissues compared to more expensive imaging techniques. The development of ultrasound, particularly for fetal examinations, has also been fostered by its safety record; no case of an adverse biological effect induced by diagnostic ultrasound has ever been reported in humans (AIUM, 1993).

Ultrasound has been used for many years to characterize biological materials. This results in large part from a desire to understand better the interaction of ultrasound with biological tissues so that clinical ultrasonic systems might be made more efficacious. However, ultrasound has also found application to the determination of rate constants in chemical reactions and in recent years has been used, via ultrasonic cavitation, to enhance desired chemical reactions that normally occur very slowly or not at all. The latter application has spawned the area of sonochemistry (Suslick, 1988), which has the potential for significantly increasing industrial production of many important chemical products, but which is beyond the scope of this article and will not be discussed further.

Section 1 discusses some of the basic principles underlying the use of ultrasound in medical imaging, therapy, and other applications. This is followed by discussions of the acoustical characteristics of biological media and the techniques for measuring them. The article ends with a brief discussion of recent developments in medical imaging and therapy.

1. BASIC PRINCIPLES

Unlike electromagnetic waves, acoustic waves require a medium for propagation. The acoustic wave phenomenon causes displacement of particles (consisting of many molecules), which results in pressure and density changes within the medium. For a traveling sinusoidal wave the variation in acoustic pressure (the difference between the total and ambient pressure) can be represented by the form

$$p = Pe^{-Ax}\cos(\omega t - kx) \qquad (1)$$

for a wave propagating in the positive x direction, where p is the acoustic pressure, P is its amplitude, $\omega = 2\pi f$ is the angular frequency where f is the frequency in hertz, $k = \omega/c$ is the propagation constant where c is the propagation speed, A is the attenuation coefficient, and t is the time. The same form applies to the excess density, particle displacement, particle velocity, and particle acceleration. The wave can experience significant attenuation, as represented by the exponential decay of amplitude with distance, during propagation in tissues. This attenuation is due in the most part to absorption—conversion of the energy in the wave to heat—and, to a much lesser degree, scattering of energy in different directions. This loss of energy with propagation is important to both diagnostic and therapeutic applications. The attenuation coefficient increases roughly linearly with frequency, but its value varies greatly among tissues (Goss *et al.*, 1978, 1980; Haney and O'Brien, 1986). It is low for most body fluids, much higher for solid tissues, and very high for bone and lung; see Secs. 2.1 and 2.2 for more detail.

The relation given by Eq. (1) is a linear relation, which applies only to low-amplitude waves. In many of the applications discussed here, the amplitude is sufficiently high that significant nonlinear propagation effects may occur. These effects include harmonic generation, where an initially sinusoidal wave will become distorted as it propagates. The distortion can be viewed as the transfer of energy from the initial, or fundamental, frequency of the wave to higher harmonics. Associated with this is an increase in attenuation of energy because the higher frequencies have a higher attenuation coefficient.

Ultrasound is typically used to image soft body tissues such as liver, but the sound beam often travels through fluids—for example, through amniotic fluid when imaging the fetus. Generally, bone and lung are not imaged with ultrasound, largely because of their very large attenuation. The attenuation processes include absorption, which is the conversion of acoustic energy to heat, and scattering, which is addressed later. The attenuation increases roughly linearly with frequency in the 2–10-MHz range typically used for medical imaging. This range represents a compromise between increased penetration at lower frequencies (due to decreased attenuation) and improved resolution associated with higher frequencies as discussed below. Thus, the lower frequencies are used when greater penetration is required such as for fetal imaging in the obese patient and higher frequencies for lesser penetration such as the examination of peripheral vascular flow.

When an acoustic wave impinges on an interface between two media of different specific acoustic impedance, a portion of the incident energy is reflected. For normal incidence on an infinite plane interface, the pressure reflection coefficient is given by (Kinsler *et al.*, 1982)

$$R = (z_2 - z_1)/(z_2 + z_1), \qquad (2)$$

where z_1 and z_2 are the specific acoustic impedances of the incident and transmitting media, respectively. For a plane wave the specific acoustic impedance is equal to the characteristic impedance, which is the product of the density and acoustic speed in the medium. The speed is dependent upon the density and the elastic properties of the medium. Thus at an interface between media exhibiting different densities or elastic properties, e.g., compressibility, some acoustic energy will be reflected. Although the reflection coefficient at an interface between muscle and bone is large (approximately 0.54), the reflection coefficient between two soft tissues such as liver and muscle is quite small (approximately 0.006). Reflection at oblique incidence obeys Snell's law (Kinsler *et al.*, 1982).

In addition to the specular reflection that occurs at an interface between two media of different specific acoustic impedance as described above (where any curvature along the interface is negligible over distances comparable to a wavelength), energy may also be scattered in all directions by inhomogeneities in the medium. An acoustic image is formed by using this scattered energy as well as specular reflections. The fraction of the incident energy reflected or scattered is very small.

Though it is convenient to consider plane waves of infinite lateral extent, as was done above, real sources generate finite beams of ultrasound. These sources may be unfocused, but for many of the applications discussed here, they are focused. Figure 1 shows the acoustic field from a typical focused source. The source consists of a piezoelectric transducer, which converts electrical to acoustic energy and vice versa. Most transducers for bioengineering and medical applications are made from ceramic materials such as a lead zirconate titanate (PZT) mixture; however, composite materials consisting of a combination of ceramic and other materials are sometimes used as sources, and polyvinylidene difluoride material is used for hydrophone transducers for measuring the ultrasound fields of sources. A circular-aperture focused source may consist of a circular disk with a plano-concave lens mounted in front to produce spherical focusing. Alternatively, the transducer itself may be a spherical segment that produces a focused field without a lens. However, increasingly these sources utilize electronic focusing methods. Such a phased-array source consists of many small individual elements, which can be excited with signals having a controlled delay with respect to one another such that the acoustic pressure fields from all elements constructively interfere at the desired focal region. Similarly, in a phased-array receiver, the signals from the different elements are combined after applying delays that result in reinforcement of the signals from a receiving focal region.

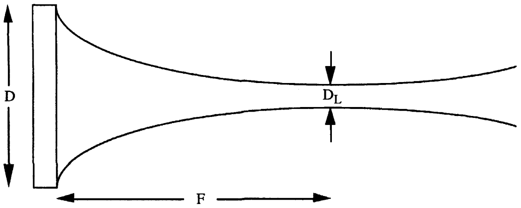

FIG. 1. Cross section of a typical focused circular ultrasound source of aperture diameter D and focal length F showing the focused beam of lateral beam width at the focus D_L.

The 3-dB lateral beam width D_L of the focused source is directly dependent upon the wavelength and focal length and inversely related to the aperture diameter (diameter of the transducer) D (Kino, 1987):

$$D_L = 1.02F\lambda/D. \tag{3}$$

Because $f\lambda = c$, the higher the frequency, the smaller is λ and D_L. For therapy systems, the energy flux per unit area (intensity) is increased when the source is strongly focused, i.e., D_L is small compared to D. For imaging systems, the smaller D_L, the better the lateral resolution near the focus, though the beam spread is greater with distance from the focus. Thus, for imaging, the strength of the focusing varies among transducers so that the user may choose very good resolution over a short region or somewhat poorer resolution that is maintained over a greater depth. With phased-array transducers, the focal region can be varied dynamically to optimize lateral resolution at all distances.

The discussion above is based on linear propagation. However, in medical imaging and therapy the amplitudes are usually so large that nonlinear propagation occurs. Nonlinear propagation is characterized by increasingly greater distortion of the wave toward the formation of a shock wave as it propagates. Thus, a wave that is initially a sinusoid will develop, in a low-loss medium, into a sawtooth wave over a propagation distance that varies inversely with initial amplitude. This distortion can also be represented in the frequency domain by the transfer of energy into higher-frequency harmonics as the wave propagates. Since energy is transferred to higher frequencies, the attenuation increases with the nonlinear propagation. In addition to the dependence on amplitude, the nonlinear distortion is dependent on properties of the medium. Specifically, the relation between acoustic pressure and density for liquids is nonlinear and varies with the medium. A parameter that characterizes the degree of nonlinearity in this relation is B/A, the ratio of the quadratic to linear coefficients in the Taylor series expansion of the relation between pressure and density; B/A is called the *nonlinearity parameter.* The larger B/A, the greater is the rate of wave distortion with propagation.

1.1 Principles of Pulse-Echo Ultrasound

Ultrasound imaging usually employs frequencies in the 2–10-MHz range, though some of the new intracavitary probes use higher frequencies. Images are formed by using a transducer within a probe to generate a short pulse (typically on the order of 1 μs or less in duration) of ultrasound that is propagated through the tissue. A portion of the energy in this pulse is reflected back toward the transducer from specular reflectors and from scatterers in the tissue. These acoustic echoes, with amplitudes much lower than the transmitted pulse, are converted by the transducer to electrical signals that are converted to a (rectified) video signal, amplified by a time-gain-controlled amplifier, and displayed. The time-gain-controlled amplifier increases the gain as a function of time so that later-arriving signals, coming from deeper within the body, are amplified more to compensate for the attenuation. The A-mode display is rarely used but simply involves display of the received echoes as amplitude versus time of arrival. The time of arrival is related by the wave speed to the tissue depth from which the echo returns, i.e., $d = ct/2$. This assumes that the speed does not vary with tissue depth, which is a good first-order approximation for soft tissues. Figure 2 provides a very simple representation of this process where the A-mode display associated with specular reflection from three different interfaces is illustrated. For clinical imaging the interfaces would not necessarily be perpendicular to the axis of the sound beam, and there would be a continuum of echoes, a continuous received signal, due to energy back-scattered from within the tissues. Since the ultrasound pulse is attenuated exponentially as it propagates, all ultrasonic imaging systems employ a logarithmic variation of amplifier gain with time to compensate the attenuation by the tissue. Thus, echoes from structures reflecting or back-scattering the same fraction of the incident signal will have the same amplitude after passing through the time-gain-controlled amplifier.

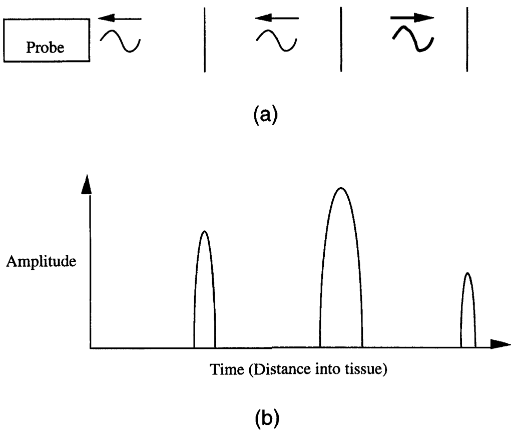

FIG. 2. Illustration of (a) the transmitted pulse (heavy wave) and echoes from reflecting structures and (b) the resulting A-mode display.

A B-mode display is typically used for ultrasound imaging. It involves display of the echoes at various brightness or gray levels corresponding to their amplitude. A two-dimensional B-mode display involves movement of the transducer (manually or automatically), movement of a mirror to change the direction of the field (automatically), or movement of the ultrasound beam directly (electrically) such that it scans a plane through the body. Figure 3 provides a simplified representation (again, echoes are shown as arising from interfaces only) of the formation of a B-mode image. The direction of the beam is monitored so that the received signals along each path are placed in their correct location on the display. Typically, the orientation information and echoes are processed by a digital scan converter for appropriate display of the two-dimensional image on a cathode-ray tube in the standard format used for television picture display. Most B-mode systems in use today create an image in 0.1 s or less, so that the image is displayed in real time for viewing of moving

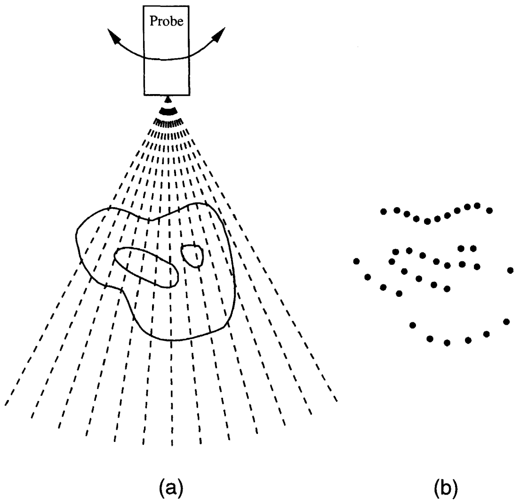

FIG. 3. Illustration of (a) the transmitted pulse paths for a rotating transducer probe and (b) the resulting two-dimensional *B*-mode display of echoes from the interfaces only.

structures, such as structures in the heart or the fetus moving within the womb. This is not possible with the typical magnetic-resonance or computed-tomography system.

Many systems now employ digital processing to enhance portions of the image. For example, it is possible to emphasize the large-amplitude, small-amplitude, or midrange signals. It is also possible to perform a more sophisticated analysis to enhance edges.

Many specialty probes have been designed for intracavitary examination. Examples include examination of the fetus with a vaginal probe, the prostate with a rectal probe, and blood vessel walls with intravascular probes. The intracavitary probe offers the advantage of decreasing the distance from the transducer to the tissue of interest and thus decreasing attenuation such that higher frequencies can be used for greater resolution. The lateral resolution of a focused probe is improved with frequency as discussed in the preceding section, but the axial (along the ultrasound beam) resolution also improves with frequency. The shorter the transmitted pulse, the better the axial resolution. Generation of shorter pulses requires sources with a larger bandwidth, which corresponds to a higher center frequency when the sources have bandwidths that are approximately the same fraction of the center frequency.

The use of ultrasound for motion detection and measurement has increased tremendously in recent years. These systems use either the Doppler principle or time-domain detection. In Doppler detection, if the ultrasound is reflected from a target moving at some speed v_t toward (away from) the source at an angle θ with respect to the beam axis, the frequency of the transmitted signal f is shifted up (down) by an amount f_D, the Doppler shift, given by

$$f_D = 2fv_t \cos\theta / c. \qquad (4)$$

In principle a measurement of f_D when f, c, and θ are known will yield the speed of the target v_t. However, it is often difficult to determine θ because the angle the transducer axis makes with a blood vessel, for example, is often unknown. Even when that angle is known, the flow is not necessarily along the direction of the vessel at every location and for all times. Time-domain detection of motion, by measuring the movement of specific echoes from one pulse to another, is an alternative to Doppler detection that is used in many ultrasound systems.

For many years duplex systems, which provide both a two-dimensional image and a Doppler signal, showing the change of target speed with time, from a particular selected target area, have been in wide use. More recently color-flow imaging has been employed, which provides a two-dimensional color (typically red or blue) image of flow toward and away from the transducer superimposed on the gray-scale image of stationary tissue structures. For these systems the speed, whether from Doppler or time-domain detection schemes, is indicated by color saturation, hue, or luminance. These systems have proven very valuable for detecting the existence of flow in a region, detecting obstructions to flow and the turbulence associated with this, detecting reduced flow, etc. Some other systems add to the color-flow image a display of speed versus time for a region that is defined by a user-movable box.

1.2 Therapeutic and Other Applications

Though therapeutic applications include the use of vibrating wires to remove plaque and augmentation of liposuction, this article is concerned with the use of ultrasound for therapeutic heating, hyperthermia, and surgery. These therapeutic applications rely almost exclusively on heating of tissues due to the absorption of the ultrasound. Therapeutic heating involves low temperature elevation in tissues and joints for a period of many minutes for physiotherapy. Typical time-averaged intensities are below approximately 3 W/cm^2. Hyperthermia produces low to moderate temperatures (in the range 43–50 °C) for approximately an hour to treat cancerous tumors, using time-averaged intensities below approximately 10 W/cm^2. In contrast, surgical treatment (sometimes called ablative hyperthermia) uses high-temperature treatment for only a few seconds to destroy tissue immediately. Time-averaged intensities below approximately 1000 W/cm^2 are used to treat the prostate, heart arrhythmia, and tumors in many regions of the body.

The beneficial effects of therapeutic heat have often been cited as increased extensibility of collagen tissues, decreased joint stiffness, pain relief, relief of muscle spasms, assistance in removing inflammatory infiltrates, edema, and exudates, and increased blood flow (Lehmann, 1990).

The rationale for hyperthermic treatment of tumor tissues is based on a belief that tumor tissues (at least some) are more susceptible than normal tissues to damage from elevated temperatures. This has been demonstrated for cells *in vitro* and clinically in patients for many tumor types. Hyperthermic treatment may involve heating the body (whole body hyperthermia), a region of the body that includes the tumor (regional hyperthermia), or the tumor alone (localized hyperthermia). Obviously, localized hyperthermia will have the least impact on normal tissues within the body. Hyperthermia is usually used in conjunction with radiation or chemotherapy. The combined modalities can be much more effective than either alone. For example, radiation has a much reduced effect on hypoxic cells, which are most affected by hyperthermia.

Several other modalities have been used for localized hyperthermia including externally applied microwaves, interstitial microwave antennas, and high-frequency currents. However, microwave frequencies useful for heating with external antennas have a longer wavelength than ultrasound and cannot be as well localized for treating the tumor and avoiding surrounding normal tissues. The use of interstitial microwave antennas involves implantation of many small antennas within the tumor to give a reasonably uniform temperature rise localized to the tumor. The use of high-frequency currents also requires invasive implantation of needle electrodes in arrays that would provide useful heating. On the other hand, bone and air spaces must be avoided with ultrasound, on account of very high attenuation and scattering, respectively. Additionally, "noninvasive" microwave or ultrasound treatment involves the use of invasive thermometry systems to monitor and control the temperature rise in the tumor and surrounding normal tissues.

Therapeutic heating and hyperthermic treatment of surface tumors can be accomplished using unfocused systems. However, since the absorbed power, $P_D = 2\alpha I$ where α is the absorption coefficient, is proportional to intensity I, the treatment depth is dependent upon the frequency because the attenuation coefficient increases with frequency and reduces the intensity much faster with depth. Thus, lower frequencies (on the order of 1 MHz or lower) are used for tumors extending deeper within the body and higher frequencies (on the order of 2–4 MHz) for shallow tumors or tumors with bone located closely behind.

Unfocused systems, which mimic plane-wave exposure, will have the greatest intensity and therefore heating at the body surface. Thus, for the treatment of deep tumors the ultrasound system must provide intensity gain to more than compensate for the attenuation along the path to the tumor so that the time-averaged intensities in the tumor are greater than those in the normal tissues between the body surface and the tumor. Simply stated, this means that the ultrasound entrance window (area) at the body surface must be substantially larger than the cross-sectional area of the tumor. Focusing systems are usually chosen to provide the required gain, but it must be remembered that the focus is scanned over the tumor and that gain in the time-averaged intensities is critical, not simply the static intensity gain of the focusing system.

Another reason that scanned focusing systems are generally used for hyperthermic treatment of deep tumors is so that the spatial power-deposition pattern within the tumor can be controlled to provide a uniform temperature throughout the tumor. Greater deposition at the tumor boundaries will lead to a more uniform temperature because of heat conduction into the tumor interior from the boundaries.

Surgical applications of ultrasound require systems with large intensity gain so that the tissue to be treated can be heated within seconds to a temperature that will destroy the tissue. Then the focal region can be relocated to treat another small volume until the tumor region is entirely destroyed.

Increasingly, systems for hyperthermic treatment of deep tumors and high-intensity focused surgical systems are changing from fixed-focus applicators that are mechanically scanned to electronic, phased-array, focusing systems. These allow rapid scanning without bulky and complex mechanical scanning systems. Additionally, the focal regions of these systems can be modified electronically. For example, the focal region can be made larger so that larger volumes can be affected with each placement of the focus.

In addition to these therapeutic applications of ultrasound, the attenuation and, to a lesser extent, the speed have been used for tissue characterization. This term generally refers to the quantitative measurement of tissue parameters as a means for diagnosis or treatment monitoring. It has been shown, for example, that the measurement of parameters associated with tissue attenuation, such as its magnitude and variation with frequency, can be quite useful to the differentiation between normal and diseased tissues. These applications have proven particularly fruitful in the eye and prostate (Feleppa *et al.*, 1996).

The main thrust of this discussion has been directed toward the medical applications of ultrasound. However, ultrasound biophysics also plays a role in determination of rate constants of chemical reactions through the measure of ultrasonic absorption and speed versus frequency, using horns to generate high intensities for breaking up of biological cells for study of their contents, and to generate cavitation for catalyzing reactions. The biophysical applications of ultrasound are many, and they cannot all be discussed in this article, but it is important to note that most of these applications rely in some way on the direct measurement of, or the knowledge of, the ultrasonic properties of the biological materials. Thus, the next sections of this article directly address the properties of biological materials and techniques for their measurement.

2. ACOUSTICAL CHARACTERISTICS OF BIOLOGICAL MEDIA

The acoustical characteristics of biological media to be discussed here include the loss parameters of attenuation and absorption, the speed of propagation, and the value of the nonlinearity parameter. Though attenuation and absorption are often used interchangeably, they are distinctly different. Absorption refers to the direct conversion of energy to heat as the acoustic wave propagates through the medium. Attenuation, on the other hand, includes absorption and all other processes by which energy is removed or redirected from the ultrasound beam, such as scattering and refraction.

Liquids and biological tissues exhibit a nonlinear relation between the acoustic pressure and the density that is important to the nonlinear propagation associated with high-amplitude waves in the medium. This nonlinear relation can be expressed as a Taylor series expansion with linear, quadratic, and higher-order terms. It has been found that the ratio of the coefficient of the quadratic term to that of the linear term, expressed as the nonlinearity parameter B/A, is very useful to describe nonlinear propagation in the medium.

2.1 Solutions and Suspensions

Solutions and suspensions of biological materials such as amino acids and proteins have been studied extensively in an effort to determine underlying mechanisms of absorption of ultrasound that might be applicable to whole tissues. They offer a simpler biological system for study and, since they are in liquid form, are amenable to measurement by more techniques. For these reasons and others many biological liquids have been measured.

The values for the attenuation and absorption coefficients are the same for solutions and nearly the same for most suspensions. Slight differences might be expected for suspensions of cells or other materials that exhibit an inhomogeneous distribution of density or compressibility that may cause scattering.

In general, all the propagation parameters (attenuation and absorption coefficients, speed, and nonlinearity parameter) increase with the concentration of the molecular species. Thus, it is not sufficient to specify a value for one of these parameters in biological liquids without specifying concentration. Specific values are listed for water, amniotic fluid, and blood in Table 1.

2.2 Tissues

Values for the attenuation coefficient, absorption coefficient, speed, and nonlinearity parameter are listed for water and selected tissues in Table 1. From Table 1 it is clear that bone and lung are very different from most soft tissues within the body. They both exhibit large loss and much higher and lower speeds, respectively. The nonlinearity parameter is generally larger in tissues than water and shows a tendency to increase with structure (Law *et al.*, 1985). On the other hand, the highest value measured for tissues to date is in fat, which also has the lowest speed.

3. MEASUREMENT TECHNIQUES

3.1 Loss Parameters

3.1.1 Attenuation Attenuation measurements may be subdivided into measurements on homogeneous and inhomogeneous media. In homogeneous materials, e.g., liquid solutions, the attenuation is equivalent to the absorption. For inhomogeneous media the attenuation includes absorption, scattering, refraction, etc., any process by which energy is removed from the wave field. While a number of attenuation-measuring techniques also yield absorption for homogeneous materials, there exist perhaps only one or two techniques that measure the absorption coefficient for inhomogeneous materials. The transient thermoelectric technique yields a measure of the absorption coefficient in tissues.

3.1.1.1 Insertion Techniques. This technique may be used with pulsed ultrasound and with phase-sensitive (first-order) or phase-insensitive (second-order) receivers. Continuous-wave (cw) signals may be used when reflection at the interfaces is negligible and when the receiver absorbs or diverts the sound beam so that a standing-wave field is not established (as with a radiation force target). The insertion technique involves the comparison of measurements of the received signal (pulsed or continuous source) with a sample of known thickness between source and receiver and with only the immersion medium between source and receiver; see Fig. 4. If the immersion fluid is of very low attenuation compared to the sample, then its attenuation can be neglected. Let A_0 or B_0 represent the amplitude of the received signal, first- or second-order quantity, respectively, with the sample removed, and let A_s or B_s represent the received signal, first- or second-order quantity, respectively, when a sample of thickness d is placed between the source and receiver. If the reflection at the interfaces is negligible or zero, the attenuation coefficient for the sample material is given by $(20/d)\log(A_0/A_s)$ or $(10/d)\log(B_0/B_s)$ dB/m and by $\ln(A_0/A_s)/d$ or $0.5\ln(B_0/B_s)/d$ Np/m, when d is in meters.

Table 1. Approximate ultrasonic propagation parameters for water and selected tissues at 3.5 MHz. Nonlinearity parameters from Law *et al.* (1985) and other data from Goss *et al.* (1978, 1980).

Tissue	Attenuation coefficient (m^{-1})	Speed (m/s)	Characteristic impedance (10^6 Pa·s/m)	Nonlinearity parameter
Water	0.2	1500	1.50	5.2
Amniotic fluid	0.3	1510	1.51	
Blood	7	1550	1.60	6.5
Fat	25	1470		11
Liver	35	1580	1.74	7.0–7.7
Muscle	50	1560	1.72	
Bone	800	3360	5.70	
Lung	1000	340	0.25	

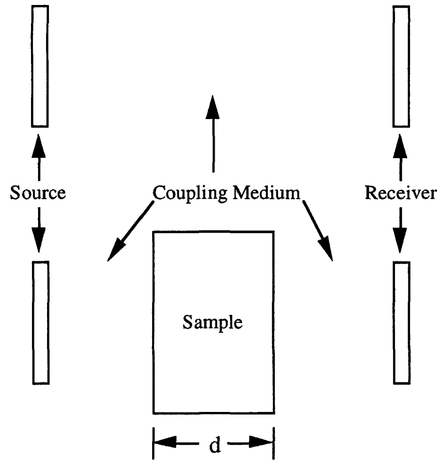

FIG. 4. Schematic representation of the insertion technique. In the upper part of the figure the source and receiver have only a coupling medium between them, whereas in the lower part of the figure a portion of the coupling medium is replaced with a sample of thickness *d*.

The effect of reflection at the interfaces can often be minimized by impedance matching. However, when solids are immersed in liquids the reflections can be very significant. To measure the attenuation coefficient within the sample for such cases, plot the measured attenuation (as opposed to the attenuation coefficient) versus the sample thickness d, as in Fig. 5. The slope gives the attenuation coefficient characteristic of the material, and the intercept ($d = 0$) gives the attenuation due to the interfaces.

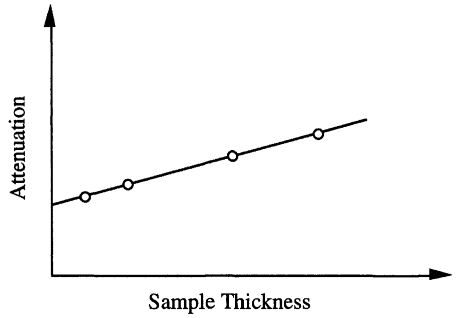

FIG. 5. Straight-line fit to attenuation versus sample thickness. The intercept is loss due to surface reflection, and the slope is the attenuation coefficient of the sample.

The insertion technique has also been used with broad-band transducers and short pulses. Such a system allows spectral analysis of the received signals, with and without the sample present, to determine the attenuation coefficient over a continuous range of frequencies limited by the bandwidth. A spectral-analysis approach has also been used for determination of the attenuation coefficient in fairly homogeneous tissues *in vivo* by measuring the decrease in signal with depth into the tissue (Kuc, 1980). This has been applied most successfully to tissues that can be examined rather directly without having to correct for effects of overlying tissues, such as tissues in the eye and the prostate (Lizzi *et al.*, 1983, 1986).

3.1.1.2 Variable-Path Pulse Techniques. Two measurement methods are described in this section. The first is a method applicable to solids and involves a sample preparation similar to that shown in Fig. 6. Transmitting and receiving transducers are mounted on opposite ends of the solid sample of length d, or a transceiving transducer is placed on one end and the other end left with an air interface to act as a reflector. When the received echos are plotted as a function of distance traveled x (determined from the speed and the length d of the rod), they look like the bold pulses (rectified and filtered rf pulses or video signals) of Fig. 7. The separation between echoes is $2d$. The attenuation coefficient A, neglecting loss at the transducer end, is determined by fitting an exponential curve of the form Be^{-Ax} to the signal levels shown in Fig. 7, where B is the amplitude at $x = 0$.

The same sort of analysis can be performed on a liquid system that has a reflector mounted at a distance d from the transducer. However, it is considerably more difficult to get good parallelism between the transducer and reflector. Therefore, in liquid systems a more common approach [based on

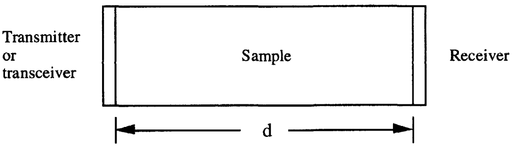

FIG. 6. Schematic diagram of solid sample of length *d* with one (transceiver) or two (transmitter and receiver) transducers mounted on the ends.

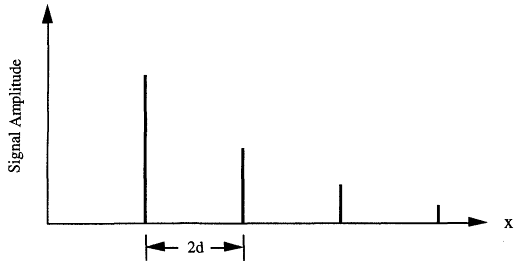

FIG. 7. Signal amplitude versus distance traveled. An exponential fit of the form Be^{-Ax} will yield the attenuation coefficient A, neglecting signal loss at the interfaces and beam diffraction effects.

a technique developed by Pellam and Galt (1946)] is to vary the distance between a source and receiver, smoothly or in discrete steps. These systems may be good over the frequency range from 3 to 100 MHz and higher; however, at the lower frequencies corrections must be made for diffraction effects in the beam.

3.1.1.3 Substitution Method. The effects of diffraction, at low frequencies, are eliminated by using the substitution technique; see Fig. 8. The fixed transducer separation minimizes the effects of diffraction. If the path in the reference medium is z and that in the test liquid is $d - z$, then the received signal A_z is

$$A_z = A_0 \exp(-\alpha_r z) \exp[-\alpha_t(d - z)], \qquad (5)$$

where α_r and α_t are the attenuation coefficients in the reference and test liquids, respectively, and A_0 is the signal with no attenuation. When the assembly is moved to a new position such that the path in the reference liquid is $z + \Delta z$, then the received signal $A_{z+\Delta z}$ is

$$A_{z+\Delta z} = A_0 \exp[-\alpha_r(z + \Delta z)] \times \exp[-\alpha_t(d - z - \Delta z)]. \qquad (6)$$

Taking the ratio of the two signals, we get

$$A_{z+\Delta z}/A_z = \exp[-(\alpha_r - \alpha_t)\Delta z]. \qquad (7)$$

Thus, the slope of the plot of the natural logarithm of the signal ratio versus Δz will give $\alpha_r - \alpha_t$. If α_r is either negligible or known, this gives α_t.

3.1.1.4 Resonant-Cavity System. The resonant-cavity system consists of two transducers separated by a fixed distance that, together with their housing, form a cylindrical cavity in which the test liquid is placed. One transducer serves as a transmitter, while the other is the receiver. When the transmitting transducer is excited with a sinusoidal voltage, standing waves result in the sample and resonances occur at particular frequencies (Eggers, 1968). At the resonance frequencies f_n, the receiving transducer registers pronounced voltage peaks, whose frequency separation depends on the sound speed in the sample, and the half-power (3 dB) bandwidth Δf of which is related to the attenuation per wavelength, $\alpha\lambda$. In fact, the attenuation coefficient of the sample may be calculated from the quality factor Q of the liquid-filled cavity, defined as the resonance frequency f_n divided by the 3 dB bandwidth Δf_n of the resonance. This quality factor is a function of the attenuation per wavelength $\alpha\lambda$ of the ultrasonic energy, and is expressed as

$$Q = (f_n/\Delta f_n) = \pi/\alpha\lambda. \qquad (8)$$

The measured Q, however, includes the effect of mechanical clamping of the transducers and losses associated with diffraction, wall effects, imperfect reflections at the transducer surface, etc., besides the desired attenuation due to the liquid. Assuming all of these energy losses are additive (Eggers and Funck, 1973), the measured quality factor Q is given by

$$1/Q_{\text{meas}} = 1/Q_{\text{liquid}} + 1/Q_{\text{extra}}, \qquad (9)$$

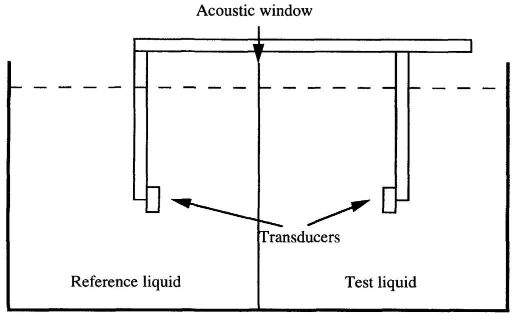

FIG. 8. Schematic diagram of the substitution apparatus.

where Q_{liquid} is the quality factor due to sound absorption in the liquid and Q_{extra} includes all the other cell losses. The absorption can be obtained by means of a reference measurement in the same cell at the same frequencies with a suitable reference liquid, having equal or very similar sound velocity to insure the same sound-field pattern for both measurements. The excess absorption per wavelength in the sample liquid is then obtained from

$$(\alpha\lambda)_{\text{excess}} = \pi(\Delta f_s - \Delta f_r)/f_n, \tag{10}$$

where Δf_s and Δf_r are the corresponding 3-dB bandwidths of the nth resonant peak in the sample and reference liquid, respectively.

In general, the transducer separation distance, the character of the ultrasonic field, the cavity shape, and the mechanical and electrical loading of the transducer, in addition to the acoustical properties of the sample liquid, all play significant roles in determining the performance of an ultrasonic resonator. Residual resonator losses such as those due to diffraction, transducer, and wall losses must be minimized so that the quality factor Q is predominantly determined by the sample-liquid absorption. Improvements of Q values for liquid-filled resonators by application of a slight static internal pressure to the cavity have been reported (Eggers and Funck, 1975). The reasons for this improvement seem to be related to the focusing of the sound beam due to the pressure-effected concavity of the transducers, reducing diffraction and side-wall effects, and to the elimination of effects of gaseous inclusions within the cavity.

With the internal pressure these systems have been used to frequencies as low as 0.2 MHz and without the pressure up to 30 MHz and more. These systems present the advantage of requiring only a small volume of sample.

3.1.2 Absorption As stated previously, for homogeneous media with no scatterers present, the absorption and attenuation coefficients are the same, and methods used to measure attenuation can be used to measure absorption. If this is not the case, as with most tissues, the transient thermoelectric technique has been used to measure the absorption coefficient.

The transient thermoelectric technique was developed in 1954 (Fry and Fry, 1954a,b) for measurement of the absorption coefficient in liquids and tissues. This method involves first imbedding a small thermocouple in a tissue sample, then irradiating the combination with an ultrasonic pulse of known intensity. The absorption coefficient α of the imbedding medium is then given as

$$\alpha = \frac{\rho CK}{2I_S}\left(\frac{dT}{dt}\right)_0, \tag{11}$$

where $(dT/dt)_0$ is the initial time rate of change of temperature (°C/s), I_S is the sound intensity at the site of the thermocouple junction (W/cm^2), and ρCK is the product of the surrounding medium's density (g/cm^3) and heat capacity at constant pressure (Cal/g-°C) and the mechanical equivalent of heat ($K = 4.186$ J/Cal) in units of J/cm$^3\cdot$°C. However, the temperature measured by use of the thermocouple junction is a true measure of the ultrasonic absorption of the surrounding medium only if the ultrasonic beam width is broad enough to minimize the effects of heat conducted away from the junction by the medium, and the size of the thermocouple is reduced to a point where the heat generated by the motion of the viscous medium relative to the thermocouple wire when subjected to ultrasound may be neglected.

The particle motion associated with the sound field causes a relative motion between the wire and the surrounding medium. Because the thermocouples are of small diameter (from a fraction of, to several, thousandths of an inch in diameter), the temperature that results from this relative motion in a viscous medium tends toward an equilibrium value in a short time (fraction of a second). However, the effect is present in a typical measurement of $(dT/dt)_0$; see Fig. 9. The heating from this source is dependent (Fry and Fry, 1954a,b) upon

1. viscosity of the medium,
2. wire size,
3. frequency,
4. the square of the particle velocity, and
5. other physical parameters.

For low-viscosity liquids and tissues, the ef-

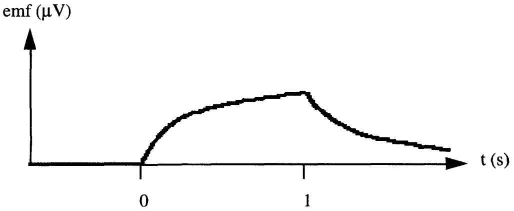

FIG. 9. Typical emf (proportional to temperature) from a thermocouple in an absorbing fluid when exposed to a 1-s ultrasound pulse.

fect of this heat source on the measurement of absorption, when $(dT/dt)_0$ is measured 0.5 s after the sound is initiated, is minimized when the wire diameter is 0.0005 in. (13 μm) or less. For additional information on this effect consult Goss *et al.* (1977).

Since real acoustic beams are not of infinite beam width, heat will diffuse from the position of peak intensity, where the thermocouple junction is located, to the surrounding lower-intensity (cooler) regions, affecting the temperature rise. The effect of this phenomenon on the measured absorption is included by adding a term to Eq. (11) to give

$$\alpha = (\rho CK/2I_S)(dT/dt)_0 + (\kappa/2I_S)\Delta^2 T, \tag{12}$$

where κ is the thermal conductivity (W/cm-°C). If the rate of heat diffusion, given by $\kappa\Delta^2 T$, is significant, then the α computed from Eq. (11) will be erroneously low. It has been shown (Goss *et al.*, 1977) that the half-power ultrasonic beam width should be at least 3–4 mm to minimize the errors from using Eq. (11) when determining α for most biological tissues.

The intensity at the site of the thermocouple junction I_S should be measured or calculated from the measured intensity with no sample present I_0 from the relation

$$I_S = I_0 e^{-2Ax}, \tag{13}$$

where A is the pressure attenuation coefficient and x is the path length in the attenuating material, i.e., the thermocouple depth. If the attenuation consists primarily of absorption, then an iterative procedure can be used to calculate α by starting with I_0 instead of I_S. The procedure involves a calculation of α from Eq. (11) with $I_S = I_0$, and the calculation of I_S from Eq. (13) with A equal to this initially calculated α. Then a new calculation of α is performed based on the computed I_S. A new I_S can then be calculated from the new α. This procedure is repeated until the value for α converges (it will converge provided that the product αx is not too large).

3.2 Speed

There exist a variety of speed-measuring techniques that are applicable to liquids and/or solids over specific frequency ranges. The techniques can be separated into pulsed and cw systems. Included in pulse techniques are the time-of-flight, sing-around, variable-path substitution, and pulse superposition methods. The cw systems employ interferometric techniques that involve either a fixed path length and a variable frequency or a fixed frequency and a variable path length. The pulse techniques are applicable to the measurement of both phase and group speeds. Broad-band pulses (short pulses) will yield group speed whereas narrow-band pulses (long pulses containing approximately 10 or 20 cycles or more) will yield the phase speed for the frequency of the rf signal constituting the pulse. Of course, the cw techniques provide phase speed. First the techniques utilizing pulses are discussed.

3.2.1 Time of Flight The straightforward measurement of the time for a pulse to travel through a known length of a specimen is perhaps the simplest means of measuring ultrasonic speed. Figure 6 illustrates the arrangement of source and receiver, or transceiver and reflector, at opposite ends of a solid specimen or a fixed path of liquid as discussed previously. The time of flight or transit time T from source to receiver or the round-trip time $2T$ may be measured by several approaches. The speed c is then given by

$$c = d/T, \tag{14}$$

where d is the length of the path.

One obvious but low-accuracy approach to determining the transit time is a simple measurement of the delay between transmitted and received pulses by measuring their separation on the time scale of an oscilloscope. Oscilloscopes are now generally available with special features that facilitate easy measurement of this time interval via digital readout after adjusting the delayed sweep to superimpose the two echoes. The accuracy of these scopes may be 1% or less, adequate for many simple measurements but rather low compared to some of the very accurate measurement techniques available.

Another means of measuring transit time is to count the number of cycles of a high-frequency timing signal that occur between triggering of the counter by the transmitted pulse and the ending of the count period by the received pulse. The errors in measurement of T for this case will depend upon the frequency of the timing signal and the timing errors of the start and stop control signals. The error arising from the count will be plus or minus one period ΔT of the wave to be counted. Thus for a timing signal of 200 MHz, ΔT will be 5 ns, resulting in a 0.3% error in the velocity of a solid of thickness 1 cm for which the true velocity is 6000 m/s.

Still another method of measuring transit time, the pulse-echo-overlap system, is discussed by Papadakis (1976). In this technique a transceiver system and several echoes from the end of the rod or the reflector are utilized. The echo signals are applied to the vertical axis of an oscilloscope, and a cw signal of variable frequency is applied to the horizontal axis. The principle of measurement is to adjust the frequency of the horizontal-axis signal so that successive echoes overlap. The transit time is then simply the period of this signal, which can be determined by an accurate measurement of frequency.

3.2.2 Sing-Around Method A block diagram of a sing-around system for velocity measurement is illustrated in Fig. 10. The principle of operation in this system is that the received pulse triggers another pulse so that a repetitive trigger signal occurs at a rate equal to the reciprocal of the propagation time. The frequency and thus the period between trigger pulses can be very accurately measured and the system is easily automated. However, any timing delays associated with the electronics will show up as errors in the determination of transit time. These electrical delays may be minimized by appropriate signal processing. This system is easily good to 1% (this is dependent upon path length) for absolute measurements but is several orders of magnitude more accurate when used as a comparison technique.

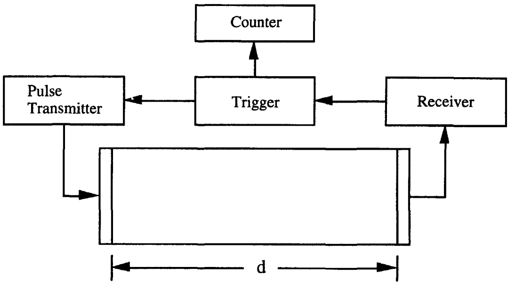

FIG. 10. Block diagram of the sing-around system for velocity measurement.

3.2.3 Variable-Path Method Another pulse method involves two transducers (a source and a receiver) whose separation is changed, e.g., increased at a constant rate by a motor and drive screw. Since the separation between transducers is continuously varied, these systems are restricted to measurements in liquids. Speed measurements are accomplished by algebraically adding a continuous-wave reference signal to the output of the receiver. The addition produces an interference pattern that exhibits a peak or minimum (a null if both signals are of equal amplitude) when the two signals are in or out of phase, respectively. The maxima occur every half wavelength, so that the velocity is easily determined after measuring the distance between maxima. These systems are used for measurements at higher frequencies where diffraction effects are smaller, e.g., over the frequency range from a few megahertz to 100 MHz.

3.2.4 Substitution Method The substitution or velocity-difference method is similar to the moving-transducer method in that the pulses are transmitted from a source to a receiver and the received signal is electronically mixed with a continuous-wave reference. However, in this method the two transducers are maintained at a fixed distance from each other, the changing phase of the received signal arising from substitution of the test liquid for a reference liquid over a portion of the signal path (Carstensen, 1954); see Fig. 8. One transducer is placed in the test liquid and the other in the reference liquid, which is separated from the test liquid by an acoustically transparent window. The substitution of one liquid for another is effected by moving the two-transducer assembly via micrometer or motor control.

The fixed transducer separation provides to this technique a way of virtually eliminating the effects of diffraction on the measurements of speed and attenuation. Thus it finds application in the low-frequency range, 0.3–15 MHz, where the errors incurred with the moving-transducer technique are unacceptably large. The accuracy of this method is good to 1 part in 10^4, provided adequate temperature control (± 0.1 °C) is maintained and the speed in the reference medium is known to that accuracy. This technique has proven useful to the investigation of dispersion in biological liquids (may be less than 0.1%). Typically, water, which is dispersionless in this frequency range, is used as the reference liquid.

To examine the technique in more detail, consider z to be the initial path length in the reference medium (taken as water in this example) and d to be the transducer separation. The number of acoustic wavelengths separating the transducers n is given by

$$n = z/\lambda_R + (d - z)/\lambda_X, \tag{15}$$

where λ_R is the wavelength in the reference medium and λ_X is the wavelength in the test liquid. If the transducer assembly is moved a distance Δz to go from one minimum in the received signal to another, the new relation for the number of wavelengths becomes, for $\lambda_X > \lambda_R$,

$$n + 1 = (z + \Delta z)/\lambda_R + (d - z - \Delta z)/\lambda_X. \tag{16}$$

This may be rearranged to give

$$c_X - c_R = c_R^2[1/(f\Delta z - c_R)], \tag{17}$$

where f is the frequency and c_R and c_X are the speeds in the reference and test liquid, respectively.

3.2.5 Continuous-Wave Techniques Continuous-wave techniques measure the variation in transducer parameters such as input impedance, voltage, or current in a standing-wave field as the transducer position or frequency is changed. Let us examine the specific acoustic impedance at the surface of a transducer located a distance L from a reflector; see Fig. 11. The acoustic pressure p_I of the wave incident on the reflector, the pressure p_R of the reflected wave, and their respective particle velocities u_I and u_R are given as follows:

$$\begin{aligned} p_I &= P_I e^{j(\omega t - kx)}, \\ p_R &= rP_I e^{j(\omega t + kx)}, \\ u_I &= (P_I/Z)e^{j(\omega t - kx)}, \\ u_R &= -(rP_I/Z)e^{j(\omega t + kx)}, \end{aligned} \tag{18}$$

where r is the complex reflection coefficient, Z is the characteristic impedance of the material, and the reflector is located at $x = 0$.

The specific acoustic impedance at a transducer located at position L will vary from infinity at a perfectly reflecting surface through zero at one-quarter wavelength from the reflector, back to infinity at one-half wavelength from the reflector, etc. Maxima in the impedance are spaced one-half wavelength apart, as are minima. Thus, the spacing for impedance maxima, or minima, can be measured to yield the speed.

3.2.6 Pulse-Superposition Method In some respects the pulse-superposition method is similar to the pulse-echo overlap technique. By superimposing the input signals over the echoes from the end of a rod of the material, the period T_0 between successive rf pulses can be measured and is given by

$$T_0 = hD - hv/2pf + n/f, \tag{19}$$

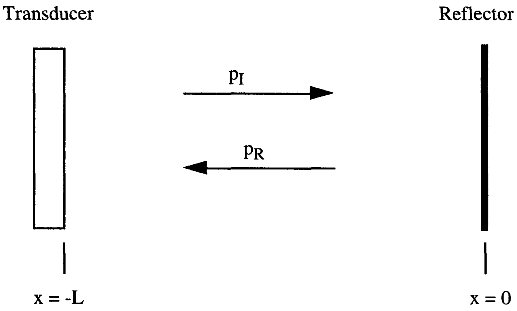

FIG. 11. A transducer and a reflector producing a standing-wave field.

where D is the round-trip delay time in the material (the parameter of interest), h is the number of round-trips through the material, v is the phase angle associated with reflection at the transducer end, n is the number of wavelengths by which pulses are shifted with respect to one another, and f is the frequency of the ultrasound pulse. The value of h is known as a part of the measurement technique, and values for v and n can be determined as described by McSkimin (1964). Thus D and the speed in a rod of known length can be determined. Consult McSkimin (1964) for more details of the technique.

A pulse-superposition technique can also be used to determine the specific acoustic impedance of shear waves in liquids. The complex reflection coefficient is determined for shear waves at the interface between a solid buffer rod of known impedance and the liquid. This is done by measuring the change in the period between successive pulses in the buffer rod (and amplitude of the pulses) when the rod termination is changed from air (perfect reflection) to the liquid to be measured.

The schematic of one system that can be used to accomplish the measurement is illustrated in Fig. 12. The repetition rate of a rf pulse generator is accurately controlled and measured. The pulse-train signal is split and each signal passed through a gate. The signal passed by gate B is attenuated before the two signals are recombined and applied to a shear transducer bonded to the buffer rod. The multiple echoes are received and displayed.

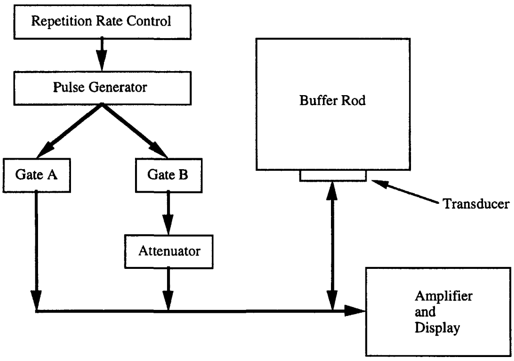

FIG. 12. Block diagram of a simple pulse-superposition system.

Figure 13 demonstrates the application of the technique. With an air interface at the end of the rod, the two gates [Fig. 13(b)] can be adjusted to let two rf pulses from the pulse train [Fig. 13(a), sinusoidal rf signal in pulses not shown], separated in time so that their echos do not overlap [Fig. 13(c)], pass to the transducer. The first echo of the B pulse is attenuated to equal the magnitude of a chosen echo of the A pulse. In Fig. 13(c) the video signals are illustrated wherein the third echo of the A pulse has been matched in amplitude by the first echo of the B pulse, $h = 2$ for this case. Then the B gate is adjusted to let an earlier pulse through so that

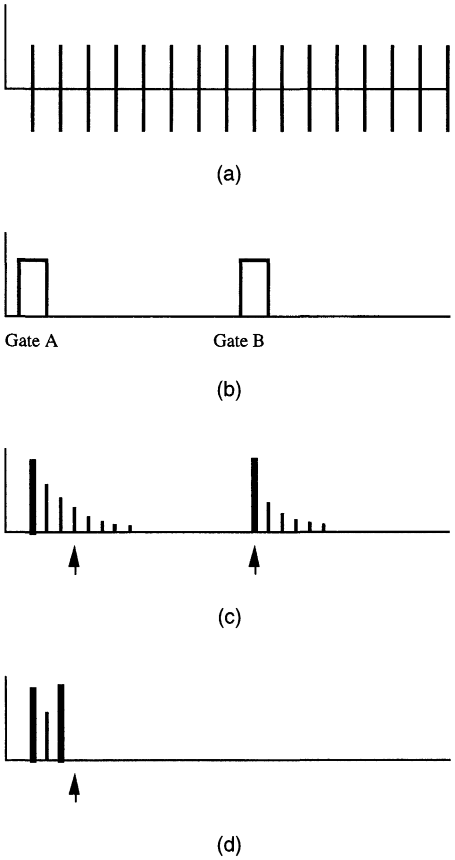

FIG. 13. Illustration of signals when using the superposition technique. (a) Selected rf signals are passed by (b) gates A and B. (c) In this example, the first echo from the gate-B series is matched in amplitude to the third echo from the gate-A series. (d) Gate B is moved and the pulse repetition frequency is adjusted to cancel echo 3 and higher from the gate-A series.

the two echoes mentioned are superimposed. The pulse repetition rate is finely adjusted to cancel the third and succeeding echos of the A pulse, Fig. 13(d). At this point the period T_0 between pulses A_3 and B_1 is given by Eq. (19) where $h = 2$. Then the liquid sample is placed on the end of the buffer rod and the same procedure followed to yield a new period:

$$T = hD - h(v - \epsilon)/2\pi f + n/f, \qquad (20)$$

where ϵ is the phase angle associated with reflection from the interface with the liquid. If T_0 and T are expressed in terms of the repetition rate frequencies $f_R = 1/T$ and $f_{R0} = 1/T_0$ and Eqs. (19) and (20) are combined, the following expression for ϵ is obtained:

$$\epsilon = 2\pi f(f_{R0} - f_R)/hf_Rf_{R0}. \qquad (21)$$

The magnitude of the reflection coefficient is determined by measuring the change in magnitude of A_4 (the change in attenuation, ΔM) that occurs upon application of the sample to the buffer rod. This is related to the magnitude of the reflection coefficient as

$$\Delta M = hB = -20h \log P, \qquad (22)$$

where ΔM is the change in the magnitude of the echo of interest in decibels, B is the change in the magnitude in decibels per impingement (echo), and P is the magnitude of the reflection coefficient (assuming total reflection from the buffer rod–air interface). This technique has proven useful in the 2–40-MHz frequency range for a number of liquids of interest (Dyro, 1972) and in tissues (Frizzell *et al.*, 1976).

3.3 Nonlinearity Parameter

The following is a brief summary of some of the techniques that have been used to measure the nonlinearity parameter B/A for biological materials. The thermodynamic method requires the accurate measure of the change in speed that occurs, either under adiabatic conditions or separately as a function of temperature and pressure; see Figs. 14 and 15. In the former approach, the speed is measured before and immediately after a rapid change in pressure, before significant heat flow can occur (change in speed measured at approximately 1 s in Fig. 15). The change in speed is determined from a measure of the change in phase of the received signal as illustrated in Fig. 14. Measurements of this type have been recently reported by Sehgal and Greenleaf (1984). From a knowledge of the change in speed with change in pressure at constant entropy, ρ_0, and c_0, B/A can be determined using the following relation:

$$\frac{B}{A} = 2\rho_0 c_0 \left(\frac{\partial c}{\partial p}\right)_{S,\rho=\rho_0}. \qquad (23)$$

It can also be shown that the expression above for B/A is equivalent to

$$\frac{B}{A} = 2\rho_0 c_0 \left(\frac{\partial c}{\partial p}\right)_{T,\rho_0} + \frac{2\beta_V T c_0}{C_P}\left(\frac{\partial c}{\partial T}\right)_{p,\rho_0}, \qquad (24)$$

where $\beta_V = V^{-1}(\partial V/\partial T)_P$ is the volume coef-

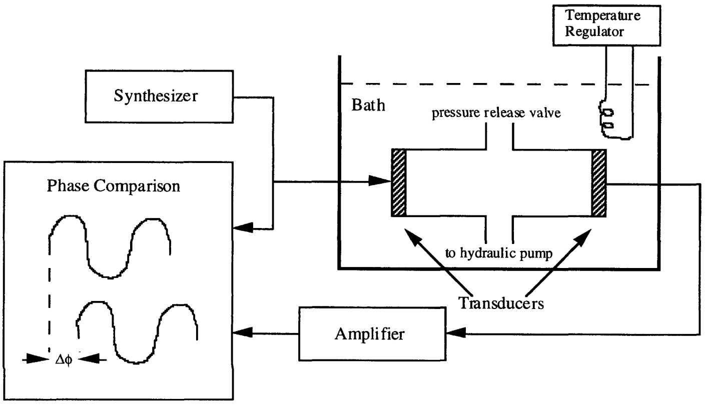

FIG. 14. Block diagram of system used to measure *B/A* by making speed measurements during a pressure change at constant entropy.

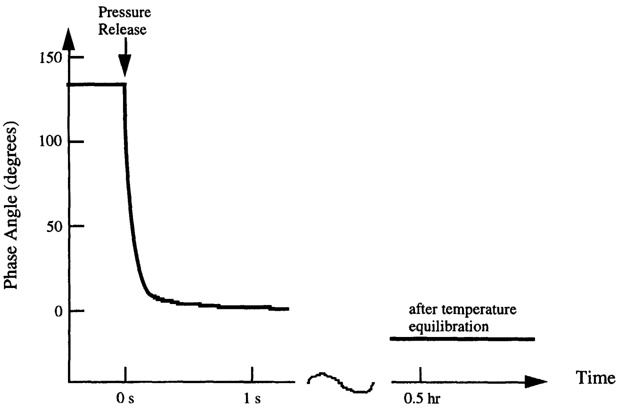

FIG. 15. Change in phase of received waveform (wave speed) with time after rapid pressure change. Final value after temperature equilibration.

ficient of thermal expansion, V is the volume, P is the pressure, C_p is the specific heat at constant pressure, and T is the temperature. Thus measurements of the speed as a function of temperature at constant pressure and as a function of pressure at constant temperature (measurement of change after approximately 0.5 h in Fig. 15) will give the two partial derivatives above. These and the values for β_v and C_p will allow computation of B/A. An example of a system that can be used to make such measurements was described by Law *et al.* (1985). This technique is also potentially very accurate but requires much longer measurement time for appropriate temperature equilibration.

Another class of measurement techniques has been referred to as finite-amplitude methods. These techniques employ the measurement of a harmonic component or components of the wave versus distance from the source. For example, for an ideal plane wave in a lossless material the Fubini solution to the nonlinear wave equation, describing the development of harmonics close to the source, gives the following rather simple form:

$$p_n(\sigma) = [2p_1(0)/n\sigma]J_n(n\sigma), \tag{25}$$

where $p_1(0)$ is the amplitude of the fundamental at the source, J_n is the nth-order Bessel function, and $\sigma = x/L$ where x is the distance from the source and L is the discontinuity distance (distance at which a shock wave starts to develop) (Beyer, 1974). Examining $n = 2$, i.e., the second-harmonic component, yields

$$\frac{B}{A} = \frac{2\rho_0 c_0^3}{\pi f}\frac{p_2(x)}{xp_1(0)^2} - 2, \tag{26}$$

where $p_2(x)$ is the value of the second harmonic as a function of distance from the source, x. This can be experimentally measured by using a receiver that is sensitive to the second harmonic and by varying the distance between source and receiver; see Fig. 16.

This is a valid determination of B/A if we take the intercept for $p_2(x)/xp_1(0)^2$. Thus

$$\frac{B}{A} = \frac{2\rho_0 c_0^3}{\pi f}\left[\frac{p_2(x)}{xp_1(0)^2}\right]_{xp_1(0)\to 0} - 2. \tag{27}$$

In lossless materials this bracketed function would be a horizontal line, but in lossy media it will intercept at an angle. However, it will be a straight line on a semilog plot (Fig. 17) such that the intercept is still valid (and easily obtained) for the determination of B/A. More details of this measurement approach can be found elsewhere (Law *et al.*, 1985). This technique is less accurate than the thermodynamic approach, but it does allow *in vivo* measurements that are not possible using thermodynamic systems, which require pressurization.

There are other acoustical methods used for measuring B/A that utilize "pump" and "probe" waves (Cain, 1986). The high-amplitude "pump" wave provides the pressure change for the low-amplitude "probe" wave. Such approaches present the possibility of imaging B/A; however, the details are quite complicated and one cannot directly measure B/A.

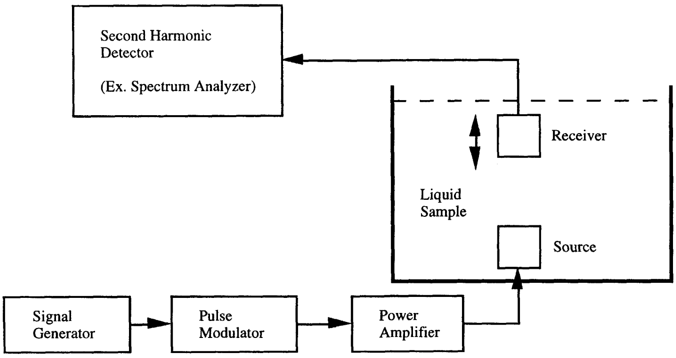

FIG. 16. Block diagram of system for measuring p_2 versus x.

4. RECENT ADVANCES IN MEDICAL IMAGING AND THERAPY

As mentioned previously, phased arrays have seen increasing use in both medical imaging and therapy. Linear arrays for medical imaging have become the norm for producing two-dimensional clinical images. However, ideally a full two-dimensional array would be used to generate a focus that could be scanned in three dimensions. The problem is that to eliminate grating lobes by keeping the interelement spacing on the order of one-half the wavelength leads to a very large number of elements that makes fabrication of fully filled transducers and the associated electronics too complex and costly. Thus, linear arrays, which allow focusing and movement of the focus in one plane, have been used almost exclusively. The thickness of this two-dimensional "slice" has been typically controlled by weak focusing in the other dimension using a cylindrical lens or a curved source.

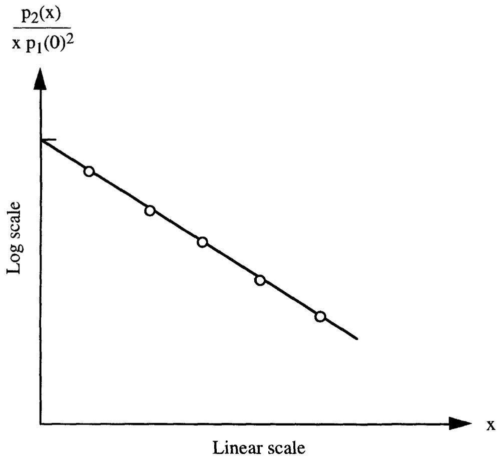

FIG. 17. Plot of parameter to determine *B*/*A*.

Recently the slice thickness has been decreased by the use of 1.5-D arrays. These are similar to the linear arrays except that they also have a few elements, to date typically no more than 5 or 7, in the other direction. Though these are not true two-dimensional arrays, they do allow the use of phasing to modify the slice thickness from what it would be with the standard mechanical focusing alone. These arrays are used increasingly in imaging systems.

Another advancement is three-dimensional imaging, the acquisition of signals from a three-dimensional volume of tissue (Tong *et al.*, 1996). This is accomplished by the systematic acquisition of two-dimensional images. The data from these can then be used, via specialized algorithms, to view two-dimensional images in various planes of choice and to determine volumes of organs, chambers, etc. much more accurately (Gilja *et al.*, 1995). Currently, three-dimensional image data are not viewed in real time, but only after some off-line processing time. However, the processing time is steadily decreasing, and these systems will be very useful in future ultrasound medical imaging.

Therapeutic ultrasound developments also center very much around the use of phased arrays for electronic control of treatment (Chapelon *et al.*, 1993; Fan and Hynynen, 1994; Wan *et al.*, 1995; Kluiwstra *et al.*, 1995; Hutchinson *et al.*, 1995; Goss *et al.*, 1996). Different groups have taken different approaches to the development of systems that employ phased-array technology but with a limited number of elements. Phased-array systems have been proposed for treatment of the heart (Kluiwstra *et al.*, 1995), the prostate (Hutchinson *et al.*, 1995), and other regions of the body (Wan *et al.*, 1995; Goss *et al.*, 1996).

7.1
Introduction

Generally, sound (sonics) refers to vibratory mechanical disturbances at all frequencies in all substances. Ultrasound (ultrasonics) refers to such disturbances in the range of frequencies above that of audible sound (approximately 20 kHz) up to pretersonic frequencies (10 GHz and higher). Recently, the term *hypersonics* has also come into use to describe sound at frequencies above 1 GHz. However, the term is somewhat ambiguous, because in aeroacoustics hypersonics refers to the study of phenomena associated with objects traveling faster than five times the velocity of sound in air.

The study and application of ultrasonics as a serious scientific discipline began about 1910 with the development of piezoelectric transducers. Early applications of ultrasound centered on the development of a primitive form of sonar, communications devices, and light modulators used in early experiments with television. Following improvement in high-frequency electronics during World War II, the pace of ultrasonics research and applications accelerated. The first acoustic delay lines were applied to radar systems to produce a moving target indicator and used as short term memories in early computers. Today, ultrasonic methods and techniques are widely used in such far-ranging fields of application as low temperature and solid state physics, signal processing and devices, materials processing and testing, nondestructive evaluation, medical diagnostics and imaging, Doppler sonar, microstructural materials characterization, acoustic microscopy, chemical kinetics, viscoelasticity, lubrication, fluid flow, ultrasonic motors, materials forming, and welding among others.

This article is divided into three broad categories: (i) physical and technical principles of ultrasound; (ii) ultrasonic generation, detection, and measurements; and (iii) applications. The first category is covered in four main sections (Sections 7.2–7.5), which establish the physical basis and phenomenological constructs of ultrasound. The development emphasizes the intrinsic connection to reversible and irreversible thermodynamics. The second category is covered in two main sections (Sections 7.6 and 7.7), which provide an overview of the most commonly used methods and equipment for the generation and detection of ultrasonic signals and techniques for measuring ultrasonic parameters. The article concludes in Section 7.8 with a survey of representative applications of ultrasound including some

recent applications in the final stage of development.

7.2
Ultrasonic Waves in Boundless Media

Many applications of ultrasound involve wave propagation that is minimally influenced by geometrical constraints or boundaries. Such conditions occur when the time duration of an ultrasonic wave, that is, an ultrasonic pulse or toneburst (gated continuous wave (cw)), is short compared to the propagation time through the medium. For sufficiently long tonebursts, the wave propagation may be modeled to a good approximation as a cw propagating in a boundless medium. The relative simplicity of such models emphasizes the basic physical properties of the propagation medium. We begin by considering the propagation of ultrasonic waves in thermodynamically reversible solids and fluids to explore the most basic physical features of these media that influence wave propagation.

7.2.1
Solids

We may consider a solid to be a material in which the thermodynamic state of equilibrium depends on the fixed mean configuration of the particles comprising the material and either the temperature T or the entropy S of the system. We denote the present configuration of the material particles by the set of particle vectors $\{\boldsymbol{x}\}$. The relevant state functions describing the system of particles are the Helmholtz free energy per unit mass $F(\boldsymbol{x}, \boldsymbol{T})$ and the internal energy per unit mass $U(\boldsymbol{x}, S)$.

7.2.1.1 **Stress, Strain, and Elastic Constants**

We assume that the present configuration of material particles of the solid is obtained by means of a small (infinitesimal) elastic deformation from some initial configuration of particles denoted by the set of particle vectors $\{\boldsymbol{a}\}$. We describe the elastic deformation by the set of transformation coefficients $\alpha_{ij} = \partial x_i/\partial a_j$ such that $x_i = \alpha_{ij} a_j$. The indices i and j take the values 1, 2, 3 representing three mutually orthogonal spatial reference axes. We define the resulting particle displacements u_i by $u_i = x_i - a_i$ and write $\alpha_{ij} = \delta_{ij} + u_{ij}$, where the displacement gradients $u_{ij} = \partial u_i/\partial a_j$, and δ_{ij} is the Kronecker delta ($\delta_{ij} = 1$ if $i = j$, $\delta_{ij} = 0$ if $i \neq j$). The deformation of the solid results in a change in the mass density of the material described by the relation (Wallace, 1970)

$$\frac{\rho_0}{\rho} = J = \det[\alpha_{ij}] \tag{7.1}$$

where $\rho_0 = \rho_0(\boldsymbol{a})$ is the mass density in the initial state and $\rho = \rho(\boldsymbol{x})$ is the mass density in the final state.

Let $\Delta\boldsymbol{a}$ be the vector between any two material particles in the initial state and $\Delta\boldsymbol{x}$ be the vector between the same two particles in the final state. If the deformation is constant over the region defined by $\Delta\boldsymbol{x}$, then the relation (Murnaghan, 1951) (repeated suffix denotes summation)

$$|\Delta\boldsymbol{x}|^2 - |\Delta\boldsymbol{a}|^2 = 2\eta_{ij}\Delta a_i \Delta a_j \tag{7.2}$$

holds where

$$\begin{aligned}\eta_{ij} &= \frac{1}{2}(\alpha_{ki}\alpha_{kj} - \delta_{ij}) \\ &= \frac{1}{2}(u_{ij} + u_{ji} + u_{ki}u_{kj})\end{aligned} \tag{7.3}$$

The symmetric parameters η_{ij} are called the *Lagrangian strains*. For sufficiently small strains, the terms $u_{ki}u_{kj}$ can be neglected in Equation (7.3) and the Lagrangian strains reduce to the stain measure $\varepsilon_{ij} = (1/2)(u_{ij} + u_{ji})$ conventionally defined in linear elasticity. The advantage of the Lagrangian strains is that the distances between all pairs of material particles can be completely specified by the initial configuration of particles $\{\boldsymbol{a}\}$ and the Lagrangian strains η_{ij} defined over any region for which the η_{ij} are constant. Because the Helmholtz free energy and the internal energy depend only on the relative positions of the particles, we may write that $F(\boldsymbol{x}, S) = F(\boldsymbol{a}, \eta_{ij}, S)$ and $U(\boldsymbol{x}, S) = U(\boldsymbol{a}, \eta_{ij}, S)$. For small deformations, we may expand $U(\boldsymbol{a}, \eta_{ij}, S)$ about $\boldsymbol{a}$ (i.e., about $\eta_{ij} = 0$) to first order in η_{ij} as (Wallace, 1970)

$$\rho_0 U(a, \eta_{ij}, S) = \rho_0 U(a, 0, S) + C^S_{ij}\eta_{ij} + \frac{1}{2}C^S_{ijkl}\eta_{ij}\eta_{kl} + \cdots \quad (7.4)$$

where

$$C^S_{ij} = \rho_0\left(\frac{\partial U}{\partial \eta_{ij}}\right)_s, \quad C^S_{ijkl} = \rho_0\left(\frac{\partial^2 U}{\partial \eta_{ij}\partial \eta_{ij}}\right)_s \quad (7.5)$$

A similar expansion may be obtained for the Helmholtz free energy with coefficients C^T_{ij} and C^T_{ijkl} defined in terms of appropriate strain derivatives of the Helmholtz free energy per unit mass.

The coefficients C^S_{ij} are the isentropic initial stresses in the solid $(\sigma_0)_{ij}$ (sometimes called the *thermodynamic tensions*) and the coefficients C^S_{ijkl} are the isentropic elastic constants (often called the *second-order Brugger elastic constants*) of the solid. The C^T_{ij} and C^T_{ijkl} are the corresponding isothermal coefficients. For sufficiently small strains such that the terms $u_{ki}u_{kj}$ can be neglected in Equation (7.3), we may take the derivative of Equation (7.4) with respect to the strains to obtain the isentropic equation of state

$$\sigma_{ij} = (\sigma_0)_{ij} + C^S_{ijkl}\varepsilon_{kl} + \cdots \quad (7.6)$$

where $\sigma_{ij} = \rho_o(\partial U/\partial \varepsilon_{ij})$ are the stress components in the final state, $(\sigma_0)_{ij}$ are the stress components in the initial state, and ε_{ij} are the conventional strains. A similar isothermal expression holds using the Helmholtz free energy. Equation (7.6), known as the *generalized Hooke's law*, clearly shows that the second-order elastic constants serve to linearly couple the stress and the strain in perfectly elastic bodies.

Both the isentropic and the isothermal C_{ijkl} are fourth rank tensors that generally have 81 components. However, the stress symmetry $(\sigma_{ij} = \sigma_{ji})$ requires $C_{ijkl} = C_{jikl}$. The strain symmetry $(\varepsilon_{kl} = \varepsilon_{lk})$ requires $C_{ijkl} = C_{jilk}$. These two conditions reduce the number of independent second-order elastic constants to 36. The quadratic dependence of the energy on the strain, shown in Equation (7.4), means that the energy must remain unchanged not only under an interchange of strain suffix pairs i, j and k, l, but also under an interchange of i, k and j, l. Thus, the relation $C_{ijkl} = C_{jikl} = C_{ijlk} = C_{klij}$ holds for the elastic constants. This relationship reduces the number of independent constants to 21.

The crystal symmetry of a material may also reduce the number of independent elastic constants, because the constants are derivatives of the thermodynamic state functions with respect to crystallographically equivalent strains. A detailed derivation of the number of independent elastic constants may be found in Nye (1960). The number of independent constants for the different crystal systems is summarized in Table 7.1. The point groups in Table 7.1

Tab. 7.1 Number of independent elastic constants for different crystal systems.

Crystal system	Laue group	Point groups	Elastic constants
Triclinic	N	1, $\bar{1}$	21
Monoclinic	M	m, 2, $\frac{2}{m}$	13
Orthorhombic	O	2mm, 222, $\frac{2}{m}\frac{2}{m}\frac{2}{m}$	9

Isotropic	I		2

reflect all symmetry operations possible for a given crystal system. A symmetry operation for a boundless crystal is an operation that interchanges the positions of the various atoms of the crystal into equivalent positions such that the crystal appears exactly the same as before the operation. For example, crystals belonging to the monoclinic system have one of three possible point groups given as m, 2, or $2/m$ in the full international notation. The symbol m denotes an operation corresponding to the reflection of the crystal atoms across a mirror plane, 2 denotes an operation corresponding to 180° rotations (twofold rotations) around a symmetry axis, and $2/m$ denotes an operation corresponding to reflection across a mirror plane normal to a twofold rotation axis. The point groups are given in the full international notation in Table 7.1 with the full set of possible point groups listed for each crystal system.

The full tensor notation C_{ijkl} for the elastic constants is often replaced by the abbreviated notation (sometimes called the *matrix* or *Voigt notation*) $C_{\alpha\beta}$ according to the prescription:

ij or $kl =$	11	22	33	23, 32	13, 31	12, 21
α or $\beta =$	1	2	3	4	5	6

It is instructive to write the set of elastic constants in Voigt notation for triclinic, cubic, and isotropic symmetry classes in the half matrix forms (the full matrices are symmetrical about the diagonal):

Triclinic : 21 constants

$$\begin{array}{cccccc}
c_{11} & c_{12} & c_{13} & c_{14} & c_{15} & c_{16} \\
 & c_{22} & c_{23} & c_{24} & c_{25} & c_{26} \\
 & & c_{33} & c_{34} & c_{35} & c_{36} \\
 & & & c_{44} & c_{45} & c_{46} \\
 & & & & c_{55} & c_{56} \\
 & & & & & c_{66}
\end{array}$$

Isotropic : 2 constants

$$\begin{array}{cccccc}
c_{11} & c_{12} & c_{12} & 0 & 0 & 0 \\
 & c_{11} & c_{12} & 0 & 0 & 0 \\
 & & c_{11} & 0 & 0 & 0 \\
 & & & c_{44} & 0 & 0 \\
 & & & & c_{44} & 0 \\
 & & & & & c_{44}
\end{array}$$

Cubic (all classes) : 3 constants

$$
\begin{array}{cccccc}
c_{11} & c_{12} & c_{12} & 0 & 0 & 0 \\
 & c_{11} & c_{12} & 0 & 0 & 0 \\
 & & c_{11} & 0 & 0 & 0 \\
 & & & \frac{1}{2}(c_{11}-c_{12}) & 0 & 0 \\
 & & & & \frac{1}{2}(c_{11}-c_{12}) & 0 \\
 & & & & & \frac{1}{2}(c_{11}-c_{12})
\end{array}
$$

For the remaining symmetry classes, see Nye (1960).

For isotropic symmetry Hooke's law, Equation (7.6) may be written as (Pollard, 1977) $\sigma_{ij} = (C_{11} - C_{12})\varepsilon_{ij} + C_{12}\varphi\delta_{ij} = 2G\varepsilon_{ij} + \lambda\varphi\delta_{ij}$, where the dilatation $\varphi = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33} = \operatorname{div} \boldsymbol{u}$ ($\boldsymbol{u}$ is the displacement vector). The Brugger elastic constants in the last equality are replaced by the Lamé constants • and G, where $\lambda = C_{12}$ and $G = (1/2)(C_{11} - C_{12})$. The constant G is also called the *shear modulus* or *rigidity modulus*.

Another important modulus is the *bulk modulus B* defined as the ratio of the change in hydrostatic pressure, Δp, to the fractional change in the volume of the material, $\Delta V/V_0 = \Delta J$, produced when pressure is applied to an isotropic material (including fluids). It is related to the Brugger constants and the Lamé constants as $B = (1/3)(C_{11} + 2C_{12}) = \lambda + (2/3)G$.

A related constant is the compressibility $K = 1/B$.

7.2.1.2 Modal Wave Propagation

For a solid of arbitrary crystalline symmetry, we may substitute Equation (7.6) into Newton's Law, $\rho_0(\partial^2 u_i/\partial t^2) = (\partial\sigma_{ij}/\partial a_j)$, where t is time and body forces are neglected. We obtain the isentropic wave equation

$$\rho_0 \frac{\partial^2 u_i}{\partial t^2} = C^S_{ijkl} \frac{\partial^2 u_k}{\partial a_j \partial a_l} \tag{7.7}$$

It is important to note that for the case of small elastic deformations, the transformation coefficients $\alpha_{ij} \approx \delta_{ij}$ and the wave equation, Equation (7.7), may be written with the variables a_i (often called the *material or Lagrangian coordinates*) replaced by x_i (often called the *spatial or Eulerian coordinates*) (Thurston, 1964). Thus, in the "linear acoustic approximation," the coordinate variables in the wave equation may be either the set a_i or x_i. In this article, both sets are used depending on notational convenience.

An equation similar to Equation (7.7) holds for isothermal wave propagation. Whether isentropic or isothermal wave propagation occurs depends on the thermodynamic properties of the material (Pierce, 1989). Although isentropic (strictly adiabatic) conditions prevail in most cases, we shall drop the isentropic and isothermal designations except where it is appropriate to distinguish a specific condition.

We assume the propagation of plane harmonic waves of the form $u_i = w_i \exp[i(k_j a_j - \omega t)]$, where w_i are the Cartesian components of the normalized wave amplitude $\boldsymbol{w}(|\boldsymbol{w}| = 1)$, k_j are the components of the wave vector $\boldsymbol{k}$, and ω is the angular frequency of the wave. Substituting this form into Equation (7.7), defining $\boldsymbol{n} = \boldsymbol{k}/|\boldsymbol{k}|$ to be the unit vector along the wave propagation direction, and defining the wave phase velocity $c = \omega/|\boldsymbol{k}|$, we obtain the Christoffel equation

$$(\rho_0 c^2 \delta_{ik} - C_{ijkl} n_j n_l) w_k = 0 \qquad (7.8)$$

For a given direction of propagation $\boldsymbol{n}$, Equation (7.8) is a set of three homogeneous equations in three unknowns w_k, where $k = 1, 2, 3$. Nonzero solutions to Equation (7.8) exist if the determinant of the set of terms in parentheses (the secular determinant) is zero. Evaluation of the secular determinant leads to a cubic equation in c^2. The three roots of this equation correspond in general to three different propagation velocities. Substitution of each of these velocities back into Equation (7.8) yields a solution set of w_k, called the *wave polarization vector*, corresponding to that velocity. The polarization vectors are mutually orthogonal. If the polarization vector is parallel or nearly parallel to the propagation vector, the wave is called a *longitudinal or quasi-longitudinal wave.* If the polarization vector is perpendicular or nearly perpendicular to the propagation vector, the wave is called a *transverse (shear) or quasi-transverse (quasi-shear) wave.* In general, the one longitudinal wave and the two shear waves have different velocities.

From Equation (7.8), we find that the velocity of propagation of a wave of polarization $\boldsymbol{w}$ along the direction $\boldsymbol{n}$ is determined as $c = (C_{ijkl} n_j n_l w_i w_k / \rho_0)^{1/2}$. It is apparent from this expression that the crystalline symmetry influences the sound velocity through the elastic constants. For example, for plane wave propagation along the [100] crystalline axis of cubic solids, the longitudinal velocity $c_1 = (C_{11}/\rho_0)^{1/2}$ and the shear wave velocities $c_2 = c_3 = (C_{44}/\rho_0)^{1/2}$; along the [110] direction $c_1 = [(C_{11} + C_{12} + 2C_{44})/2\rho_0]^{1/2}$, $c_2 = (C_{44}/\rho_0)^{1/2}$, and $c_3 = [(C_{11} - C_{12})/2\rho_0]^{1/2}$; and along [111] $c_1 = [(C_{11} + 2C_{12} + 4C_{44})/3\rho_0]^{1/2}$ and $c_2 = c_3 = [(C_{11} - C_{12} + C_{44})/3\rho_0]^{1/2}$.

Along any wave propagation direction in materials having isotropic symmetry, the longitudinal velocity $c_1 = (C_{11}/\rho_0)^{1/2} = [(\lambda + 2G)/\rho_0]^{1/2} = [(B + (4/3)G)/\rho_0]^{1/2}$ and the shear wave velocities $c_2 = c_3 = [(C_{11} - C_{12})/2\rho_0]^{1/2} = (G/\rho_0)^{1/2}$. This result can also be obtained by substituting the isotropic Hooke's law, $\sigma_{ij} = 2G\varepsilon_{ij} + \lambda\varphi\delta_{ij}$, into Newton's law to obtain (after some manipulation) (Pollard, 1977)

$$\begin{aligned}\rho_0 \frac{\partial^2 \boldsymbol{u}}{\partial t^2} &= (\lambda + 2G)\nabla(\nabla \cdot \boldsymbol{u}) \\ &\quad - G\nabla \times (\nabla \times \boldsymbol{u}) \qquad (7.9)\end{aligned}$$

where ∇ is the vector operator $\nabla = (\partial/\partial a_1)\boldsymbol{e}_1 + (\partial/\partial a_2)\boldsymbol{e}_2 + (\partial/\partial a_3)\boldsymbol{e}_3$ and $\boldsymbol{e}_i$ are the unit vectors along the Cartesian axes. For the case of pure dilatational (compressional or longitudinal) waves, $\nabla \bullet \boldsymbol{u} \neq 0, \nabla \times \boldsymbol{u} = 0$ and Equation (7.9) reduces to $(\partial^2 \boldsymbol{u}/\partial t^2) = c_l \nabla^2 \boldsymbol{u}$, where $c_1 = [(\lambda + 2G)/\rho_0]^{1/2}$ is the longitudinal wave velocity. For the case of pure rotational (shear or transverse) waves, $\nabla \bullet \boldsymbol{u} = 0$, $\nabla \times \boldsymbol{u} \neq 0$ and Equation (7.9) reduces to $(\partial^2 \boldsymbol{u}/\partial t^2) = c_t \nabla^2 \boldsymbol{u}$, where $c_2 = c_3 = (G/\rho_0)^{1/2}$ is the shear wave velocity.

7.2.2
Fluids

We define a fluid as a material that will yield under the action of a shear stress, no matter how small it is. A fluid is ordinarily understood to be isotropic. We define a perfect fluid to be an idealized material in which there never exists a shear stress. Hence, the shear modulus G must be zero. The wave equation, Equation (7.7) or Equation (7.9), also holds for fluids and the results obtained for isotropic solids can be directly used for fluids with appropriate consideration of the isotropic symmetry and the vanishing of the shear modulus. Thus, the transverse wave velocity $c_2 = c_3 = 0$ and the longitudinal (also called *compressional*) wave velocity $c_1 = [B/\rho_0]^{1/2}$, where B is the bulk modulus.

It is instructive to consider an alternative form of the wave equation often used for fluid media. For a frictionless or nonviscous perfect fluid, the stress σ_{ij} is the thermodynamic pressure p obtained as $\sigma_{ij} = -p\ \delta_{ij}$. For small variations in the mass density ρ about the initial mass density ρ_0, the equation of state, Equation (7.6), may be approximated using the isotropic symmetry properties of the elastic constants and Equation (7.1) as $\rho = \rho_0 + (\rho_0/B_S)(p - p_0) + \ldots$. Substituting this equation into the equation of continuity $(\partial\rho/\partial t) = \partial(\rho v_i)/\partial a_i \approx \rho_0(\partial v_i/\partial a_i)$, where $v_i = \partial u_i/\partial t$ is the particle velocity, we obtain $(\partial p/\partial t) = -B_S(\partial v_i/\partial a_i)$. Taking the derivative of this expression with respect to time and using Newton's Law $\rho_0(\partial^2 u_i/\partial t^2) = \rho_0(\partial v_i/\partial t) = (\partial\sigma_{ij}/\partial a_j) = -(\partial p/\partial a_i)$, we obtain the pressure wave equation

$$\frac{\partial^2 p}{\partial t^2} = \frac{B_S}{\rho_0}\frac{\partial^2 p}{\partial a_i \partial a_i} = \frac{B_S}{\rho_0}\nabla^2 p \tag{7.10}$$

where ∇^2 is the Laplacian operator. It is apparent from Equation (7.10) that the compressional wave velocity $c_1 = (B_S/\rho_0)^{1/2}$.

The isentropic equation of state used in obtaining Equation (7.10) may be recast in the more traditional Hooke's Law form $p = p(\rho, S) = p_0 + (\partial p/\partial\rho)_S(\rho - \rho_o) + \ldots = p_0 + (B_S/\rho_0)(\rho - \rho_o) + \ldots$. This form reveals that the isentropic wave velocity for fluids, $c = (B_S/\rho_0)^{1/2}$, can be generally obtained from the equation of state as $c = [(\partial p/\partial\rho)\rho_0]^{1/2}$. For the special case of an ideal gas, the adiabatic condition is expressed as $p = p_0(\rho/\rho_0)^\gamma$, where γ is the ratio of isobaric to isochoric specific heats. Hence, the adiabatic sound velocity is obtained as $c = [\gamma(p_0/\rho_0)]^{1/2}$. The ideal gas equation of state involving temperature T may be written as $p = p(\rho, T) = \rho RT$, where $R = R_0/M$, R_0 is the universal gas constant, and M is the average molecular weight of the molecules comprising the gas. Thus, we find the temperature dependence of the adiabatic sound velocity to be $c = (\gamma RT)^{1/2}$.

7.3
Ultrasonic Waves in Bounded Media

The presence of surfaces and interfaces bounding two media having different acoustic properties gives rise to a variety of acoustic phenomena having important applications. We consider here conditions leading to wave reflection, refraction, acoustic mode conversion, inhomogeneous and evanescent waves, and guided waves.

7.3.1
Reflection and Refraction

We consider a plane harmonic pressure wave of unit amplitude of the form $p_{inc} = \exp[i(\boldsymbol{k}\bullet\boldsymbol{x} - \omega t)]$ incident on a plane boundary between two liquid or gas media as illustrated in Figure 7.1. We orient and center the coordinate axes such that the planar interface occurs at $z = 0$. We assume that the plane of the incident wave is coincident with the xz-plane such that $k_x = k\sin\theta$, $k_y = 0$, $k_z = k\cos\theta$, and $k = \omega/c$, where c is the sound velocity in the incident wave propagation medium (upper medium in figure) and θ is the angle of incidence formed by the normal to the wave front and the z axis. The density of

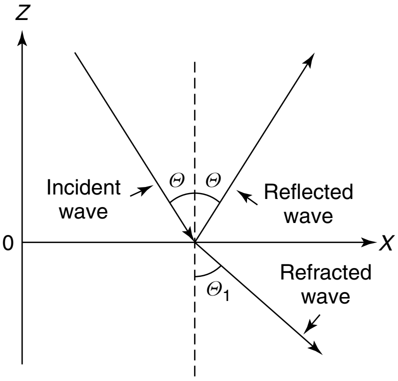

Fig. 7.1 Reflection and refraction of an incident sound wave.

the upper medium is ρ and the density and the sound velocity of the lower medium are ρ_1 and c_1, respectively.

In general, we expect that the incident wave of unit amplitude will be partially reflected from the interface with some amplitude R called the *stress (pressure) reflection coefficient*. The expressions for the incident and reflected waves are written respectively as $p_{inc} = \exp[ik(x\sin\theta - z\cos\theta)]\exp(-i\omega t)$ and $p_{refl} = R\exp[ik(x\sin\theta + z\cos\theta)]\exp(-i\omega t)$. Note that we assume specular (geometrical) reflection of the reflected wave such that the angle of incidence is equal to the angle of reflection. The total pressure field in the upper medium is then

$$p = p_{\mathrm{inc}} + p_{\mathrm{refl}} = (e^{-ikz\cos\theta} + Re^{ikz\cos\theta}) \times e^{i(kx\sin\theta - \omega t)} \tag{7.11}$$

The remaining energy of the incident wave will be transmitted into the lower medium with an amplitude W called the *stress (pressure) amplitude transmission coefficient*. The pressure field in the lower medium consists only of the transmitted wave, which we write as

$$p_1 = We^{ik_1(x\sin\theta_1 - z\cos\theta_1) - i\omega t} \tag{7.12}$$

where $k_1 = \omega/c_1$ is the wavenumber in the lower medium. The angle of refraction θ_1 does not generally equal the incident angle θ, indicating that the wave in the lower medium (the refracted wave) deviates from the incident wave direction.

The quantities R, W, and θ_1 are determined from the conditions that the pressure and the normal component of the particle velocity $v_z = \partial u_z/\partial t$ must be continuous across the boundary. In acoustics, often analogies between acoustic and electromagnetic quantities are used. The acoustic pressure can be identified with the electromotive force or voltage and the particle velocity with the electrical current (Pierce, 1989). Thus, in analogy with the concept of electrical impedance (ratio of voltage to current), we define the acoustic impedance Z normal to the surface as

$$Z = -\frac{p}{v_z} \tag{7.13}$$

The boundary conditions can now be expressed equivalently as the continuity of pressure and acoustic impedance at $z = 0$.

The continuity of pressure requires that $p = p_1$ at $z = 0$. From Equations (7.11) and (7.12), we find that $1 + R = W\exp[i(k_1\sin\theta_1 - k\sin\theta)x]$. Because the left side of this equation is independent of x, so must be the right side. We thus obtain

Snell's law

$$\frac{\sin\theta}{\sin\theta_1} = \frac{k_1}{k} = \frac{c}{c_1} = n \qquad (7.14)$$

where n is the index of refraction. Thus, we have $1 + R = W$.

The continuity of particle velocity may be replaced by the continuity of acoustic impedance. In the lower medium, the impedance $Z_1 = -i\omega\rho_1 p_1(\partial p_1/\partial z)^{-1} = \rho_1 c_1/\cos\theta_1$; in the upper medium $Z = (\rho c/\cos\theta)\,[\exp(-ikz\cos\theta) + R\exp(ikz\cos\theta)]/[\exp(-ikz\cos\theta) - R\exp(ikz\cos\theta)]$. Because $Z = Z_1$ at $z = 0$, we obtain from the above equations that

$$R = \frac{Z_1 - Z_{\text{inc}}}{Z_1 + Z_{\text{inc}}},\ Z_{\text{inc}} = \frac{\rho c}{\cos\theta} \qquad (7.15)$$

For fluid–solid and solid–solid interfaces, the number of reflected and refracted waves is dramatically increased, because both longitudinal and shear wave motion must be considered. Correspondingly, the reflection and transmission coefficients must include shear wave impedance terms as well as longitudinal impedance terms. For further information, see Brekhovskikh (1980).

7.3.2
Resonance Phenomena

Consider the one-dimensional case of a sample of length $L/2$ having flat and parallel opposing faces. We assume complete reflection of the sound waves normally incident on the surfaces. We assume that the face $x = 0$ is caused to vibrate with a time harmonic disturbance having particle velocity $v = \partial u/\partial t = \cos(\omega t)$. The disturbance propagates from the surface as a plane wave along the direction x described by the complex expression $v' = \exp[i(\omega t - kx) - \alpha x]$. The factor $\exp(-\alpha x)$ represents the decay of the waveform as the result of attenuation in the medium (see below); the parameter α is the attenuation coefficient. We assume that the wave is totally reflected at the opposing surface $x = L/2$ and the reflected wave after propagating back to the surface $x = 0$ is superimposed on the original driving vibration. The wave continues to reflect between the opposing surfaces giving rise to a superposition of waves of the form (Bolef and Miller, 1971)

$$\begin{aligned} v' &= \exp(i\omega t)(1 + \exp[-(ikL + \alpha L)] \\ &\quad + \exp[-2(ikL + \alpha L)] + \ldots) \\ &= \exp(i\omega t)/(1 + \exp[-(ikL + \alpha L)] \end{aligned} \qquad (7.16)$$

Taking the real part of the above expression, we obtain

$$v = \operatorname{Re} v' = v_1\cos\omega t + v_2\sin\omega t \qquad (7.17)$$

where

$$v_1 = \frac{e^{\alpha L} - \cos kL}{2(\cosh\alpha L - \cos kL)},$$
$$v_2 = \frac{\sin kL}{2(\cosh\alpha L - \cos kL)} \qquad (7.18)$$

The term v_1 is in phase with the driving vibration and the term v_2 is 90° out of phase (in quadrature). The amplitude of v is

$$\begin{aligned} |v| &= (v_1^2 + v_2^2)^{1/2} \\ &= \frac{e^{\alpha L/2}}{[2(\cosh\alpha L - \cos kL)]^{1/2}} \end{aligned} \qquad (7.19)$$

Plots of these terms as a function of $kL (= \omega L/c)$ are given in Figure 7.2. The curves show a resonance behavior at a value of kL corresponding to the condition that the sample length $L/2$ is equal to an integral number of half wavelengths (wavelength $\lambda = 2\pi c/\omega$). Such standing wave resonances occur at all frequencies

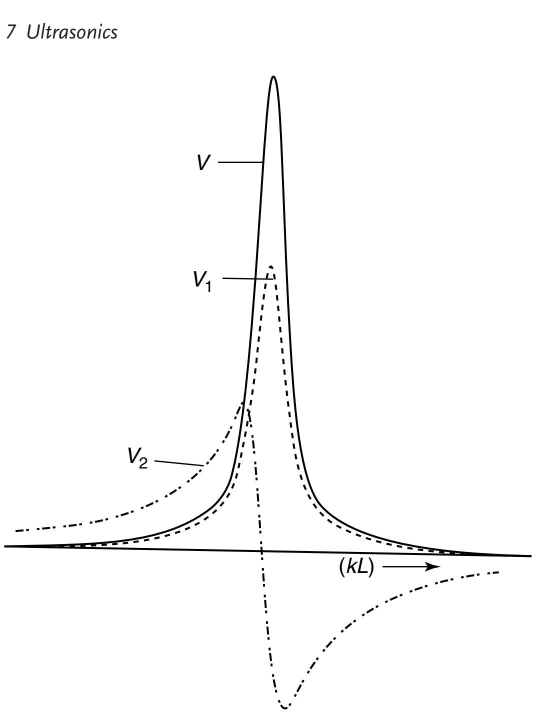

Fig. 7.2 Plots of ν (solid curve), ν_1 (dashed curve), and ν_2 (dashed-dotted curve) as functions of kL about a resonance value.

ω_m such that the resonance condition $L/2 = m(\lambda_{m/2})$ is satisfied, where m is an integer (harmonic number) and $\lambda_m = 2\pi c/\omega_m$. Using $k = \omega/c$, we obtain from the resonance condition that the mth resonance frequency is $\omega_m = 2\pi mc/L$ and that $\omega_m - \omega_{m+1} = 2\pi c/L$. The latter expression can be used to determine the ultrasonic velocity from the measurement of two successive resonance frequencies. The attenuation can be determined from the frequency width $\Delta\omega$ of the resonance at half power as $\alpha = \Delta\omega/(2c)$ (Bolef and Miller, 1971).

7.3.3
Surface and Interface Waves

We consider the situation at a fluid–fluid interface where the index of refraction $n < 1 (c_1 > c)$ and the angle of incidence of a plane wave exceed the critical angle $\theta_0 = \arcsin n$. For $\theta > \theta_0$, we rewrite Equation (7.15) in the complex form $R = [(\rho_1/\rho) \cos\theta - i(\sin^2\theta - n^2)^{1/2}]/[(\rho_1/\rho)\cos\theta + \mathrm{i}(\sin^2\theta - n^2)^{1/2}]$. Because $|R| = 1$, there is total reflection of the wave. Writing $R = \exp(i\phi)$, we find that the phase ϕ of the reflected wave varies, $\phi = -2\ \arctan[(\rho(\sin^2\theta - n^2)^{1/2}/\rho_1\cos\theta)]$. For the case of complete internal reflection, the field in the lower medium can be written as (Brekhovskikh, 1980)

$$z < 0,\ p_1 = (1 + R)\mathrm{e}^{\delta z}\mathrm{e}^{\mathrm{i}kx\sin\theta - \mathrm{i}\omega t},$$
$$\delta = k(\sin^2\theta - n^2)^{1/2} \qquad (7.20)$$

The wave represented by Equation (7.20) is an example of an inhomogeneous wave. Such waves propagate along a given direction with an amplitude that decays exponentially in a direction perpendicular to the direction of propagation. The wave of Equation (7.20) propagates along the boundary (a surface wave) with exponential decay perpendicular to the boundary.

Inhomogeneous waves can propagate on a boundary in the absence of an incident wave. Consider the case of an isotropic elastic halfspace that forms a planar interface with a vacuum on the $z = 0$ plane (we assume same axes orientation and centering as in Figure 7.1). A monochromatic wave propagating along the solid–vacuum surface (x direction) must satisfy the wave equation in Equation (7.7). In analogy with Equation (7.20), we assume that the form of the surface wave is given by $u_i = \exp(\delta z)\exp[i(kx - \omega t)]$. From Equation (7.14) (Snell's law) and the relations $k_1 = \omega/c_1, k_{1x} = k_1 \sin\theta_1$, we may recast the δ given in Equation (7.20) in the form $\delta = [k_{1x}^2 - (\omega/c_1)^2]^{1/2}$. We assume for the present case that δ can be written in the analogous form $\delta = [k^2 - (\omega/c)^2]^{1/2}$ where the subscripts have been dropped.

Let us resolve the displacement $\boldsymbol{u}$ (or u_i) into a longitudinal displacement $\boldsymbol{u}_l$ (or u_{li}) and a transverse displacement $\boldsymbol{u}_t$ (or u_{ti}) as $\boldsymbol{u} = \boldsymbol{u}_l + \boldsymbol{u}_t$(or $u_i = u_{l,I} + u_{t,i}$). The transverse component must satisfy the condition $\boldsymbol{\nabla}\bullet\boldsymbol{u}_t = (\partial u_{t,1}/\partial x) + (\partial u_{t,3}/\partial z) = 0$. We assume $u_{t,I} = \exp(\delta_t z)\exp[i(kx - \omega t)]$, where $\delta_t = [k^2 - (\omega/c_t)^2]^{1/2}$ and c_t is the shear wave velocity. We find from these relations that $u_{t,1} = \delta_t A_1 \exp(\delta_t z)\exp[i(kx - \omega t)]$ and $u_{t,3} = -ikA_t \exp(\delta_t z)\exp[i(kx - \omega t)]$, where A_t is a constant (Pollard, 1977).

The longitudinal part of the displacement satisfies the condition $\boldsymbol{\nabla} \times \boldsymbol{u}_l = (\partial u_{l1}/\partial z) - (\partial u_{l,3}/\partial x) = 0$. Performing an analysis similar to that for the transverse components above, we find that $u_{l,1} = kA_l \exp(\delta_l z)\exp[i(kx - \omega t)]$ and $u_{l,3} = -i\delta_l A_l \exp(\delta_l z)\exp[i(kx - \omega t)]$, where A_l is a constant. The boundary conditions to be satisfied for a free surface are $\sigma_{ij} n_j = 0$, where n_j are the components of the unit vector $\boldsymbol{n}$ normal to the surface (parallel to z axis). Application of these boundary conditions provides the relationship $2ik\delta_l A_l + (k^2 + \delta_t^2)A_t = 0$. We obtain from these expressions that the component of the displacement parallel to the surface $u_1 = u_{l,1} + u_{t,1}$ and perpendicular to the surface $u_3 = u_{l,3} + u_{t,3}$ are (in real form) (Briggs, 1992)

$$u_1 = A_2 k\left(e^{-\delta_l z} - \frac{2\delta_l\delta_t}{\delta_t^2 + k^2}e^{-\delta_t z}\right)\sin(kx - \omega t)$$

$$u_3 = A_2 \delta_l\left(e^{-\delta_l z} - \frac{2k^2}{\delta_t^2 + k^2}e^{-\delta_t z}\right)\cos(kx - \omega t) \qquad (7.21)$$

and that the wave velocity $c_R = \omega/k$ is given by

$$16G^2\left(1 - \frac{c_R^2}{c_l^2}\right)\left(1 - \frac{c_R^2}{c_t^2}\right) = \left[\frac{4G}{3} - \left(\lambda + \frac{4G}{3}\right)\frac{c_R^2}{c_l^2}\right]^2\left[2 - \frac{c_R^2}{c_l^2}\right]^2 \qquad (7.22)$$

According to Equation (7.21), both the longitudinal and transverse components decay exponentially in the direction z perpendicular to the propagation direction x. The wave represented by Equation (7.21) is thus a type of inhomogeneous wave known as the *Rayleigh wave*. An approximate solution to Equation (7.22) yields the expression (Scruby, Jones, and Anatoniazzi, 1987) $c_R \approx c_t(1.14418 - 0.25771\mu_P + 0.12661\mu_P^2)^{-1}$ for the Rayleigh wave velocity, where $\mu_P = [1 - 2(c_t/c_l)^2]/\{2[1 - (c_t/c_l)^2]\}$ is Poisson's ratio for the material (see Section 7.3.4).

Figure 7.3 shows the particle displacement field given by Equation (7.21) for a Rayleigh surface wave. The motion is generally elliptical with the major axis perpendicular to the surface. The motion reverses the sense of rotation below a depth of approximately 0.2λ.

If the solid surface on which the Rayleigh wave propagates is in contact with a fluid medium, the velocity of the Rayleigh wave

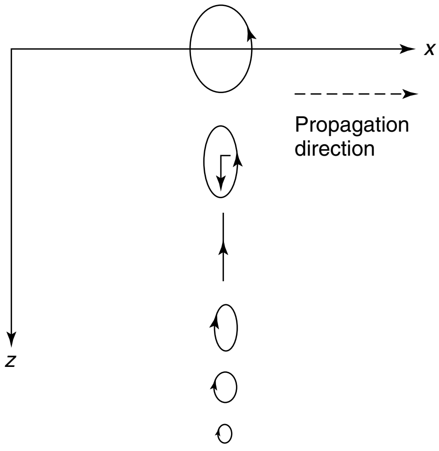

Fig. 7.3 Particle displacement field for a Rayleigh surface wave. The arrows indicate sense of particle motion. From Sabine and Cole, 1971.

will be slightly altered as a result of the reaction of the fluid medium. If the velocity of the Rayleigh wave is greater than the velocity of sound in the fluid medium, then the wave will be partially radiated into the fluid medium. The Rayleigh wave in this case belongs to a class of surface acoustic waves (SAWs) called "*leaky*" waves.

Many other types of surface waves can propagate in materials that depend on the properties of the materials forming the interface. The interface between two elastic media gives rise to an interface wave called the *Stonely wave*. The field distribution in each medium is that of two partial waves with particle displacements parallel and normal to the interface, the motion on either side of the interface being of the Rayleigh type. The Stonely wave velocity lies between that of the Rayleigh waves in each medium and the shear wave in the denser medium.

Other interface waves include the Love wave and the lateral wave. The Love wave involves solid–solid interfaces and is characterized by a transverse component parallel to the surface with particle displacement perpendicular to the direction of wave propagation. The lateral wave may occur at various interface combinations (solid–solid, fluid–solid, fluid–fluid) and is generally associated with the reflection of spherical waves. See Brekhovskikh (1980) for more information.

7.3.4
Guided Waves

Guided waves are characterized by energy flow primarily along the direction of some guiding configuration. Strictly, SAWs are guided waves, but we concern ourselves here with propagation in configurations such as cylinders and plates. These structures are capable of supporting an infinite number of waveguide modes. For simple configurations, the modes may be analyzed as composed of traveling waves along the waveguide axis and standing waves in the transverse direction (the transverse resonance principle). A general expression for the propagation of a sound wave along the direction x in a medium bounded in the (y, z) plane can written as an expansion in terms of the complete set of eigenfunctions $f_n(y, z)$ arising from the solution of the three-dimensional wave equation subject to transverse boundary conditions (i.e., boundary conditioned referred to the y and z dimensions) (Morse and Ingard, 1968). We thus write

$$v(x, y, z, t) = \sum_n b_n f_n(y, z) \mathrm{e}^{-\alpha_n x} e^{\mathrm{i}(\omega t - k_n x)} \tag{7.23}$$

where the constant $k_n = [(\omega/c)^2 - K_n^2]^{1/2}$ is the propagation constant for the nth mode and K_n is the eigenvalue corresponding to the eigenfunction $f_n(y, z)$, b_n is an expansion coefficient, and a_n is the attenuation coefficient for the nth mode.

If a solution corresponding to the eigenvalue $K_n = 0$ exists, it is called the *fundamental mode* and corresponds to one-dimensional wave propagation along the x direction. Higher order modes corresponding to $K_n^2 > 0$ reflect from the sides of the waveguide in a zigzag fashion but have a net propagation in the x direction. For a given frequency, eigensolutions exist only if $(\omega/c)^2 > K_n^2$. A given mode thus has a frequency cutoff below which the mode does not propagate. Such nonpropagating disturbances that are periodic only in time and decay exponentially in all spatial coordinates are called *evanescent waves.*

For a solid isotropic cylinder, the simplest modal solution may be obtained by considering the solid to be subjected to a stress σ_{11} along the cylindrical axis x and stress free conditions on the sides of the cylinder. The application of Hooke's law for an isotropic solid to this case yields the equations: $\sigma_{11} = 2G\varepsilon_{11} + \lambda\varphi; 0 = 2G\varepsilon_{22} + \lambda\varphi; 0 = 2G\varepsilon_{33} + \lambda\varphi$, where the dilatation $\varphi = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}$. From these equations, we define and obtain Young's modulus as $E = \sigma_{11}/\varepsilon_{11} = G(3\lambda + 2G)/(\lambda + G)$ and Poisson's ratio $\mu_p = -\varepsilon_{22}/\varepsilon_{11} = \lambda/[2(\lambda + G)]$. Substituting the defining relation for Young's modulus into Newton's law gives the wave equation $\rho_0(\partial^2 u_1/\partial t^2) = E(\partial^2 u_1/\partial a_1^2)$. We identify from this wave equation that $c_L = (E/\rho_0)^{1/2}$ is the velocity of propagation of bounded longitudinal waves in an isolated solid cylinder. This velocity is in general less than that of a plane longitudinal wave propagating in an unbounded solid. Rayleigh obtained a correction to c_L by accounting for "lateral inertia" and obtained the longitudinal phase velocity $c_L' = c_L[1 - \mu_p^2\pi^2(r_0/\lambda)^2]$, where r_0 is the radius of the cylinder. More general solutions require more powerful approaches such as that leading to Equation (7.23) or methods employing Green's functions. For more information, see Auld (1990).

For a free isotropic plate, horizontally polarized shear (SH) wave modes (characterized by having a polarization direction parallel to the surface) and Lamb wave modes (characterized by a coupling of vertically polarized shear waves and longitudinal waves) may propagate. In the limit $kL \to \infty$, where L is the thickness of the plate, the fundamental symmetrical and antisymmetrical Lamb wave modes degenerate into Rayleigh waves bound to the surfaces. An isotropic plate on an isotropic elastic substrate gives rise to generalized Lamb waves which yield tightly bound Stonely waves at the plate-substrate interface in the limit $kL \to \infty$. For further information on guided waves, see Brekhovskikh (1980) and Auld (1990).

7.4
Ultrasonic Attenuation

Attenuation refers to the total loss of amplitude (or energy) of a sound wave along its propagation path resulting from all mechanisms responsible for such losses, including but not limited to absorption, scattering, and diffraction. Absorption refers to the loss of amplitude (or energy) of an acoustic wave that results in an increase in temperature (however slight) in the propagation medium and is often associated with relaxation phenomena. Scattering results in a redirection of wave energy from the original propagation direction. Diffraction refers to scattering that occurs from the boundaries or edges of objects. Generally, attenuation produces an exponential decrease in the wave amplitude. For plane wave propagation along the x direction, we may write

$$u(x, t) = u_0 e^{-\alpha x} e^{i(kx-\omega t)} \tag{7.24}$$

where α is the attenuation coefficient. It is generally assumed that the contributions from all sources to the attenuation is additive such that $\alpha = \alpha_{\mathrm{abs}} + \alpha_{\mathrm{sc}} + \alpha_{\mathrm{diff}} \ldots$ where the subscripts refer to the absorption, scattering, and diffraction contributions, respectively.

7.4.1
Scattering

Generally, scattering refers to the redirection of wave energy from the original propagation direction or equivalently to the deviation of a ray or pencil of ultrasound from a straight path. Scattering may be classified into geometric contributions and diffraction-based contributions (Überall, 1997). Geometric contributions include specular reflections, transmission, refraction, and internal reflections of ultrasonic waves. Diffraction-based contributions refer to phenomena whereby an inhomogeneity in the path of a sound wave produces secondary waves spreading out from the inhomogeneity in various directions. Generally, an inhomogeneity refers to any object or region in the wave propagation path that exhibits a difference in density or elastic properties from that of the incident wave propagation medium. The object could be, for example, a defect in a crystal, a region of atmospheric turbulence, a fish in the ocean, or a tumor in the brain. Geometric scattering was considered in Section 7.3.1. We consider here general diffraction-based scattering. Diffraction is treated in Section 7.4.2.

If the region of inhomogeneity (having characteristic dimensions of order d) is small compared to the wavelength λ of the incident wave (i.e., $kd \ll 1$), the scattering is called *Rayleigh scattering*. The general features of Rayleigh scattering may be obtained from the consideration of constant frequency plane waves propagating along the direction $\boldsymbol{e}_k = \boldsymbol{k}/|\boldsymbol{k}|$ ($\boldsymbol{k}$ is the wave number vector) that impinge on a rigid immovable object centered at the origin of the coordinate system. The total acoustic pressure is $p = B\ \exp(i\boldsymbol{k}\bullet\boldsymbol{x}) + p_{\mathrm{sc}}(\boldsymbol{x})$, where B is the amplitude of the incident wave and $p_{\mathrm{sc}}(\boldsymbol{x})$ is the complex amplitude of the scattered wave. A rigid scattering surface imposes the requirement that $\nabla p\bullet\boldsymbol{n} = 0$ at the surface S of the scatterer, where $\boldsymbol{n}$ is the unit normal pointing outward from the surface (Pierce, 1989). Substituting the total acoustic pressure equation into the boundary condition gives $\nabla p_{\mathrm{sc}}\bullet\boldsymbol{n} = -iB[\exp(i\boldsymbol{k}\bullet\boldsymbol{x})](\boldsymbol{k}\bullet\boldsymbol{n})$. Thus, the scattered wave field may be viewed as that of a radiating body of the same size and shape as that of the scatterer with an amplitude that is the negative of that associated with the incident wave field.

For a small wavenumber, we may expand the exponential in the above equation in a power series to first order in k and integrate the results over the surface of the scatterer. The procedure yields the results (Pierce, 1989) $p_{\mathrm{sc}} = p_{\mathrm{sc}}$, mono $+p_{\mathrm{sc}}$, dipole. The term $p_{\mathrm{sc,mono}} = -(k^2 BV/4\pi)[\exp(ikr)/r]$, where r is the radial coordinate and V is the scatterer volume of order d^3, is due to monopole radiation. The term $p_{\mathrm{sc,dipole}} = (k^2 B/4\pi)\{\boldsymbol{e}_r \bullet \boldsymbol{M} \bullet \boldsymbol{e}_k[(1+(i/kr)]\}[\exp(ikr)/r]$, is due to dipole radiation. The factor $\boldsymbol{M}$ is a tensor, which scales as d^3, that is dependent on the scatterer size and shape. The sum of the monopole and the dipole terms produces a far-field scattered wave amplitude that scales as $(k^2 d^3/r)$. Thus, both the monopole and the dipole radiations are dependent on the square of the wavenumber (or frequency). Because the intensity of the scattered sound wave is proportional to the square of the pressure, the intensity of the scattered wave field is then dependent on the fourth power of the sound frequency. This strong dependence on the frequency in Rayleigh scattering has an analog in optics and leads to an explanation of why the sky is blue: higher frequency blue light scatters more than lower frequency red light.

In the limit $kd \gg 1$ (high frequencies), geometric scattering dominates and the scattering is more appropriately calculated in terms of impedance ratios described in Section 7.3. The transition region between the low- and the high-frequency limits is not easily assessed in terms of simple expressions. For wavelengths of the same magnitude as the dimensions of the scatterer, the scattered waves form complex patterns that must be calculated numerically. Figure 7.4 shows the angular distribution of scattered energy for waves incident from the left onto a sphere of radius d for $kd \ll 1$ (Rayleigh scattering), $kd = 6$, and $kd \to \infty$.

Relative motion between the scattering object (viewed as a source of sound) and the sound receiver causes a shift in the frequency of sound received relative to that of the source. This change in frequency is called the *Doppler shift* and can be understood by reference to Figure 7.5. We consider a sound source fixed in reference frame 2 moving with a velocity $\boldsymbol{V}_{21}$ relative to a sound receiver fixed in reference frame 1. A point vector $\boldsymbol{x}_1$ referred to frame 1 is related to a point vector $\boldsymbol{x}_2$ referred to frame 2 by the Galilean transformation $\boldsymbol{x}_1 = \mathbf{x}_2 + (t - t_0)\boldsymbol{V}_{21}$, where at $t = t_0, \boldsymbol{x}_1 = \boldsymbol{x}_2$. We describe the phases of the same sound disturbance in each of the two reference frames by $\phi_1(\boldsymbol{x}_1, t)$ and $\phi_2(\boldsymbol{x}_2, t)$. The wave vector $\boldsymbol{k}$ in either frame is defined by $\boldsymbol{k} = -\boldsymbol{\nabla}\phi$ and the angular frequency $\omega = \partial\phi/\partial t$. For the same sound disturbance, we must have $\phi_1(\boldsymbol{x}_1, t) = \phi_1(\boldsymbol{x}_2 + (t - t_0)\boldsymbol{V}_{21}, t) = \phi_2(\boldsymbol{x}_2, t)$. Differentiation of this expression with respect to the spatial and time coordinates, respectively, yields the relations $\boldsymbol{k}_1 = \boldsymbol{k}_2$ and $\omega_2 = \omega_1 - \boldsymbol{k}_1 \bullet \boldsymbol{V}_{21}$.

We first consider the case where reference frame 1 (with fixed receiver) is stationary relative to the sound propagation medium and frame 2 (with fixed source) is moving through the propagation medium. Assuming that the source generates sound at frequency ω_0, we may write $\omega_2 = \omega_0$. Because the receiver is stationary in the propagation medium, we may also write that $\boldsymbol{k}_1 = (\omega/c)\boldsymbol{e}_R$, where c is the sound velocity and $\boldsymbol{e}_R$ is the unit vector determined at the instant of sound emission along the direction from the sound source to the receiver. We thus find $\omega_2 = \omega_0 = \omega_1 - \boldsymbol{k}_1 \bullet \boldsymbol{V}_{21} = \omega - (\omega/c)\boldsymbol{e}_R \bullet \boldsymbol{V}_{21}$. Solving this equation for ω, we obtain $\omega = \omega_0(1 - c^{-1}\boldsymbol{e}_R \bullet \boldsymbol{V}_{21})^{-1}$.

We now consider the case where reference frame 1 (with fixed receiver) is moving in the propagation medium and frame 2 (fixed sound source) is stationary in the propagation medium. Then we may write $\omega_2 = \omega_0$ and $\boldsymbol{k}_1 = \boldsymbol{k}_2 = (\omega_0/c)\boldsymbol{e}_R$. Thus $\omega_2 = \omega_0 = \omega - (\omega_0/c)\boldsymbol{e}_R \bullet \boldsymbol{V}_{21}$. Solving for ω, we obtain $\omega = \omega_0(1 + c^{-1}\boldsymbol{e}_R \bullet \boldsymbol{V}_{21})$. In each case, we find that the frequency

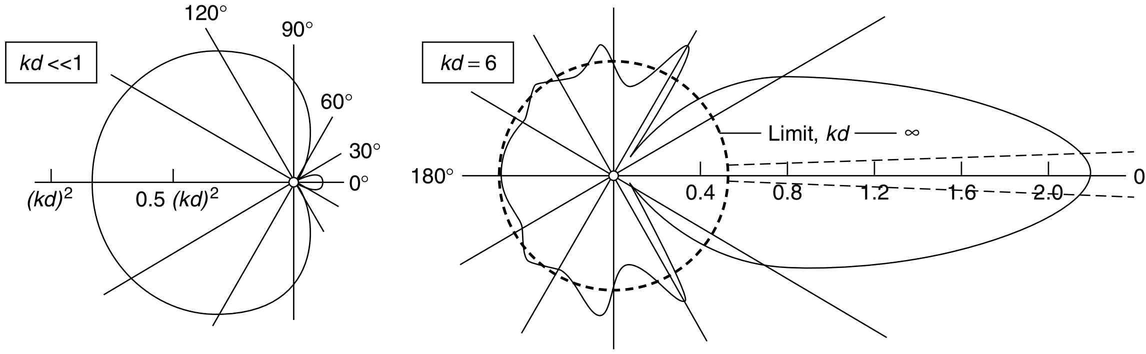

Fig. 7.4 Angular distribution of scattered wave energy for waves incident from the left onto a sphere of radius d for $kd \ll 1, kd = 6$, and $kd \to \infty$ (dotted curves). From Pierce, 1989.

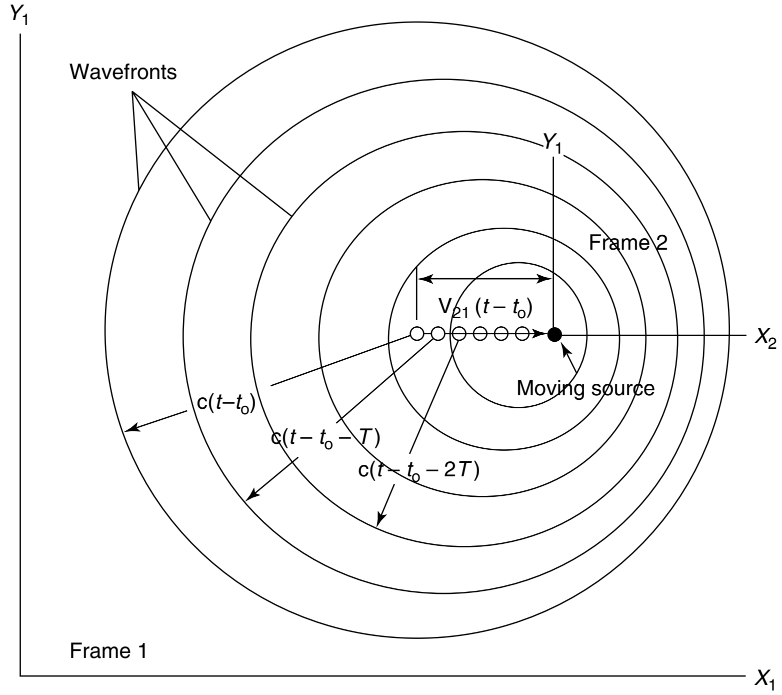

Fig. 7.5 Schematic of Doppler shifted crests of waveforms emitted with period T by source fixed in reference frame 2 moving at velocity V_{21} with respect to the propagation medium fixed in reference frame 1. Adapted from Pierce, 1989.

increases if the source and receiver are moving toward each other and decreases if the source and receiver are separating. The magnitude of frequency shift is determined by the component of the relative velocity along $\boldsymbol{e}_R$.

In many applications, a transmitting transducer fixed in a propagation medium (reference frame 1) is used to transmit sound to a scatterer fixed in a second propagation medium (reference frame 2) moving relative to reference frame 1 with velocity $\boldsymbol{V}_{21}$. A receiving transducer also fixed in frame 1 is then used to receive the scattered sound waves. The boundary between propagation media 1 and 2 is assumed to occupy well-defined instantaneous positions with respect to frame 1. With respect to the scatterer fixed in frame 2, the sound waves incident and scattered at the scatterer have the same frequency ω_2. However, with respect to frame 1, the transmitter frequency is $\omega_{\mathrm{tr}} = \omega_2 + \boldsymbol{V}_{21}\bullet\boldsymbol{k}_{1\mathrm{tr}}$ and the receiver frequency is $\omega_{\mathrm{rec}} = \omega_2 + \boldsymbol{V}_{21}\bullet\boldsymbol{k}_{1\mathrm{rec}}$, where $\boldsymbol{k}_{1tr}$ and $\boldsymbol{k}_{1\mathrm{rec}}$ are the transmitted and received wave vectors referred to frame 1. Eliminating ω_2 from these two equations yields the frequency shift between the transmitted and received signals as $(\omega_{\mathrm{rec}} - \omega_{\mathrm{tr}}) = \boldsymbol{V}_{21})\bullet\boldsymbol{k}_{1rec} - \boldsymbol{k}_{1\mathrm{tr}})$. Typical applications of Doppler frequency shift measurements include the assessment of flow velocities and fluid volume flowing per unit time in blood vessels ducts and tubes, the remote sensing of tropospheric wind velocities, and the measurement of subsurface ocean current velocities.

7.4.2
Diffraction

Generally, diffraction refers to scattering that occurs at the "edges" of objects. It also includes the influence of boundaries on radiation sources such as piston transducers. Mathematically, diffraction phenomena can be described in terms of monopole and dipole radiation patterns as is done with diffraction-based scattering phenomena generally (see Section 7.4.1). One of the most important applications of diffraction theory in ultrasonics is to account for beam spreading from circular transducers, the most common shape for ultrasonic sources.

Because the transducer is of finite size, the acoustic wave generated in the sample spreads out into a diffraction field that leads to an attenuation of the wave along the original propagation direction and to errors in velocity and source amplitude measurements if not corrected. The effects of diffraction are usually treated for the case of circular, axially concentric transmitting and receiving transducers of the same radius r. The transmitting transducer is treated as a finite piston source in a semi-infinite medium. The acoustic field is found at each point in the propagation medium and an integration is performed over the area in the field presented by the receiving transducer. In one treatment (Benson and Kiyohara, 1974), the effects of diffraction can be represented for waves of wavelength λ propagating along the z direction in an isotropic medium by the expression $u(z, t) = 2(I_x^2 + I_y^2)^{1/2}\cos[kc_p t - kz - \phi]$, where $\phi = \tan(I_y/I_x)$ and the quantities Ix and Iy are integral functions of the dimensionless parameter $S = z\lambda/r^2$.

These equations show that the diffraction involves an intensity variation in the diffraction pattern and a distortion of the otherwise planar wave front. Phase variations in the surface plane of the receiving transducer give rise to interference effects and a loss in signal (attenuation) when integrated over a phase-sensitive transducer surface. The factor ϕ in the above equation produces a variation in the phase of the propagating wave that results in an error in the velocity measurements, if not properly corrected.

A useful aspect of diffraction occurs for the focusing of sound fields from curved transducers. The field of a focused sound beam has diffraction characteristics similar to that of a plane piston transducer. Along the axis of the curved transducer, the intensity of the sound field goes through a series of maxima and minima in accordance with the interference patterns produced by diffraction. The maximum intensity occurs at an interference maximum corresponding to the focal zone of the transducer.

7.4.3
Relaxation Processes

The propagation of sound waves based on Hooke's Law is such that the stress (or pressure) at any point in the body is a linear function only of the instantaneous strain (or mass density) at that point. Upon removal of the stress, the strain fully and instantly recovers. The reversibility of the elastic deformation means that no dissipation or loss of energy in the wave occurs and that the wave propagates indefinitely. However, wave propagation in real materials always exhibits an amplitude loss resulting from the conversion of acoustic energy into other forms. Such conversions may involve, for example, thermal motion, the vibration or rotation of atoms in a molecule, structural rearrangements (including chemical reactions and electrolytic processes), or the motion of lattice constituents such as dislocations, point defects, and so on. The energy dissipation destroys the isentropic character of the sound propagation (although it may still be adiabatic) and requires the formalism of irreversible thermodynamics for a proper description.

7.4.3.1 **Relaxation in Solids**

We consider a process described by the reaction (Beyer and Letcher, 1969) $n_1 + n_2 + \ldots + n_k \leftrightarrow n_{k+1} + n_{k+2} + \ldots + n_m$, where $n_i (i \le k)$ is the number of moles of the ith reactant and $n_i (i > k)$ is the number of moles of the ith product involved in the reaction. The reaction process is driven by the acoustic wave and may describe, for example, the excitation of higher vibrational or rotational states of a gas or the jumping of interstitial atoms in a solid lattice to a new equilibrium site. We account for such reactions by modifying the internal and Helmholtz free energies per unit mass to include a dimensionless quantity ξ describing the extent to which the reaction has taken place. This variable, called the *degree of reaction*, ranges from a value of 0 when the state of the system is all reactant to a value of 1 when the state of the system is all product. In analogy to Equation (7.4), we may expand the modified internal energy per unit mass $U(\boldsymbol{a}, \eta_{ij}, S, \xi)$ to first order in all variables as

$$\begin{aligned} U(a, \eta_{ij}, S, \xi) &= U(a, 0, S_0, \xi_0) + \frac{1}{\rho_0} C^S_{ij} \eta_{ij} + \frac{1}{2\rho_0} C^S_{ijkl} \eta_{ij} \eta_{kl} \\ &\quad + T(S - S_0) + A(\xi - \xi_0) + \cdots \end{aligned} \tag{7.25}$$

The constant $A = (\partial U / \partial \xi)_{\eta, S}$ is called the *affinity* for the reaction and is related to n_i as $A = \Sigma (\mu_{CP})_i n_i$, where $(\mu_{CP})_i$ is the chemical potential for the reaction leading to a change in n_i.

It can be established from thermodynamic considerations (Beyer and Letcher, 1969) that (i) if $Ad\xi > 0$, where $d\xi$ is a small variation in ξ, then the process naturally occurs and will take place; (ii) if $Ad\xi = 0$, the process is reversible; and (iii) if $Ad\xi < 0$, the process cannot occur by itself. Thus, the value $A = 0$ corresponds to equilibrium at some value ξ_0 of the degree of reaction. Acoustically, equilibrium corresponds to zero frequency. Displacements from equilibrium result in natural system forces reacting to restore equilibrium such that the displacement rate $(d\xi / dt) = bA$, where b is a constant. A constant ξ occurs when the acoustic frequency is so large that the system cannot follow the amplitude changes in the sound wave.

It is clear that irreversible thermodynamics requires the independent thermodynamic variable ξ in addition to the usual reversible thermodynamic variables. As in reversible thermodynamics, the irreversible thermodynamic "variables" σ_{ij}, η_{ij}, T, S, A, and ξ are not completely independent, but are related, for example, through Equation (7.25). Any of the irreversible thermodynamic "variables" may be expressed in terms of any three other irreversible thermodynamic "variables." Thus, the affinity A, although introduced as a constant in Equation (7.25) (as is the temperature T), may also be regarded as a variable in a different thermodynamic state equation. In particular, the affinity may be regarded as a function of σ_{ij}, S, and ξ, which can be expanded in a triple Taylor series about the equilibrium point $A[(\sigma_0)_{ij}, S_0, \xi_0] = 0$. Performing the expansion to first order, using standard relations among partial derivatives, and recombining terms, we obtain the relation (Bauer, 1965)

$$A(\sigma_{ij}, S, \xi) = \left(\frac{\partial A}{\partial \xi}\right)_{\sigma,\mathrm{S}} [\xi - \xi'(\sigma_{ij}, S)] \tag{7.26}$$

$$\xi'(\sigma_{ij}, S) = \xi_0 + \left(\frac{\partial \xi}{\partial \sigma_{ij}}\right)_{\mathrm{A,S}} [\sigma_{ij} - (\sigma_0)_{ij}] + \left(\frac{\partial \xi}{\partial S}\right)_{\mathrm{A},\sigma} (S - S_0) \tag{7.27}$$

where the subscripted zero denotes the initial value of the parameter. Substituting Equation (7.26) into the rate equation $(d\xi/dt) = bA$, holding the stress and entropy constant, and integrating, we obtain

$$\xi = \xi'(\sigma_{ij}, S) + const \cdot \exp(-t/\ \tau_{\sigma\mathrm{S}})$$

$$\tau_{\sigma\mathrm{S}} = -(1/\ b)(\partial\xi\ /\ \partial A)_{\sigma\mathrm{S}} \tag{7.28}$$

The parameter $\tau_{\sigma S}$ is the relaxation time for processes in which the stress and entropy remain constant. A corresponding relaxation time $\tau_{\eta S}$ may defined for processes in which the strain and entropy remain constant. The two time constants are related as $(\tau_{\sigma S}/\tau_{\eta S}) = (M_\infty/M_0) = (c_\infty/c_0)^2$, where M_∞ is the appropriate modulus (combination of elastic constants) and c_∞ is the sound speed at infinitely large frequency; M_0 is the modulus and c_0 is the sound speed in the limit of zero frequency.

Combining the above triple Taylor series expansion of $A(\sigma_{ij}, S, \xi)$ with a similar expansion of the strain $\eta_{ij}(\sigma_{ij}, S, \xi)$ and performing several transformations of partial derivatives, we obtain the equation of state for a given propagation mode in the form

$$\tau_{\sigma\mathrm{S}}\frac{\partial \varepsilon}{\partial t} + \varepsilon = \frac{\tau_{\sigma\mathrm{S}}}{M_\infty}\frac{\partial \sigma}{\partial t} + \frac{1}{M_0}(\sigma - \sigma_0) \tag{7.29}$$

where ε and σ denote (quasi)longitudinal or (quasi)shear strains and stresses, respectively, as appropriate. Combining Equation (7.29) with Newton's Law in the form $(\partial^2\sigma/\partial a^2) = \rho_0(\partial/\partial t)(\partial\varepsilon/\partial t) = \rho_0$ $(\partial^2\varepsilon/\partial t^2)$ and using the relation $(\tau_{\sigma S}/\tau_{\eta S}) = (M_\infty/M_0)$, we obtain the wave equation

$$\frac{\partial^2\psi}{\partial t^2} + \tau_{\sigma\mathrm{S}}\frac{\partial^3\psi}{\partial t^3} = \frac{M_0}{\rho_0}\left(\frac{\partial^2\psi}{\partial a^2} + \tau_{\eta\mathrm{S}}\frac{\partial^3\psi}{\partial a^2\partial t}\right) \tag{7.30}$$

where ψ denotes either σ or ε.

We assume harmonic waves of the form $\psi = \psi_0\exp[i(k'a - \omega \mathrm{t})$, where $k' = k + i\alpha = (\omega/c) + i\alpha$ is the attenuation coefficient, and $c = (\omega/k)$ is the phase velocity of the sound wave. Substituting this form into Equation (7.30) and defining $\tau = (\tau_{\sigma S}\tau_{\eta S})^{1/2}$, we obtain that the phase velocity is given by

$$c = \frac{\omega}{k} = \left[\frac{M_\infty}{\rho_0}\left(1 - \frac{\Delta M\ /\ M_\infty}{1 + \omega^2\tau^2}\right)\right]^{1/2} \tag{7.31}$$

where the relaxation strength ε_r is defined by

$$\varepsilon_\mathrm{r} = \frac{\Delta M}{M_\infty} = \frac{M_\infty - M_0}{M_\infty} = \frac{c_\infty^2 - c_0^2}{c_\infty^2} \tag{7.32}$$

and the wave attenuation (absorption) coefficient α is given by

$$\alpha = \frac{\omega^2(\tau_{\eta\mathrm{S}} - \tau_{\sigma\mathrm{S}})}{2c(1 + \omega^2\tau^2)} \approx \frac{1}{2}\varepsilon_r\frac{\omega^2\tau}{1 + \omega^2\tau^2} \times \left(\frac{\rho_0}{M_\infty}\right)^{1/2} \tag{7.33}$$

Relaxation in solids can result from a number of different mechanisms. The diversity of mechanisms include atomic movement by diffusion, stress-induced ordering whereby point defects producing a localized strain will move from one state of equilibrium to another under the action of a sound wave, thermoelastic loss involving heat flow between hot and cold regions of the sound field, Bordoni peaks in metals involving the "jumping" of dislocation segments between equilibrium positions, and Akhieser loss in which time-varying strains continually change the equilibrium conditions for the thermal phonon distribution in the solid (Berry and Nowick, 1966).

7.4.3.2 **Relaxation in Fluids**

For a fluid medium, we again assume that the stress σ_{ij} is the thermodynamic pressure p obtained as $\sigma_{ij} = -p\delta_{ij}$. Assuming small variations in the mass density ρ about the initial mass density ρ_0 in Equation (7.1) and using the isotropic symmetry properties of the elastic constants, we may recast Equation (7.29) in the form

$$\tau_{\mathrm{pS}}\frac{\partial\rho}{\partial t} + \rho - \rho_0 = \frac{\tau_{\mathrm{pS}}}{c_\infty^2}\frac{\partial p}{\partial t} + \frac{1}{c_\infty^2}(p - p_0) \tag{7.34}$$

where we have used the relation $(t_{\mathrm{pS}}/\tau_{\rho S}) = (M_\infty/M_0) = (B_\infty/B_0) = (c_\infty/c_0)^2$, where B is the bulk modulus. Combining Equation (7.34) with Newton's law and assuming harmonic wave propagation as before, we obtain that the absorption coefficient at unit wavelength $\alpha\lambda$, where λ is the wavelength given as

$$\alpha\lambda = \left(\frac{c^2}{c_0^2}\right)\varepsilon_{\mathrm{r}}\frac{\pi\omega\tau_{\mathrm{pS}}}{1+\omega^2\tau_{\mathrm{pS}}^2} \tag{7.35}$$

where ε_r is the relaxation strength given by Equation (7.32). The phase velocity c is given by

$$\frac{c^2}{c_0^2} = \frac{1+\omega^2\tau_{\mathrm{pS}}^2}{1+\left(c_0^2\big/c_\infty^2\right)\omega^2\tau_{\mathrm{pS}}^2} \tag{7.36}$$

If we define $\tau = (\tau_{pS}\tau_{\rho S})^{1/2}$, then

$$\frac{c^2}{c_0^2} = 1 + \left(\frac{\varepsilon_{\mathrm{r}}}{1-\varepsilon_{\mathrm{r}}}\right)\left(\frac{\omega^2\tau^2}{1+\omega^2\tau^2}\right) \tag{7.37}$$

which can be recast in the form of Equation (7.31) using the definition of ε_r, Equation (7.32).

In the case of gases, the relaxation phenomena are often recast in terms of heat capacities. The ideal gas is assumed to consist of identical molecules all of which are capable of being excited into different energy states each characterized by specific energy differences per mole. The relaxation strength for ideal gases is often written as $\varepsilon_r = (C_p^0/C_p^\infty)[(C_\rho^\infty/C_\rho^0) - (C_p^\infty/C_p)]$, where the $C_p^j (j = 0, \infty)$ are the appropriately indicated heat capacities. An understanding of the physical phenomena involved for a given gas is obtained from an examination of the physical models used for the relaxation processes. It is generally assumed in gases that equilibrium involves collisions among pairs of molecules, so that the reaction rate (reciprocal of relaxation time) is directly proportional to the product of the probability that an excited molecule will lose its energy in a given collision and the average collision frequency. In an ideal gas, the collision frequency is a linearly proportional gas density or pressure, so the relaxation time $\tau \sim 1/p_0$. Thus, $\omega\tau \sim \omega/p_0$ and the absorption coefficient α and the phase velocity c are functions of the ratio of the sound frequency to gas pressure. Experimentally, this means that data can be taken equivalently as a function of sound frequency or gas pressure.

In liquids, the modeling is complicated by the fact that, unlike gases, the molecular collisions are not generally binary but involve both nearest neighbor and next nearest neighbor molecules. The collision rate in liquids is also usually much higher than in gases. This raises the relaxation frequency in most cases to ranges above that is experimentally attainable. Further, the number of vibrational states in liquids is considerable, complicating the relaxation processes. Nonetheless, the application of relaxation concepts has proven useful in connection with theories of the liquid state, and vibrational relaxations have been discovered in numerous liquids. The nature of the relaxation processes involved has been accurately established for liquids with rotational isomers. Generally, the attenuation in viscous fluids and in some biological tissues is proportional to the frequency or to some power of the frequency that is less than one. For more details, see Beyer and Letcher (1969) and Bauer (1965).

7.4.3.3 **Viscoelasticity**

Historically, viscoelasticity was introduced before the constructs of irreversible thermodynamics were established. The classical Maxwell (1867), Kelvin (1875) and Voigt (1892) models of viscoelasticity and the Zener (1948) anelastic solid model were based on various mathematical combinations of elastic and flow elements of the material. The elastic behavior is represented by springs and the viscous behavior is represented by a dashpot in these models. Although each of the classical models can be obtained from the more general relaxation model based on irreversible thermodynamics, it is instructive to consider each model independently.

Maxwell Material The Maxwell model (1867) was introduced to explain the behavior of fluids whereby the fluid responds to an applied shear stress with both elasticity and flow. Maxwell combined Hooke's law, $\sigma_{12} = G\varepsilon_{12}$, where σ_{12} is the shear stress, ε_{12} is the shear strain, and G is the shear modulus, with Newton's law for a viscous fluid, $\sigma_{12} = \mu(d\varepsilon_{12}/dt)$, where μ is the shear viscosity coefficient. He obtained the equation

$$\frac{d\varepsilon_{12}}{dt} = \frac{1}{G}\frac{d\sigma_{12}}{dt} + \frac{1}{\mu}\sigma_{12} \tag{7.38}$$

Using the relation $(\tau_{\sigma S}/\tau_{\eta S}) = (M_\infty/M_0) = (G_\infty/G_0)$ in Equation (7.29) and comparing the resulting expression with Equation (7.38) reveals that $G = G_\infty$ and that $\mu = \tau_{\eta S}G_\infty$. Assuming sinusoidal variation in σ_{12} and ε_{12} (i.e., sinusoidal wave propagation) and recalling the definition of the shear modulus (Hooke's law), we find from Equation (7.38) that

$$G = G_\infty \frac{\omega^2\tau_{\eta S}^2}{1+\omega^2\tau_{\eta S}^2} + iG_\infty \frac{\omega\tau_{\eta S}}{1+\omega^2\tau_{\eta S}^2} \tag{7.39}$$

Because the shear modulus G is complex, the sound velocity is also complex and gives rise to an attenuation of the sound wave along the propagation path. At very high frequencies, $G \to G_\infty$ and the fluid exhibits a shear rigidity that allows shear wave propagation. At very low frequencies, $G \to 0$ and the fluid loses its solidlike properties. Maxwell's model has been successfully applied to the characterization of the shear properties of such substances as pitch, simple liquids, and polymers.

Kelvin-Voigt Material Kelvin (1875) and Voigt (1892) independently suggested that

Hooke's law be modified to include a contribution from the strain rate as

$$\sigma_{ij} = C^S_{ijkl}\varepsilon_{kl} + \mu_{ijkl}\frac{\partial \varepsilon_{kl}}{\partial t} \qquad (7.40)$$

where μ_{ijkl} is the viscosity tensor. Substituting Equation (7.40) into Newton's law and assuming isotropic symmetry, we obtain the following equation (using Lamé elastic constants) for longitudinal wave propagation:

$$\rho_0\frac{\partial^2 u_1}{\partial t^2} = (\lambda + 2G)\frac{\partial^2 u_1}{\partial a_1^2} + (\chi + 2\mu)\frac{\partial^3 u_1}{\partial a_1^2 \partial t} \qquad (7.41)$$

where χ is the compressional viscosity coefficient.

We assume a plane harmonic wave disturbance of the form $u_1 = w_1 \exp[i(k'a - \omega t)]$, where the wave number $k' = k + i\alpha = (\omega/c_1) + i\alpha$, α is the attenuation coefficient, and c_1 is the longitudinal velocity. Substituting this form into Equation (7.41) and solving for c_1 and α gives $c_1 = [(\lambda + 2G)/\rho_0]^{1/2}$ as before and

$$\alpha \approx \frac{\omega^2(\chi + 2\mu)}{2\rho_0 c_1^2} \qquad (7.42)$$

A similar procedure for shear waves in isotropic materials yields the values $c_2 = (G/r_0)^{1/2}$ for the shear wave velocity and

$$\alpha \approx \frac{\omega^2 \mu}{2\rho_0 c_1^2} \qquad (7.43)$$

for the shear wave attenuation coefficient.

7.5
Wave Dispersion

The dependence of sound velocity on wavelength, such as that arising from modal propagation in waveguides, for example, is known as *wave dispersion*. A wave disturbance of finite duration such as an ultrasonic pulse or toneburst (a gated cw) may be viewed as composed of an integrated sum of monochromatic waves where the integration is performed over a continuous range of infinitesimally differing frequencies of the waves. In a linear, dispersive, propagation medium, the acoustic waveform $u(x,t)$ at position x and at time t in the medium is given by the expression (Whitham, 1974)

$$u(x,t) = F(x,t)e^{i\Omega(x,t)} + c.c.$$
$$\Omega(x,t) = kx - \omega t \qquad (7.44)$$

where *c.c.* denotes the complex conjugate of the preceding term providing

$$\frac{d\omega}{dk} - \frac{x}{t} = 0$$
$$\frac{d^2\,\omega}{dk^2} \neq 0 \qquad (7.45)$$

where ω is the angular frequency. The functional dependence of angular frequency on wave number k defines the dispersion relation $\omega = \omega(k)$. The condition $(d^2\omega/dk^2) \neq 0$ is the defining condition for a dispersive propagation medium and $(d\omega/dk) = c_g$ is defined to be the group velocity. For a given choice of x and t, Equation (7.45) may be solved for k if the dispersion function $\omega(k)$ is known. Thus, different parts of the waveform, corresponding to different given pairs (x, t), propagate with different group velocities $c_g(k)$ corresponding to specific wave numbers determined from Equation (7.45). The group velocity corresponds to the velocity of energy propagation of the wave (Whitham, 1974; Pierce, 1989).

Both the complex amplitude $F(x, t)$ and the phase function $\Omega(x,t)$ in Equation (7.44) are functionally dependent on x and t. Equation (7.44) has the form of an elementary waveform, but $F(x, t)$

is actually a position- and time-varying envelope of the waveform with the position- and time-varying phase $\Omega(x, t)$ defining nonuniformly spaced maxima and minima of the wave. Equation (7.44) thus defines a disturbance, which in general changes shape during its propagation through a dispersive medium.

The propagation of a given constant value of phase Ω_o defined by $\Omega(x, t) = \Omega_o$ moves with the phase velocity $c_p(x, t) = dx/dt = \omega/k$. The phase velocity $c_p(x, t)$ is generally different for different values of Ω_o and for different values of x and t. An observer following a particular phase (e.g., crest of a wave) moves with the local phase velocity having a locally varying frequency and wave number. Thus, the phase velocity of a wave of finite length propagating in a dispersive medium can only be defined locally (i.e., for given x and t) and for a given phase Ω_o. Hence, if a given pulse measurement technique (see Section 7.7) follows a given phase Ω_o of the waveform at different monotonically increasing or decreasing values of the space-time coordinates (x_i, t_i), then the local phase velocity at (x_α, t_α) for phase Ω_o can be obtained by plotting x_i as a function of ti and measuring the tangent to the curve at (x_α, t_α). For dispersive media, the curve is generally nonlinear, but for nondispersive media the curve is linear and coincides with the curve for the group velocity, $c_g = x/t$. But in general, the group velocity is related to the phase velocity as $c_g = c_p - \lambda(dc_p/d\lambda)$, where λ is the phase velocity wavelength (Pollard, 1977).

7.6
Ultrasonic Generation and Detection

The generation and detection of ultrasonic waves can be achieved using a variety of methods. One of the earliest and simplest methods for generating ultrasound was the Galton whistle, which produced sound waves in air by blowing high-pressure air against a sharp metal edge. Some methods require direct physical contact between the ultrasonic source and the propagation medium and are usually, but not always, associated with piezoelectric generation and detection of sound. Other methods, not requiring direct contact, are found to be useful in some applications.

7.6.1
Piezoelectric Transducers

When a mechanical stress σ_{ij} is applied to a piezoelectric crystal, an electric polarization P_i is produced according to the relation $P_i = d_{ijk}\sigma_{jk}$, where d_{ijk} are the piezoelectric coefficients. Similarly, when an electric field E_i is applied to a piezoelectric crystal, a strain ε_{jk} is produced in the crystal according to the relation $\varepsilon_{jk} = d_{ijk}E_i$. Thus, piezoelectric crystals can both generate and detect sound waves.

Although there are in general 27 piezoelectric coefficients, the crystal symmetry considerably reduces the number. Quartz, for example, has only five independent coefficients. If the quartz is cut such that a compressive stress σ_{11} occurs along the x (a_1) axis, then $P_1 = d_{111}\sigma_{11}$, $P_2 = P_3 = 0$. The electric polarization is also along the x axis. Conversely, if an electric filed is applied along the x axis, the resulting strains include a component $\varepsilon_{11} = d_{111}E_1$. Thus, the same piezoelectric crystal can be used to generate and detect compressional sound waves.

Generally, piezoelectric crystals can be cut in specific ways to generate and detect compressional waves or shear waves. The fundamental frequency of vibration f_1 for thickness longitudinal modes is

$f_1 = (1/2L_x)(c_{11}/\rho_0)^{1/2}$, where L_x is the thickness of the crystal along the x direction and c_{11} is the elastic coefficient. For shear modes, the fundamental vibration is determined from $f_1 = (1/2L_y)(c_{44}/\rho_0)^{1/2}$, where L_y is the thickness of the crystal along the y direction. Harmonics of the fundamental frequency in each case may be generated, but only for odd multiples of the fundamental. This occurs because the strain changes sign for each half wavelength and the polarization can be detected only when opposite charges appear at the opposing crystal surfaces.

Other single crystal materials used for piezoelectric transducers include ethylene diamine tartrate (EDT), sodium potassium tartrate (Rochelle salt), dipotassium tartrate (DKT), and ammonium dihydrogen phosphate (ADP).

Polycrystalline ceramic materials such as barium titanate, lead zirconate titanate (PZT), lead metaniobate, and sodium metaniobate have also been popular materials for ultrasonic transducers. In contrast to inherently piezoelectric materials such as quartz, these ferroelectric ceramics are initially isotropic. Because an essential feature of piezoelectricity is the absence of a center of crystallographic symmetry, the ceramics must be electrically polarized above the Curie temperature to induce the anisotropy in the materials responsible for the piezoelectric properties. A particular advantage of these materials is that the transducer can be made in a variety of shapes and focusing forms. Further, the resonances of the polycrystalline ceramic transducers (low Q value) are generally much less sharp than those of single crystal materials (high Q value). If sound absorbing material is added to the back of the ceramic material, the resonance will be flattened even more. This occurs because waves propagating in the backward direction will be eliminated from the superposition of resonance-forming waveforms (see Section 7.3.2). The result is a transducer having a broadband frequency capability for both generating and receiving sound.

High-frequency transducers made from thin film zinc oxide and cadmium sulfide deposited on a base material are capable of generating waves with frequencies in the pretersonic range of frequencies. Piezoelectric polymer film transducers such as polyvinylidene fluoride (PVDF) have a broad frequency bandwidth that is advantageous for use with short pulses. For more information on piezoelectricity, see Berlincourt, Curran, and Jaffe (1964) and O'Donnell, Busse, and Miller (1981).

7.6.2
Noncontacting Methods

In many applications, it is desirable to generate and detect sound by methods that are not in direct physical contact with the material to be measured. These applications may include, for example, materials for which the temperature is too high, materials that are too corrosive, or materials that are too inaccessible to use contacting transducers. A variety of noncontacting generation and detection techniques have been developed for such situations.

7.6.2.1 Capacitive Transducers

For solids, the capacitive transducer (also called the electrostatic acoustic transducer or ESAT) is a simple parallel plate arrangement in which a flat sample surface functions as the ground plate. The other plate is a flat electrode recessed (typically of the order $7-10\,\mu\text{m}$) from the sample surface. A dc bias V_b (typically 50–150 V) is applied through a large resistor to the electrode. An ultrasonic wave incident at the solid surface varies the gap spacing (hence capacitance) of the parallel plate arrangement. The measured output voltage V_{out} from this arrangement is related to the displacement amplitude u of the incident wave amplitude u as $V_{\text{out}} = V_{\text{b}}(2us^{-1})$, where s is the gap spacing between the plates in the absence of the sound wave. The capacitive transducer for solids has a flat frequency response from dc to well into the gigahertz range of frequencies.

The capacitive transducer may also be used as a sound generator by applying an ultrasonic drive voltage across the electrodes, which produces an electric field E at the sample surface. The resulting electrical force per unit area σ at this surface is $\sigma = (1/2)\varepsilon_0 E^2$, where ε_0 is the dielectric permittivity of air. For a sinusoidal drive voltage $E = E_0 \sin \omega t$, the driving stress $\sigma = (1/4)\varepsilon_0 E_0^2(1 - \cos 2\omega t)$. Thus, the driving stress and resulting ultrasonic wave have a frequency that is twice that of the driving voltage. Typically, in a capacitive driving transducer, a material with a high dielectric permittivity such as mica is sandwiched between the electrodes. The material allows higher drive fields to be obtained without electrical breakdown.

A capacitive transducer for immersion in liquids is generally constructed by stretching a conductive membrane over an electrically isolated, dc biased, cylindrical electrode again recessed approximately $10\,\mu$m from the membrane inner surface. Unlike the capacitive transducer for solids, the liquid immersible capacitive transducer does not have a flat frequency response. In the ultrasonic range of frequencies, the inertia of the membrane and the coupling to the fluid produces a frequency roll-off that varies as $[1 + (\sigma_A \omega/Z)]^{-1/2}$, where σ_A is the area density of the membrane and Z is the acoustic impedance of the immersion fluid (Cantrell and Yost, 1989).

7.6.2.2 **Electromagnetic Acoustic Transducers (EMATs)**

A useful noncontacting transducer for generating SAWs in electrically conductive materials is the electromagnetic acoustic transducer (EMAT). The transducers are based on the body forces produced by the presence of both static and time-varying magnetic fields. Figure 7.6 shows one configuration for generating surface waves. An alternating current is passed through a flat meander coil held near the surface of the conductor and produces an alternating magnetic field in the conductor. If a static magnetic field is also produced in the conductor having the field lines parallel to the surface, Lorentz forces on the electrons within the conductive material will couple to the material lattice. The lattice coupling will serve as a source for the generation of surface waves propagating along the static field lines. The elementary sources represented by each meander coil wire segment add coherently, if the periodic distance between the parallel wire segments equals one half of the acoustic wavelength at the frequency of operation. For more information on EMATs, see Thompson (1990) and Frost, Sethares, and Szabo (1977).

7.6.2.3 **Laser Generation and Detection**

The generation of sound waves by incident optical laser radiation occurs by a number of mechanisms including radiation pressure, material vaporization, thermal expansion, Brillouin scattering, and electrostriction (due to electric polarization-induced movement of atoms into regions of different optical intensity). In most cases, the thermal

expansion mechanism dominates. If the incident laser energy is a pulse having energy E_0 that passes through a length L of a medium having an absorption coefficient α, then it can be qualitatively shown (Hutchins, 1988) that the resulting acoustic pressure amplitude p in the material is $p = K\beta cE_0\alpha/C_p$, where β is the volume expansion coefficient, C_p is the isobaric specific heat, c is the sound velocity, and K is a constant that depends on the configuration geometry and laser pulse shape. The details of the laser-induced acoustic pressure profile depends on whether the medium is solid or fluid, the shape of the acoustic source formed by the interaction of the laser light with the material, and the physical constraints placed on the propagation medium.

Laser detection of sound is commonly accomplished using an interferometric technique or a variation thereof. A variation useful for noncontact probing of pulsed SAWs is illustrated in Figure 7.7. Light from a laser is divided into two parallel and slightly separated collimated beams of equal intensity by a fixed beamsplitter. The beams are partially transmitted by a second beamsplitter and focused to points separated by a fixed distance on the surface of the specimen. Upon reflection, the beams are partially reflected by the second beamsplitter and superimposed to form a straight line interference pattern which is filtered with a spatial filter. This interferometer is sensitive to differential changes in the optical pathlengths of the two beams resulting from the passage of an SAW. The sound field causes a relative motion of the output fringe pattern with respect to the fixed spatial filter. For more information on optical detection of ultrasound, see Wagner (1990).

7.6.2.4 Modulated Particle Beam Generation

Atomic particles incident on a material surface lose their energy in scattering or collision processes with target atoms as they penetrate into the material. Although the ions accelerated through an electric field have been used as particle beam sources, more typically accelerated electrons are used. Electron beams formed by accelerating electrons through a potential V (in kilovolts) will lose most of their energy due to atomic scattering in a roughly spherically shaped region (the interaction volume) of radius $d_s = V^{1.43}/(10\rho_0)$, d_s in microns, (Reimer, 1979). The electron scattering results in thermal generation as well as in momentum transfer. A modulated or chopped electron beam source generates both a thermal wave and acoustic waves simultaneously. A number of bulk and SAW modes are generated including modes resulting from thermal-to-acoustic wave mode conversion and from the driving source of electron in the interaction volume itself. Their amplitudes depend on the intensities of the driving source and the thermal waves and on their gradients at the material boundaries (Qian and Cantrell, 1989).

7.7
Measurement Techniques

Measurements of sound velocity and attenuation can provide considerable information about the physical properties of solids, liquids, and gases. Measurement of the variation of the sound velocity as a function of some intrinsic material variable, such as temperature or pressure, provides additional information about basic (often nonlinear) material properties. It is important to distinguish between group and phase velocities in the measurements of velocity. This distinction was addressed in Section 7.5 in the context of acoustic propagation in a dispersive medium. Similarly, it is important to distinguish between absorption and other attenuation mechanisms in acoustic measurements as addressed in Section 7.4.

Numerous techniques have been reported in the literature for making velocity and attenuation measurements. The most common techniques are based on optical, pulse, and cw methods, or on hybrids of these methods. The choice of technique is dictated in part by the availability of equipment and ease of setup for the particular application, the specific material and ultrasonic properties of the material to be measured, and the accuracy and precision desired in the measurement. Here, we briefly consider only representative techniques. For more information on measurement methods, see the review articles by McSkimin (1964), Papadakis (1968, 1976), Breazeale, Cantrell, and Heyman (1981), and Cantrell and Yost (1997).

7.7.1
Pulse Techniques

Pulse techniques utilize either broadband acoustic pulses or gated continuous acoustic waves (tonebursts) generated by an ultrasonic source.

7.7.1.1 Basic Pulse-Echo Method

An equipment arrangement for the basic pulse-echo system that allows for both velocity and attenuation measurements is shown in Figure 7.8. A pulsed ultrasonic signal is transmitted into the sample by means of a transducer attached to the sample surface. The ultrasonic pulse travels through the sample and reflects between the sample boundaries, eventually decaying away because of sample attenuation. Each time the ultrasonic pulse strikes the end of the sample coupled to the transducer, an electrical signal is generated, which is amplified and displayed on an oscilloscope. The received signals are commonly rectified and filtered (i.e., detected) before being displayed on the oscilloscope. The velocity of ultrasonic wave propagation is determined by measuring the transit time between the corresponding reference points of the reflected pulses and the corresponding pulse propagation distance in the sample. The ultrasonic attenuation can also be read directly from the calibrated attenuator by adjusting the attenuator to maintain a constant receiver signal level for each displayed echo. Accuracies of a few parts in 10^3 for absolute velocity measurements and five parts in 10^2 for attenuation measurements are typically achieved with the basic pulse-echo method. Numerous modifications and variations of the basic pulse-echo system have been developed that result in measurement accuracies of a few parts in 10^4 for absolute velocity measurements, one part in 10^7 for relative velocity measurements, and two parts in 10^3 for attenuation measurements. The reader is referred to McSkimin (1964), Papadakis, (1968, 1976), and Breazeale, Cantrell, and Heyman (1981) for details.

7.7.1.2 Pulse Superposition Method

The pulse superposition method uses a series of tonebursts introduced into the sample by a radiofrequency (rf) pulse generator. The repetition rate of these pulses is controlled by the frequency of a cw low-frequency oscillator. The repetition rate is adjusted to correspond to some multiples of an acoustic round-trip transit time in the sample corresponding to an "in-phase" superposition of pulses such that maximum amplitude is achieved. The measured time delay between the superimposed pulses is used to obtain the sound velocity. Accuracies of two parts in

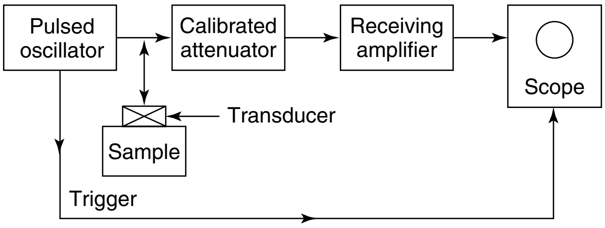

Fig. 7.8 Basic ultrasonic pulse-echo measurement system.

10^4 for absolute velocity measurements and one part in 10^7 for relative velocity measurements are possible with the pulse superposition method (see McSkimin, 1964, for more details).

7.7.1.3 Echo-Overlap Method

In the pulse-overlap method, a series of rf pulses from an rf-pulsed oscillator is transmitted into the sample. The trigger signal is derived by frequency dividing the output of a cw low-frequency oscillator (typically 100–1000 kHz) by a factor of 10^3. The trigger is used to control the pulse repetition rate and to trigger a double time delay (strobe) generator that actuates the z axis intensity gate on the oscilloscope. The delays are adjusted to intensify any chosen pair of displayed echoes. The cw oscillator frequency is adjusted to correspond to the reciprocal of the travel time between the echoes so that the echoes can be made to overlap cycle-for-cycle. The sound velocity is calculated from the measured travel between echoes after correcting for phase shifts due to reflections. Accuracies of a few parts in 10^4 for absolute velocity measurements are typical with the pulse superposition method (see Papadakis, 1976, for more details).

7.7.1.4 Pulse Interferometer Methods

In the pulse interferometer methods, an ultrasonic toneburst is transmitted into the sample by gating a cw reference oscillator. The received pulse (an echo in a single transducer arrangement) is combined with the cw reference signal in a phase-sensitive detector. If the relative phase between the received acoustic signal and the cw reference signal is then changed, the output of the phase-sensitive detector varies in response. The change in relative phase may result, for example, from a variation in the acoustic path or from a variation in the sound velocity as a function of temperature.

Two basic means are reported to measure the change in relative phase. One of the means employs a phase shift network that monitors the amount of phase added to the reference signal necessary to maintain a constant output from the phase-sensitive detector. The frequency of the cw reference signal is held fixed during this process. The second means uses a change in the frequency of the cw reference signal to maintain a constant detector output. In the pulse phase-locked loop system, a voltage controlled oscillator network replaces the phase shift network.

In both the constant frequency and variable frequency techniques, the total phase seen by the phase detector includes acoustic contributions related to the acoustic wavelength relative to sample length as well as collective nonacoustic contributions. The frequency-dependent nonacoustic contributions include those from electrical signal propagation paths and phase perturbations associated with various electrical components. In measurements of phase velocity in fluids, for example, the change in phase corresponding to a given change in path length may be measured. For the constant frequency technique, both the wavelength and the nonacoustic phase term are constants. The phase velocity is obtained from the measurement of the slope of the linear curve giving the change in phase as a function of the change in path length. For the variable frequency technique, the wavelength and the nonacoustic phase term are not fixed and the velocity can be calculated only after correcting for the variations in the nonacoustic phase term. The pulse interferometer methods have a sensitivity of parts in 10^8 for relative velocity measurements. The accuracy of absolute velocity measurements is comparable to that of the

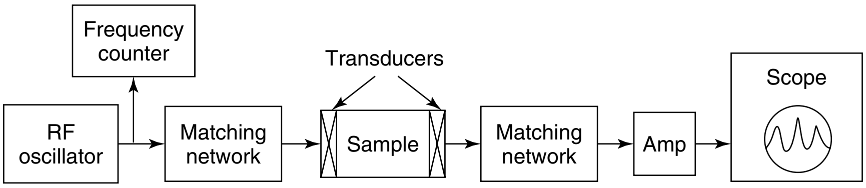

Fig. 7.9 Continuous wave ultrasonic interferometer.

pulse superposition and the echo-overlap methods. For more information on pulse interferometer methods, see Yost, Cantrell, and Kushnick (1992).

7.7.2
Continuous Wave Techniques

The cw techniques employ uninterrupted harmonic waves introduced into bounded material and are among the most expedient methods for measuring sound velocity and attenuation of materials with appropriate geometry. An advantage of cw methods is the increase in sensitivity to variations in velocity and attenuation resulting from the resonance conditions established by the material geometry and the physical properties. The effective gain in sensitivity can be measured in terms of "sensitivity enhancement factors."

Consider the one-dimensional resonances discussed in Section 7.3.2. For any observable A, the variation in amplitude $\Delta|A|$ may be expressed as $\Delta|A| = (\partial|A|/\partial\alpha)\Delta\alpha + (\partial|A|/\partial k)\Delta k$ for small variations in the attenuation α and wavenumber k. The partial derivatives are the sensitivity enhancement factors for attenuation and wavenumber, respectively. If the observable is the particle velocity $|v|$, the sensitivity enhancement factors are found from Equation (7.18) to be

$$\frac{\partial|v|}{\partial\alpha} = \frac{L(e^{-\alpha L/2} - e^{\alpha L/2})\cos kL}{8^{1/2}(\cosh\alpha L - \cos kL)^{3/2}} \tag{7.46}$$

and

$$\frac{\partial|v|}{\partial k} = \frac{Le^{\alpha L/2}\sin kL}{8^{1/2}(\cosh\alpha L - \cos kL)^{3/2}} \tag{7.47}$$

These factors together with similar factors for v_1 and v_2 can be used to separate the effects of dispersion and attenuation on the measurement parameters.

A simple transmission cw measurement system called the *continuous wave* ultrasonic interferometer is shown in Figure 7.9. In this technique, an oscillator is swept through a series of resonance peaks as observed on an oscilloscope screen. The frequencies at which the peak amplitudes occur are used to determine the ultrasonic velocity, and the frequency width $\Delta\omega$ at half power is used to calculate the attenuation in the manner described in Section 7.3.2. The addition of a mixer and 0 and 90° phase shifters to the system permits the assessment of the in-phase (v_1) and quadrature (v_2) resonance signals. Several modifications to the basic cw transmission spectrometer have been reported. The reader is referred to Breazeale, Cantrell, and Heyman (1981) for details.

For materials having a fixed length and sufficiently small dispersion, the phase velocity *cp* can be determined from the frequency difference ($f_n - f_{n-1}$) between two adjacent resonances in the manner discussed in Section 7.2.2. The attenuation α can be calculated from the determination of the frequency width at half power, $\Delta\omega$ as $\alpha = \Delta\omega/2c_p$. These results are based on the assumption that the sample responds as a simple resonator driven by noncontacting transducers. If contacting transducers are used, the sample and the transducers form a composite resonating system whose resonant frequencies are predicted by the roots of a transcendental equation. Approximate solutions to the transcendental equation have resulted in correction factors for the above formulas (Chern, Cantrell, and Heyman, 1981). However, errors in the velocity determination can exceed 10% under certain conditions.

For samples requiring analysis in a three-dimensional geometry, the method of resonant ultrasonic spectroscopy (Demarest, 1971; Ohno, 1976; Migliori *et al.*, 1993; Anderson, 1992; Visscher *et al.*, 1991) can be used. In this method, the modal frequencies for a sample of given three-dimensional geometry are compared to predictive analytical models of the sample modal frequencies. Analysis of the amplitude–frequency spectrum allows an assessment of the elastic constants as well as the internal friction (attenuation) of the sample.

7.7.3
Optical Techniques

Optical techniques can be used for sound velocity measurements in transparent media. Generally, the methods are based on the optical determination of acoustic wavelength either from diffraction or from scattering of light by the sound waves. The wavelength together with the acoustic frequency allows the determination of the phase velocity. For techniques based on diffraction, it is essential to know the type of diffraction experienced by the light.

7.7.3.1 Diffraction of Light by Sound

Consider an ultrasonic transducer generating compressional waves in a transparent propagation medium. If the propagating sound wave encounters light traversing the same medium at some angle incident to the sound wave, the light is diffracted. Assuming that the Fraunhofer conditions hold for the light diffraction (i.e., parallel light rays are brought to a focus), two distinct physical processes can produce the diffraction effects. One involves the formation of a corrugation in the phase fronts of the light due to the acoustically induced spatial variation of the index of refraction. This phenomenon is called *Raman–Nath diffraction*. The second process involves the reflection of light from the (evenly spaced) crests of the sound wave that occurs under conditions similar to that of X-ray diffraction. This phenomenon is called *Bragg diffraction*.

A dimensionless parameter has been introduced to determine which type of diffraction predominates for given experimental conditions. The parameter Q is defined by $Q = k^2 L/\mu_0 k^*$, where k is the ultrasonic propagation constant, L is the width of the ultrasonic beam, μ_0 is the index of refraction, and k^* is the propagation constant of the light in vacuo (Klein, Cook, and Mayer, 1965). If $Q > 9$, Bragg diffraction is predominant. If $Q < 1$, Raman–Nath diffraction occurs. If $1 < Q < 9$, the diffraction is mixed. Both types of diffraction can be used to determine the sound velocity of the material.

For Raman–Nath diffraction with the light incident at an angle $(\pi/2 - \phi)$ to the sound beam direction, the light is diffracted into diffraction orders given by the expression $\sin(\theta_n + \phi) - \sin(\phi) = n\lambda^*/\lambda$, where θ is the angle of diffraction with respect to the incident beam, λ^* is the wavelength of light in the medium, λ is the ultrasonic wavelength, and n is an integer denoting the diffraction order. The ultrasonic wavelength can be determined from the above equation.

For Bragg diffraction, the angle of diffraction θ_n is set to be equal to twice the negative angle of incidence $(-\phi)$ such that $n\ \lambda^* = 2\lambda \sin\phi_B$, where ϕ_B is the Bragg angle. Bragg diffraction is used to measure wave velocities in the frequency range from approximately 100 MHz to several gigahertz. The accuracy of velocity measurements using diffraction of light by sound methods is estimated to be of the order of 0.01–0.1% for homogeneous samples.

7.7.3.2 **Brillouin Scattering**

Lattice vibrations are caused by thermal and other excitations of the crystal lattice. These vibrations form vibrational modes (normal modes) within the lattice and play a major role in determining the thermal properties (e.g., heat capacity) of the solid. The normal modes form two major branches. The acoustic branch includes normal mode frequencies, which vanish linearly as the propagation vector $\boldsymbol{k}$ approaches zero (long wavelength limit). The optical branch includes normal mode frequencies that do not vanish as the propagation vector approaches zero.

The quantum mechanical treatment of the lattice vibrations predicts that the normal modes gain and lose energy in quantized units just as in the case of the harmonic oscillator. Because of the similarity of the lattice vibrations to the electromagnetic radiation field in a cavity, a quantum of lattice vibrational energy called the *phonon* is defined, primarily for convenience, in analogy to the electromagnetic quantum of energy called the *photon*. As with photons, phonons are given the property that each phonon carries an energy $\hbar\omega$, where $\hbar$ is the Planck's constant divided by 2π, and under certain conditions behaves as if it carries a crystal momentum of value $\hbar k$.

Light interacting with the normal modes in the material can gain or lose energy and momentum. Brillouin scattering occurs when the modes of the acoustic branch interact with light. Consider the interaction of a photon with a material whose index of refraction is μ_o. Application of the laws of conservation of energy and momentum, respectively, to the scattering process gives $\hbar\boldsymbol{\omega}^{*'} = \hbar\boldsymbol{\omega}^* \pm \hbar\omega$ and $\hbar\mu_o\boldsymbol{k}^{*'} = \hbar\mu_o\boldsymbol{k}^* + \hbar\boldsymbol{k} + \hbar\boldsymbol{K}$, where $\omega^{*\prime}$ and $\boldsymbol{k}^{*\prime}$ are the frequency and propagation vector, respectively, of the incident photon, ω^* and $\boldsymbol{k}^*$ are the frequency and propagation vector of the scattered photon, ω and k are the frequency and the crystal momentum assigned to the phonon, and $\boldsymbol{K}$ is the reciprocal lattice vector (assumed to be zero in this case). Because the photon frequency shifts are small for this process, the propagation vectors are very nearly of the same length. The vector addition expressed by the above equations gives an isosceles triangle whose apex angle is θ, the complement of the scattering angle. The equations lead to the result (Ashcroft and Mermin, 1976)

$$\omega = \pm 2\,\omega^* \left(\frac{c}{C_1}\right) \sin\left(\frac{\theta}{2}\right) \tag{7.48}$$

where C_1 is the speed of the photon in the medium, c is the speed of the phonon, and θ is the scattering angle. The frequency ω is equal to the difference in frequencies between the incident and scattered photons.

The technique produces a scattered photon spectrum of three lines, one of which is unshifted. The two frequency-shifted lines are called the *Stokes line* (a phonon is created) and the *anti-Stokes line* (a phonon is annihilated). These lines can be separated and measured with optical devices such as the Fabry–Perot interferometer to obtain ω. If desirable, the Bragg condition can be used for constructive reinforcement by adjusting θ. Equation (7.45) can be solved for the velocity c in terms of the other quantities measured.

Brillouin scattering is useful in the investigation of the sound velocity of solids and liquids especially near a phase transition where attenuation can become very large. The technique is also advantageous in that it is one of the few techniques capable of assessing sound velocity at frequencies of several gigahertz. The technique has been used for sound velocity measurements for both longitudinal and mixed (longitudinal-transverse) modes.

7.7.4
Sources of Error

A number of sources of error arise in the measurements of velocity and attenuation. Errors arising from time or length measurements can be evaluated directly, but among the less easily evaluated errors are those arising from velocity dispersion, material inhomogeneity, phase cancellation effects, diffraction, and the effects of thickness of the transducer and transducer bond. Many aspects of the sources of error are best addressed in the context of the measurement technique used, but certain characteristics of the error sources have more generic implications.

For example, as indicated in Section 7.5, any technique employing a change in frequency ω to measure the sound velocity c_p must account for dispersion, because the velocity is a function of the frequency. Measurements using gated cws (tonebursts) of finite length contain a spectrum of frequencies around the frequency of the generating continuous waveform. Such measurements can be made to approximate narrowband cw conditions, hence minimizing the effects of dispersion, if the pulse lengths are sufficiently long. The appropriate pulse length L is dependent on the intrinsic error M of the pulse measurement method and is given by the expression $L \geq \pi(d^2\omega/dk^2)/Mc_p$, where k is the wave number (Yost, Cantrell, and Kushnick, 1992).

A variation in the phase of the wave over the area presented by the surface of a phase-sensitive transducer can give rise to phase cancellation of different portions of the received signal that sets limits on the measurement accuracy of both velocity and attenuation. Sources of such phase variation include diffraction, media inhomogeneity, temperature gradients, wedging, and nonparallelism of the sample surfaces. Nonparallelism of opposite surfaces of the sample by an angle θ is representative of the effects of phase cancellation. For example, in measurements employing acoustic pulses of wave number k reflecting from the ends of the sample, the amplitude of the pulse received after n double reflections is diminished by the factor $[J_1(2kan\theta)/kan\theta]$ due to nonparallelism Truell, Elbaum, and Chick, 1969). The use of phase-insensitive devices such as the "acoustoelectric transducer" can minimize phase cancellation errors (Heyman, 1978), although such devices are generally less sensitive than the commonly used phase-sensitive piezoelectric elements.

A major source of error in measurements of velocity results from the effects of the transducer and the bond that couples the transducer to the sample. Both the transducer and bond introduce additional phase into the measurement system that can lead to errors of the order of parts in 10^2 for the measurement of velocity. Methods for correcting such errors are well established and have been addressed as appropriate to the specific measurement techniques discussed (for details see the review articles by McSkimin (1964), Papadakis (1968, 1976), Breazeale, Cantrell, and Heyman (1981), and Cantrell and Yost (1997). An alternative to such corrections is the use of noncontacting transducers such as capacitive transducers (Cantrell and Breazeale, 1977), electromagnetic transducers (Meridith, Watts-Tobin, and Dobbs, 1969), and optical techniques.

7.8
Applications of Ultrasound

Ultrasonic methods have long been used to characterize various properties of materials ranging from the fundamental to the most practical applications. Ultrasonic measurements of fundamental material properties, for example, have provided some of the first experimental evidence of the double well interatomic potential in vitreous silica, have been used to quantify the superconducting state of materials, and have provided well-established methods of testing lattice dynamical theories of the solid state. More practical uses of ultrasound span a wide range of disciplines including medical and industrial applications, nondestructive evaluation and testing of materials, acoustic microscopy, and underwater acoustics.

7.8.1
Medical Applications

Many medical applications of ultrasound center on the scanning or imaging of organs and tissues. The simplest scanning technique is the basic pulse-echo technique, often called the *A-scan method*. In the A-scan, an ultrasonic pulse is transmitted into the body. Changes in the acoustic impedance along the propagation path at tissue interfaces result in the partial reflection and transmission of sound from the interfaces. The reflected pulses (echoes) are received by the transducer and the echoes are displayed on the x trace of an oscilloscope and recorded. The amplitude of the echo is proportional to the magnitude of the reflection coefficient at the interface involved. A measurement of the time delays, calibrated in terms of distance, of ultrasonic echoes reflected from various anatomical landmarks provides the basis for the measurements. The A-scan is useful, for example, in the assessment of the anterior and posterior chambers of the eye. A variation of the A-scan is the M-scan in which a time record of variations in the x trace echo pattern is serially recorded along the y trace of the oscilloscope. The M-scan has proven useful in heart monitoring.

A B-scan image is formed by linking the time-base direction in the oscilloscope with the direction of propagation of the ultrasonic beam. The image is built up by using the amplitude of the received echoes to modulate the intensity of the oscilloscope beam as the ultrasonic beam is scanned.

In the ultrasonic C-scan, the x and y positions of the oscilloscope beam are made to track the x and y positions of the transducer as the transducer is made to areally scan a portion of the body. The z direction is the direction of ultrasonic propagation. A gated time delay is used to set the depth (z direction) at which ultrasonic echo information is received. The brightness of a given image point is dependent upon the amplitude of the received ultrasonic signal. In the C-scan mode, the ultrasonic images most closely resemble X-ray images.

Various modifications of the basic A-, B-, and C-scan imaging techniques have been developed including transducer array methodologies with electronic beam steering and acoustic holographic techniques. Among the many applications of ultrasonic imaging in its various forms are fetal monitoring, heart and cardiac structure imaging, assessment of the depth and severity of skin burns, and more recently high-resolution ultrasonic breast examination.

Ultrasound is also used in numerous medical applications other than imaging. For example, the Doppler shift associated with sound scattering from moving targets is used to measure both blood flow velocity and flow volume in blood vessels. Lithotripsy, a nonsurgical procedure, uses high-intensity sound focused into a small volume and directed onto hard objects such as kidney stones in the body. The acoustic impedance mismatch between the kidney stone and the surrounding soft tissue produces a sufficiently large pressure on the stones to break them into smaller pieces which can be excreted. The absorption of ultrasound directed into a muscle is used for heat therapy and message. The ultrasonic syringe utilizes the ability of ultrasound to temporarily disrupt surface tissue organization to permit the injection of medicine through the skin into the body. More recent applications of ultrasound (currently undergoing clinical evaluation) include the nonsurgical assessment of decubitus ulcers (bedsores) using spectral analysis profiles of tissue reflected echoes (amplitude versus frequency curve) and the noninvasive monitoring of intracranial dynamics and pressure (ICP) using pulse phase-locked loop ultrasonic interferometry.

7.8.2
Industrial Applications

Among the most common uses of ultrasound in industry is that in the nondestructive evaluation and testing of materials. Basic ultrasonic pulse-echo techniques are widely used for the detection and locations of cracks and flaws during routine inspection of machine and structural components and fixtures. The propagation of cracks is also passively monitored using the acoustic signals emitted during microfracture (acoustic emission monitoring). Ultrasonic imaging techniques are widely used for the assessment of material integrity, particularly for the assessment of delaminations and debonds in advanced composite materials. Ultrasonic velocity and attenuation measurements are often employed to obtain mechanical property data, such as the elastic constants or parameters associated with relaxation processes (internal friction) of the material. Such data can also be used for the assessment of the purity or the processing conditions of the material. The data is also useful in the assessment of basic microstructure-property relationships for the development and manufacturing of materials with improved or modified properties.

Residual stresses formed during materials processing or alterations in the stresses during the fatigue of materials are often of concern in critical components subjected to high cycle stresses. Because the magnitude of the sound velocity is sensitive to the stresses in the material, ultrasonic techniques are often used for the evaluation of such stresses. The acoustoelastic birefringence method relies on a stress-induced anisotropy in the material, which splits an incident shear wave into two components having different measured sound velocities. The difference in the two sound velocities is proportional to the stress in the material. Another method of assessing the presence of stresses depends on the measurement of stress-induced changes in the longitudinal velocity using either ultrasonic interferometry or pulse time-of-flight measurement techniques. The latter technique is also used for the precise tensioning of threaded fasteners in critical applications such as the disconnect studs linking the external fuel tank to the space shuttle orbiter.

Among the most important uses of SAWs is that in electronic SAW signal processing devices. Generally, the SAW device consists of an interdigital transducer formed by depositing an array of interlacing, alternately, charged electrodes on the surface of a piezoelectric substrate. The interdigital transducer generates an SAW. The SAW propagates to an output interdigital transducer. The intervening path between the input and output transducer is designed to produce a desired change in the input signal that is captured at the output. The intervening path may provide, for example, a propagation time delay, a waveform distortion, or alterations in the spectral frequency components of the waveform. Among the many SAW devices are delay lines, mixers, filters, correlators, resonators, coders, oscillators, and convolvers. Because the sound velocity is dependent on temperature and pressure, measurements of the SAW velocity on calibrated standards are also used to provide a sensitive monitor for both temperature and pressure. SAWs have been used to sense the position of a pointer (stylus or human finger) on a computer-controlled graphical input screen. SAW filters are widely used in cellular telephones. For more information on SAW devices, see Kino (1987).

Optical interactions with SAWs are used to make surface wave optical modulators, deflectors, and filters. For example, SAWs generated onto a thin optical-guiding film causes periodic variations in the optical index of refraction of the material. These periodic variations serve as Bragg diffraction gratings for incident optical beams coupled into the film. The incident optical waves are deflected in accordance with the Bragg reflection conditions as they encounter the SAWs. Optical output couplers can then be placed to receive only optical signals having a desired angle of deflection. Ultrasonic-induced frequency shifts of several megahertz in the diffracted light of optical modulators are used for single sideband mixing or demodulation of laser Doppler devices.

Applications of ultrasound other than materials characterization or SAW devices are also widely used in industry. For example, acoustic Doppler shift measurements are often used for monitoring the flow velocity of gases and molten solids. Doppler techniques are also used for measuring the velocity of objects moving in a fluid and ultrasonic Doppler sensors are commonly used in entry alarm systems. High-frequency acoustic vibrations in crystals are used in devices requiring precise frequency or time control. Basic pulse time-of-flight techniques are used for measuring the distance between an object and the sound source (range-finding). Ultrasonic rangefinders are found on many autofocusing cameras. The pressure in resonating high-intensity sound fields can be used to support and manipulate objects in air without mechanical contact with the object (acoustic levitation). Such manipulation is useful for handling contact sensitive or corrosive materials. SAWs can be used to manipulate and position small particles on a material surface. High-intensity sound is used in ultrasonic cutting and drilling machines, ultrasonic cleaners, and ultrasonic humidifiers (atomizers). High-intensity ultrasound is also used for soldering, welding (both metals and plastics), stress relieving previously welded joints, and metal forming and drawing.

Ultrasonic motors have become an important development for self-focusing cameras and robotic devices. Although there are many variations, the ultrasonic motor basically consists of a vibration-driven stator frictionally coupled to a rotor. A piezoelectric element is used to excite a flexural wave in the stator. The stator is placed in direct contact with the rotor. The transverse undulations of the flexural wave produces points on the stator surface that are in direct contact with the rotor and other points that are not in contact. As the wave propagates, a given point on the stator surface moves in an elliptically shaped, retrograde pattern similar to that of the Rayleigh wave. The motion of the stator–rotor contact point corresponding to the maximum wave amplitude is opposite to that of the wave propagation direction. The frictional forces between the stator and the rotor cause the rotor to move in that direction (Inaba *et al.*, 1987).

Thermoacoustic heat pumps have been developed that utilize a heat source and heat sink configured to an acoustic resonator having a stacked heat exchanger. The action of acoustically driven thermodynamics processes in the resonator gases has allowed the development of reliable, inexpensive engines, and refrigerators with a significant Carnot efficiency (∼40%) (Swift, 1995).

7.8.3
Acoustic Microscopy

The microstructural variation in the acoustic properties of materials (including biological material) has been the key to the development of a new class of microscopes that utilize acoustic waves in some fashion for obtaining microscopic images. The images so obtained are quite different from those obtained in conventional light or electron microscopes. Different types of acoustic microscopes use different energy sources such as electron beams or piezoelectric transducers for generating the acoustic images and are descriptively named, for example, the scanning acoustic microscope, the scanning electron acoustic microscope, the thermoacoustic microscope, and the scanning laser acoustic microscope (SLAM). Although the image contrast and spatial resolution attainable in such microscopes are in large measure dictated by the details of energy source-material interactions, the dependency on the local variations in the material elastic or thermoelastic properties, including residual stresses, is a necessary consideration in such interactions.

7.8.3.1 Scanning Acoustic and Laser Acoustic Microscopes

In scanning acoustic microscopy (SAM), plane acoustic waves are generated by a piezoelectric transducer attached to a cylindrical rod (typically made of sapphire) as shown in Figure 7.10. The opposite end of the rod is made into a concave spherical surface to form an acoustic lens. Coupling fluid (usually water) is placed between the rod surface and the specimen surface. Wave refraction at the acoustic lens-coupling fluid interface provides a focusing action for the plane waves incident from the transducer. The focused waves impinge on the specimen surface. In general, the waves incident on the specimen surface are specularly (geometrically) reflected back to the transducer. At certain critical angles of incidence (if the material properties permit), leaky surface

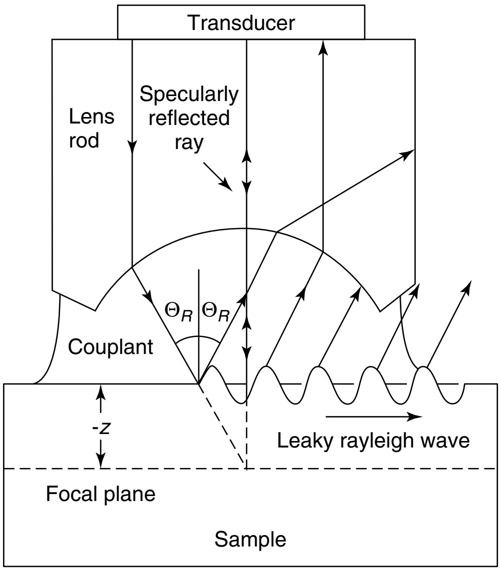

Fig. 7.10 Scanning acoustic microscope acoustic lens configuration for generating signals via the interference between "leaky" Rayleigh waves generated at the Rayleigh critical angle θ_R and specularly reflected waves (illustrated by the central specularly reflected wave). Adapted from Briggs, 1992.

waves (usually leaky Rayleigh waves) can also be generated. Under proper defocus conditions (lens-specimen distance), the leaky surface waves find their way back to the transducer. The total acoustic signal reaching the transducer in this mode of operation is composed of contributions from the geometrically reflected waves and the leaky surface waves. The interference of these two waves gives rise to the SAM output signal. If the acoustic lens–specimen distance is allowed to vary, the periodic variation in the signal amplitude as a function of this can be used to obtain the surface wave velocity of the material.

If the focused acoustic beam is rastered over the specimen surface, variations in the acoustic impedance of the specimen or in the surface wave velocity or geometrical irregularities in the specimen surface can change the magnitude and phase of the output signal. The variations in output signal at each point on the surface are recorded on a visual display to generate an SAM image. The images can be analyzed to obtain information related to the variations in the mechanical properties of the specimen over micron scale regions. Commercially available scanning acoustic microscopes use acoustic waves with frequencies as high as 2 GHz. For more information on SAM, see Briggs (1992).

The SLAM uses unfocused plane acoustic waves (usually in the range 100–500 MHz) to insonify the specimen. Internal elastic microstructures or other acoustic inhomogeneities in the specimen cause the propagating sound wave to locally scatter, distort, or attenuate. The sound field then impinges on and deforms a flat, polished area of the specimen surface producing a surface pattern reflective of the specimen inhomogeneity. A laser beam reflected from this surface is rastered to trace out an optical phase replica of the sound field at the surface. The laser signals are electronically processed and displayed on a television monitor to produce a visual image of the surface pattern. For more information on the SLAM, see Kessler and Yuhas (1979).

7.8.3.2 **Scanning Electron Acoustic and Photoacoustic Microscopes**

In scanning electron acoustic microscopy (SEAM), the signal generation source is derived by chopping or modulating the electron beam (most often in the range 0.1–1.0 MHz) in a scanning electron microscope (SEM) by means of electrostatic deflector plates inserted into the electron beam column of the SEM. The deflector plates are driven by a periodic signal (typically a square wave) of frequency f derived from a function generator. The chopped electron beam is focused on the specimen surface. The electrons lose their energies by means of atomic collision processes in a scattering interaction volume as discussed in Section 7.6.2.4, resulting in thermal and acoustic waves of the same frequency being generated simultaneously in the interaction volume. The acoustic waves are detected by a transducer (typically a piezoelectric element) attached to the specimen. The signals from the transducer are commonly processed by means of a lock-in amplifier that derives its reference signal from the modulation signal of the function generator. The signal from the lock-in amplifier is differentially amplified and used to drive the z axis of a cathode ray tube (CRT) display. As the chopped electron beam rasters the specimen surface, an electron-acoustic image is generated on the CRT display.

The acoustic SEAM signal output $V(f)$ may be approximated for isotropic materials as $V(f) = \alpha_T(3\lambda + 2G)R(f)/(\rho_0 C_H \kappa)^{1/2}$, where α_T is the thermal expansion coefficient, C_H is the specific heat, κ is the thermal conductivity, and ρ_0 is the mass density of the material (Qian and Cantrell, 1989). $R(f)$ is a function of the chopping frequency that collectively includes those factors not directly involving thermoelastic parameters. We see from this expression that the electro-acoustic signal is primarily governed by the thermoelastic properties of the material. The resulting SEAM images thus reflect variations in the thermoelastic parameters of the material and allow variations in material properties affecting the thermoelastic parameters to be imaged. Because the acoustic signal is derived from the electron interaction volume, both surface and subsurface features including residual stresses can be imaged with the SEAM, as illustrated in Figure 7.11. For further information on SEAM, see Cargill (1988).

The photoacoustic microscope uses intensity-modulated light rather than an electron beam to generate the acoustic signals. The acoustic signals are generally detected by a piezoelectric transducer bonded to the sample or by various optical methods. The original photoacoustic arrangement consists of a specimen enclosed in a gas-filled cell. Periodic heat flow and thermal expansion of the specimen leads to a corresponding pressure variation of the gas in the cell, which is detected by a microphone. The acoustic signals generated in the photoacoustic microscope are primarily governed by the thermoacoustic properties of the material in a manner similar to that of the SEAM. Measurements of the photoacoustic signal amplitude as a function of the light modulation frequency leads to a materials characterization modality known as *photoacoustic spectroscopy*. Among the uses of photoacoustic spectroscopy are the measurements of optical absorption and spectroscopic depth profile analyses of opaque materials. For more information on the phenomenological aspects of photoacoustic microscopy, see McDonald and Wetsel (1988) and for information on photoacoustic spectroscopy, see Sawada and Kitamori (1988).

(b) Scanning electron acoustic microscope (SEAM) image showing additionally the presence of residual stresses and subsurface cracks. From Cantrell *et al.*, 1990.

7.8.3.3 **Acoustic-Atomic Force Microscopes**

Acoustic-atomic force microscopy (A-AFM) is a dynamic implementation of atomic force microscopy (AFM) (Bennig, Quate, and Gerber, 1986) that combines the attributes of AFM with the bulk propagation properties of ultrasound to produce images of near surface and subsurface features within the material at the nanoscale. A-AFM includes such modalities as atomic force acoustic microscopy (AFAM) (Rabe *et al.*, 2002), force modulation microscopy (FMM) (Maivald *et al.*, 1991), ultrasonic force microscopy (UFM) (Kolosov and Yamanaka, 1993), heterodyne force microscopy (HFM) (Cuberes *et al.*, 2000), and resonant difference-frequency atomic force ultrasonic microscopy (RDF-AFUM) (Cantrell, Cantrell, and Lillehei, 2007). All modalities require that the AFM cantilever tip engage the sample surface, as indicated in Figure 7.12. Upon engagement, the cantilever tip encounters an interaction force that in general varies nonlinearly with the tip-surface separation distance. In hard tip-surface contact, the force-separation curve is linear to a good approximation. In soft tip-surface contact, the force-separation curve is extremely nonlinear at certain tip-separation distances.

Two basic equipment arrangements are used for A-AFUM depending on the modality. The simplest arrangement is that used for AFAM and FMM and is shown in Figure 7.12, where the indicated switches are in the open positions. AFAM and FMM utilize ultrasonic waves transmitted into the material by a transducer attached to the bottom of the sample. After propagating through the bulk of the material, the wave impinges on the sample top surface where it excites the engaged AFM cantilever. For AFAM and FMM, the cantilever tip is set to engage the sample surface in hard contact corresponding to the roughly linear interaction region of the force-separation curve. The response of the excited cantilever is monitored by a laser beam reflected from the cantilever

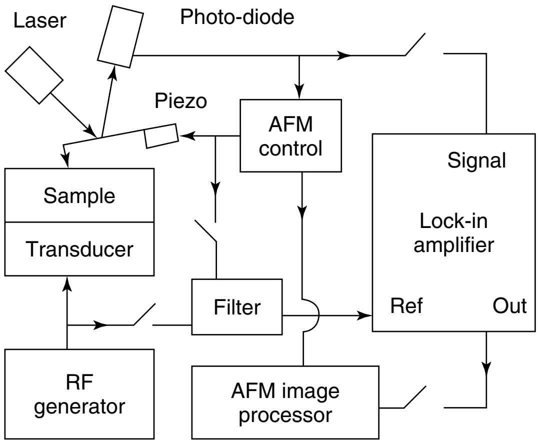

Fig. 7.12 Acoustic-atomic force microscope equipment configuration: switches open for AFAM, FMM, and UFM: switches closed for HFM and RDF-AFUM. Adapted from Cantrell, Cantrell, and Lillehei, 2007.

surface and detected by a photodiode. The signal from the photodiode is processed by the AFM image processor. The image processor and AFM controller are used to generate a raster image of subsurface, nanoscale, material features resulting from changes in the A-AFM signal produced by the features. The image may be an amplitude or phase-generated image depending on whether it is the change in the amplitude or the phase of the ultrasonic wave propagating through the material that is measured. The basic equipment arrangement used for UFM is the same as that for AFAM and FMM, except that the cantilever tip for UFM is set to engage the sample surface in soft contact, corresponding to the highly nonlinear interaction region of the force-separation curve. The UFM output response is a static or "dc" signal resulting from the interaction nonlinearity.

The equipment arrangement used for HFM and RDF-AFUM is shown in Figure 7.12, where the indicated switches are in the closed positions. In a manner similar to UFM, HFM and RDF-AFUM employ ultrasonic waves launched from the bottom of the sample, while the AFM cantilever tip engages the sample top surface in soft (nonlinear regime) contact. However, in contrast to UFM, the cantilever is also driven in the HFM and RDF-AFUM modalities. In RDF-AFUM, the cantilever drive frequency is set to differ from the ultrasonic frequency by one of the contact resonance frequencies of the cantilever. In HFM, the difference frequency is generally set to a value well below the lowest contact resonance of the cantilever. As shown in Figure 7.12, the cantilever drive and transducer drive signals are split and fed to a mixer. The mixer output signal, consisting of sum- and difference-frequency signals, is sent to the reference input of a lock-in amplifier that, because of its limited bandpass, filters out the sum frequency. The mixing of the oscillating cantilever and the ultrasonic wave in the nonlinear region defined by the cantilever tip-sample surface interaction force generates difference-frequency oscillations in the cantilever. The AFM photodiode signal, derived from the cantilever response at all frequencies, is sent to the signal input of the lock-in amplifier where all frequencies except the difference-frequency are filtered out. The lock-in amplifier measures both the amplitude and phase of the input difference-frequency signal. Variations in the amplitude and phase of the ultrasonic bulk wave due to the presence of subsurface nano/microstructures as well as variations in near surface material parameters affect the amplitude and phase of the difference-frequency signal. These variations are used to create spatial mappings generated by near surface and subsurface structures.

For a detailed mathematical analysis of signal generation, image contrast, and the relation of image generation to the physical properties of materials for each of the above-cited A-AFM modalities, see Cantrell and Cantrell (2008).

7.8.4
Underwater Acoustics

Because of the relative opacity of water to electromagnetic signals in the visible, infrared, radio, and radar ranges of frequencies, sound waves are used as the means of propagating information in underwater environments. The development of underwater sound systems has been among the most long-standing applications of ultrasound. Among the many developments are ultrasonic systems for both passive and active sound navigation ranging (sonar), depth sounding, mapping and profiling of the ocean floor, underwater geophysical prospecting, and fish detection.

Glossary

Acoustic Impedance: Ratio of the pressure to the particle velocity of the acoustic wave field.

Affinity: A measure of the ability of a reaction to occur and defined as the sum of the products of the chemical potential for a reaction and the number of moles of reactant–product involved.

Attenuation: The loss of acoustic amplitude (or energy) of a sound wave along its propagation path resulting from all mechanisms responsible for such losses, including but not limited to absorption, scattering, and diffraction.

Absorption: The loss of amplitude (or energy) of an acoustic wave that results in an increase in temperature (however slight) in the propagation medium.

Diffraction: Wave scattering occurring at the ‘‘edges’’ or boundaries of objects, including the influence of boundaries on radiation sources.

Dispersion: The variation of phase velocity with wavelength or wavenumber.

Elasticity: A material property characterized by a thermodynamically reversible relationship between stress and strain.

Evanescent Wave: A nonpropagating wavelike disturbance periodic only in time and decaying exponentially in all spatial directions.

Group Velocity: The velocity associated with the propagation of wave energy and defined as the derivative of the angular frequency with respect to the wavenumber.

Inhomogeneous Wave: A sound wave having an amplitude that decays exponentially in a direction perpendicular to the direction of propagation.

Phase Velocity: The sound velocity of a monochromatic wave defined as the ratio of the angular frequency to the wavenumber.

Refraction: The deviation in the propagation direction of a sound wave as the wave crosses the boundary at nonnormal incidence between two propagation media having different sound velocities.

Relaxation: A reaction process whereby the energy state of the material is caused to change from one state of equilibrium to another state of equilibrium by the driving action of an ultrasonic wave.

Relaxation Time: A time constant characterizing the time exponential approach to equilibrium following a sudden deviation from equilibrium of a relaxing medium.

Scattering: That phenomenon whereby an inhomogeneity in the path of a sound wave produces secondary waves spreading out from the inhomogeneity in various directions.

Viscoelastic Material: A material possessing both elastic and viscous properties.

Viscosity: A material property characterized by the dependence of the stress on the strain rate.

INTRODUCTION

Sound waves, whether audible or not, are mechanical disturbances that propagate through a material and can cause physical changes to occur. In fluids with negligible viscosity, sound waves are longitudinal waves: the molecules move back and forth in the direction of propagation of the wave. In viscous liquids and solids, transverse waves can exist in which the molecules of the material move perpendicular to the direction of propagation. Other types of waves, such as shear waves or Rayleigh waves, can exist at interfaces between materials. Both energy and momentum are transferred by sound waves, although for audible frequencies and moderate sound levels in air, energy densities are typically less than a millionth of a joule per cubic meter. For very intense sounds, however, or for interactions between acoustic waves and highly resonant mechanical systems, sound energies can become concentrated enough to produce physical effects such as acoustic levitation, tissue heating, or even light production. The mechanical changes in the medium due to the sound waves can affect electrical, magnetic, or optical properties of the material, resulting in important secondary effects such as acoustic modulation of the optical index of refraction.

As sound waves propagate, they modify the spatial and temporal properties of the medium, producing compressional and rarefactional regions. Associated with these regions are changes in mechanical stress, strain, and motion that are described by such parameters as pressure, density, tension, particle velocity, and temperature. The kinetic energy of a sound wave is the energy of motion gained by the particles of the medium set in motion by the wave. The potential energy is due to the elasticity of the medium, the tendency of compressed or expanded material to return to its equilibrium state. The energy of the sound wave E is the sum of the kinetic and potential energies and is given by

$$E = \tfrac{1}{2}\rho_0 V_0(u^2 + p^2/\rho_0^2 c^2), \qquad (1)$$

where ρ_0 is the equilibrium density of the medium, u is the particle velocity, p is the instantaneous pressure above the equilibrium pressure, c is the sound speed, and V_0 is the volume occupied by the sound wave. The energy density ϵ of the wave is the ratio of E to V_0 and is an important measure of the strength of the wave. Other such measures are the *acoustic intensity I*, expressing the amount of energy per unit time (power) that flows through a given cross-sectional

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

area of a medium, and its logarithmic counterpart, the *intensity level* IL, expressed in decibels:

$$I = \frac{1}{T}\int_{t=0}^{T} pu\, dt, \tag{2}$$

$$\mathrm{IL} = 10 \log_{10}(I/I_{\mathrm{ref}}), \tag{3}$$

where T is the acoustic period, t is time, and I_{ref} is a reference intensity of 10^{-12} W/m^2 for sounds in air (Kinsler *et al.*, 1982). Physical effects begin when sound intensities exceed about 100 W/m^2 or 140 dB, although the nature of the effects varies depending upon the system considered.

Two important physical effects of intense sounds on fluids are acoustic radiation force and acoustic streaming. Acoustic radiation force, like that from light, results when a wave is reflected from an object with less momentum than it had previously (Henry, 1957), or when the momentum of the wave changes direction. The time rate of change of this momentum difference is the force exerted on the object in the direction of the momentum change. It follows that an object that is acoustically transparent and nondissipative will experience no acoustic radiation force, while one that reflects all of the incident energy 180° will experience the maximum acoustic radiation force. If the object perfectly absorbs the sound wave, it will experience half the maximum acoustic radiation force, and if the incident beam is deflected, the force on the object will be in the direction opposite to the surface normal. Streaming, on the other hand, is the bulk translational motion of an acoustically attenuating fluid due to its proximity to a sound source. The fluid is set in motion because the sound wave deposits more momentum into the fluid near the source than it does farther away. Thus streaming is the result of radiation force acting on a viscous liquid that is the propagation medium. Both streaming and radiation force are proportional to the intensity of the sound, while streaming also depends upon the acoustic absorption of the fluid and its shear viscosity (Nyborg, 1965). For more information, see the section on acoustic streaming in ACOUSTICS, NONLINEAR, and a description of acoustic radiation force in BIOLOGICAL EFFECTS OF SOUND AND ULTRASOUND.

The present article outlines the various consequences of the interaction of intense sound waves with the materials though which they propagate. We begin by considering the conversion of sound to thermal energy, both directly through absorption in the medium and indirectly through the interaction of thermal boundary layers with a standing wave field. We then consider nonthermal effects, beginning with electrical and resonance properties of the propagation medium. Finally, we move to specific phenomena related to these physical effects: acoustic cavitation and shock waves, along with some of their consequences. Treatment of SONOLUMINESCENCE and the BIOLOGICAL EFFECTS OF ULTRASOUND is left to the corresponding articles elsewhere. See ENGINEERING ACOUSTICS for a discussion of surface acoustic waves.

1. HEATING EFFECTS

As a mechanical disturbance, a sound wave ultimately dissipates its energy via friction into heat, a process called acoustic absorption. Depending upon the properties of the propagation medium, an acoustic wave may lose energy from different frequency components at different rates, causing distortion of the wave form as well as its lowered amplitude. For many homogeneous media, the intensity of the sound is reduced exponentially as the wave progresses in time or space:

$$I = I_0 e^{-\alpha z}, \tag{4}$$

where I_0 is the intensity at the source, z is the distance from the source, and α is the absorption coefficient of the medium. Energy in a plane acoustic wave will be converted into heat at the rate of $2\alpha I$ per unit volume (NCRP, 1983), and if there is no mechanism for conduction (or diffusion) of that heat out of the medium, the temperature Θ will rise linearly according to

$$\Theta(t) = \frac{2\alpha I}{\rho_0 C_p} t + \Theta_0, \tag{5}$$

where C_p is the specific heat at constant pressure and Θ_0 is the temperature of the medium at time $t = 0$. If convection or conduction is present, however, the temperature will reach a saturation level that balances the deposition of heat energy with the losses. Once sound energy is converted into heat, the physical effects that the heat has on the medium are indistinguishable from heating by any other means.

2. THERMOACOUSTICS

Under certain conditions, heat input may be made to cause a sound wave to be generated, and the result is a thermoacoustic engine or "prime mover" (Swift, 1988). Likewise, sound waves can be made to produce a temperature gradient in the thermal boundary layer of a surface, such as a stack of plates inserted in an intense standing wave field. The basic mechanism for this ability of sound energy to generate a temperature gradient is shown in Fig. 1. A small parcel of gas near a plate is forced back and forth by the sound wave, and it is compressed and expanded as it moves parallel to the plate surface. During the compression, the temperature of the gas parcel increases adiabatically, and the gas then transfers some of its heat at constant pressure to the plate, which warms slightly. During the rarefaction, the parcel expands and moves leftward, cooling adiabatically to a lower temperature. Heat from the leftmost portion of the plate enters the gas parcel at constant pressure and the cycle repeats, with a net amount of heat "lifted" from the plate at the left position and deposited at the right. Many microscopic interactions of this kind contribute to a "bucket brigade" of gas parcels that can move substantial amounts of heat from one end of the plate (or a stack of plates) to the other. For applications of this principle to specific devices such as acoustic refrigerators, please refer to the article THERMOACOUSTIC ENGINES AND REFRIGERATORS.

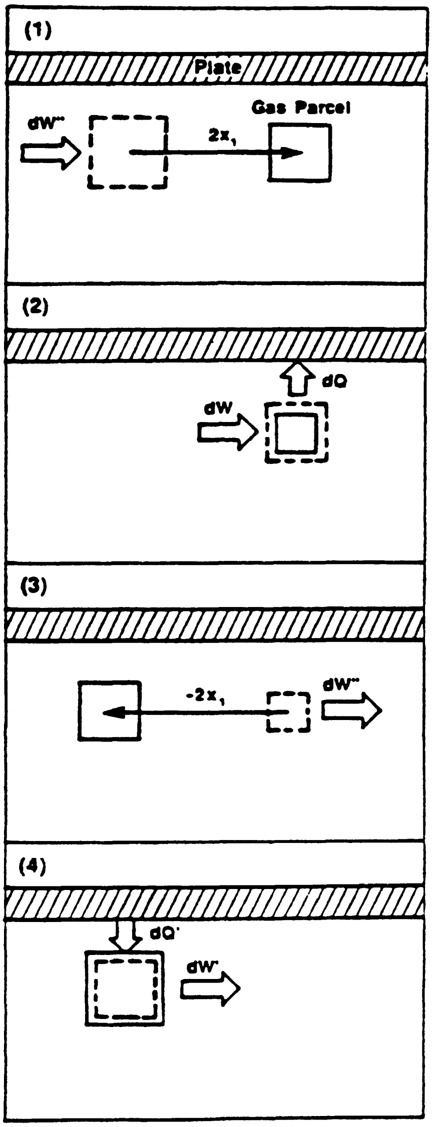

FIG. 1. Simplified mechanism of a thermoacoustic heat-pump cycle. A parcel of gas inside the resonator tube moves horizontally from left to right near a surface, compressing adiabatically in step (1), transferring heat dQ to the surface isobarically in step (2), expanding adiabatically in step (3), and picking up heat dQ′ from the surface isobarically in step (4). 3. EFFECTS ON ELECTROMAGNETIC SYSTEMS

3.1 Nuclear Effects

Ultrasonic energy can induce transitions in the energy levels of nuclear spins subjected to electric or magnetic fields. This phenomenon, called nuclear acoustic resonance (NAR), is analogous to nuclear magnetic resonance (NMR) but relies not upon an externally generated magnetic field but rather upon ultrasound to cause internal interactions among the magnetic or electrical multipole moments of a nucleus. While NMR cannot be used to characterize the properties of metal alloys because of the poor penetration of radio-frequency electromagnetic fields in metals, NAR can couple phonons readily into bulk metals since ultrasonic absorption is low. The lattice vibrations caused by the acoustic wave couple energy into the nuclear spins by two primary mechanisms (Bolef and Sundfors, 1992): the dynamic nuclear electric quadrupole interaction and the dynamic nuclear dipolar (or Alpher-Rubin) interaction. In both interactions, the acoustic wave generates time-dependent gradients of electric field due to modulation of the distances between atoms. The changes in nuclear spin are usually detected with a superconducting quantum interference device (SQUID), which increases the sensitivity of magnetic measurements considerably (Holland and Sundfors, 1985).

3.2 Electron Effects

Acoustic paramagnetic resonance (APR) is similar to NAR except that ultrasonic phonons are used to excite transitions in electron spins rather than nuclear spins. The acoustoelectric effect describes the flow of electric charges in a conducting film that has been deposited upon a piezoelectric substrate through which a surface acoustic wave travels (Levy, 1992). The surface acoustic wave will lose energy through the dissipation caused by the motion of the charges, and this energy loss can be detected to yield information about the electrical conductivity of the surface layer. A similar phenomenon known as the magnetoelastic interaction occurs when surface acoustic waves traveling through thin nickel films over a quartz substrate are attenuated by changes in applied magnetic field (Levy, 1992). The attenuation is due to interactions between the phonons and electrons or magnetic moments in the surface film.

3.3 Optical Effects

Ultrasound interacts with materials to produce optical effects by modifying a material's index of refraction, n. The change in n is due entirely to instantaneous changes in density ρ that accompany the compressional and rarefactional pressure variations of the sound wave. Liquid water, for instance, has an index of refraction whose changes with pressure are given to within 5% at 20 °C by the following expression (Straudenraus and Eisenmenger, 1993):

$$\Delta n = 1.4 \times 10^{-4} \Delta p, \tag{6}$$

where the pressure variation Δp is in units of megapascals. Thus a ten-atmosphere variation in acoustic pressure Δp would produce a change Δn of about 1.4×10^{-4}, and for $p = 1000$ atm, $\Delta n \approx 1.4 \times 10^{-2}$ (Yadav *et al.*, 1973). Likewise, the changes of refraction index with pressure for silica glass are given by

$$\Delta n \approx 5 \times 10^{-6} \Delta p, \tag{7}$$

where Δp is again in units of megapascals (Barker and Hollenbach, 1970). The difference in changes of n with pressure between silica glass and water provides a method of using optical fibers to measure large-amplitude ultrasonic waves (Wurster *et al.*, 1994). Interferometric techniques have also been used to measure the changes of optical index of refraction caused by sound waves (Barker, 1972).

4. OSCILLATIONS AND RESONANCE

4.1 Structural Resonance

An acoustic wave that encounters a structure exerts a time-dependent force upon elements of that structure. This force is equal to the instantaneous acoustic pressure times the area upon which that pressure acts and is usually negligible for moderate sound intensities. Resonances of the structure, however, can allow significant oscillation amplitudes to occur after many acoustic cycles have each deposited energy in the structure over a long time. For instance, a structure with mass m, stiffness k, and damping b will have a well-defined resonance frequency at $f_R = \omega_d / 2\pi$, where

$$\omega_d = \sqrt{\omega_R^2 - \frac{b^2}{4m^2}}, \tag{8}$$

and

$$\omega_R = \sqrt{\frac{k}{m}}. \tag{9}$$

4.2 Bubble Resonance

Bubbles of a gas such as air or water vapor are more compressible than the surrounding fluid and hence may be considered to have an effective spring constant resulting from the increases in gas pressure that accompany any decrease in volume. If the gas in the bubble is considered an ideal gas, the adiabatic ideal gas relationship can be used (Everbach, 1989) to derive the linear, small-amplitude stiffness of the bubble as $12\pi a\gamma P_0$, where γ is the ratio of specific heats for the gas (approximately 1.4 for air), P is the instantaneous absolute pressure, P_0 is the mean absolute pressure, and a is the bubble radius. The effective mass of a bubble is due less to the gas inside it than to the inertia of the liquid surrounding the bubble when the bubble oscillates radially. Assuming the liquid is incompressible in comparison to the bubble, the effective mass m can be shown (Leighton, 1994) to be $4\pi a^2\rho_L$, where ρ_L is the density of the liquid. Thus a low-amplitude resonance frequency f_R exists for the bubble given by

$$f_R = \frac{1}{2\pi a}\sqrt{\frac{3\gamma P_0}{\rho_L}}, \tag{10}$$

where the R subscript signifies resonance. This relation was first derived by Minnaert (1933) to explain the "pitch" of bubbles in a babbling brook. Damping of the bubble oscillations occurs via three mechanisms:

1. acoustic waves produced by the bubble radiate energy away,
2. thermal conduction between the gas in the bubble and the surrounding liquid removes energy, and
3. viscous friction at the bubble wall dissipates energy.

Figure 2 shows graphically the variation of the different damping constants b as functions of frequency for resonant air bubbles in water (for algebraic expressions, see Eller, 1970).

When infinitesimally low-amplitude acoustic waves traveling in a liquid encounter a bubble, the bubble oscillates radially at the angular frequency ω of the incident wave with a radial amplitude given by (Leighton, 1994, Eq. 4.23, p. 295)

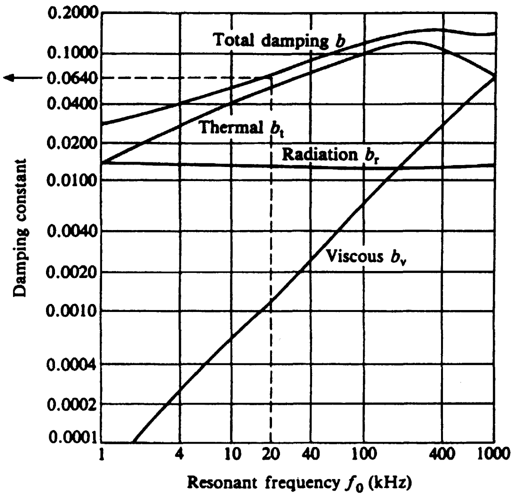

FIG. 2. Plot of damping constants b versus bubble resonance frequency for bubbles at resonance: b_v is damping due to the viscosity of the liquid surrounding the bubble, b_r is damping due to radiation losses, b_t is damping due to thermal losses via heat conduction, and b is the total damping constant (from Young, 1989; by permission).

$$\frac{P_A}{a\rho_L\sqrt{(\omega_R^2 - \omega^2)^2 + (2\beta_{\text{tot}}\omega)^2}}, \tag{11}$$

where P_A is the acoustic pressure amplitude, $\omega_R = 2\pi f_R$ is the resonance angular frequency of the bubble, and β_{tot} is the damping factor considering all dissipation mechanisms: $\beta_{\text{tot}} \approx b/2m$ for lightly damped bubbles. For finite-amplitude incident waves, oscillations of the bubble can have an effect on nearby objects, such as blood cells or ocean micro-organisms, because of the hydrodynamic flow patterns developed in the fluid around the bubble. In particular, shear forces sufficient to disrupt cell membranes have been observed to cause, for example, lysis of red blood cells (Williams *et al.*, 1986; Miller and Williams, 1983).

4.2.1 Acoustic Cavitation When a bubble is driven at or near resonance by an incident acoustic wave, it may oscillate in a continuous fashion (stable cavitation) or grow and collapse violently (transient or inertial cavitation), depending upon the bubble characteristics and the insonification parameters. Bubbles act as very nonlinear oscillators, and so even weakly driven bubbles may undergo changes in radius with time that demonstrate deterministic chaos (Cramer and Lauterborn, 1981; Parlitz *et al.*, 1990). As mentioned in the previous section, stable cavitation can produce microstreaming and large local shear forces in the fluid near the oscillating bubble walls. Transient cavitation, however, can result in additional physical effects including sonoluminescence, shock-wave production, liquid jet formation, and free-radical production. These effects are the result of a concentration of energy of up to 12 orders of magnitude from the relatively weak spatial ultrasonic field into the small volume occupied by the radially collapsing bubble.

For a bubble to grow and collapse violently, it must be inertially controlled: the bubble must grow during one or several rarefactional periods of the incident sound wave to two or three times its equilibrium radius. Once this rapid expansion occurs, the pressure is very low inside the expanded bubble, and during the next acoustic compression half-cycle, the walls of the bubble are accelerated radially inward. The stiffness of the gas inside the bubble is then far less important than the inertia of the moving liquid. The bubble walls thus converge, launching secondary shock waves and compressing whatever gas exists in the bubble to temperatures above 5000 K (Suslick, 1990). Such a spherically symmetric "hot spot" collapse is one mechanism suggested to account for the interesting chemistry and physics that can occur due to transient cavitation. Electrohydrodynamic mechanisms have also been proposed (Lepoint *et al.*, 1997). Please see the article on SONOLUMINESCENCE for more information.

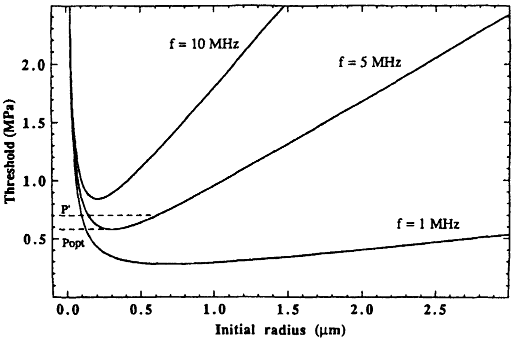

FIG. 3. Plot of the cavitation threshold (peak negative pressure) in water as a function of initial air-bubble radius for three frequencies of ultrasound: 1, 5, and 10 MHz, from an analytical model by Apfel and Holland (1991, by permission). As the threshold increases, a broader range of bubbles grow within a single acoustic cycle and collapse adiabatically to a temperature of 5000 K.

Bubbles are driven most efficiently at the resonance frequencies approximated by the formula in Sec. 4.2. In a bubble population containing a range of radii, therefore, those that are near resonance size collapse first and are called "prompt" cavitation nuclei. Figure 3 shows a plot of the peak negative acoustic pressure (called the cavitation threshold) that is sufficient to cause inertial growth and collapse air bubbles in water within a single acoustic cycle, as a function of initial bubble radius for three insonification frequencies. As the pressure amplitude increases at a particular insonification frequency (e.g., pressure *P'* for 5 MHz), a broader size range of nuclei act as "prompt" nuclei and cavitate within a single acoustic cycle. Those bubbles smaller than resonance size may grow via the process of rectified diffusion (Atchley and Crum, 1988) if the pressure amplitude is sufficiently high, as represented schematically in Fig. 4. Since the surface area of the bubble is slightly larger during a rarefactional half-cycle than during a compressional half-cycle, more gas diffuses into the bubble from the surrounding liquid during rarefaction than diffuses out during compression. Also, the layer of liquid surrounding the bubble tends to increase in thickness when the bubble contracts, decreasing the gas concentration gradient in the liquid closest to the bubble wall. The opposite effect occurs during the bubble expansion, increasing the local gas concentration gradient. Since the diffusion rate of gas is proportional to the concentration gradient, the result is a slow pumping of gas into the bubble over many acoustic cycles. Bubbles initially smaller than resonance size will tend to grow to resonance size and collapse, while bubbles larger than resonance size may grow large enough to rise via buoyancy out of the sound field. Under some conditions (Church, 1988), bubbles may become trapped in a stable cyclical process indefinitely, oscillating

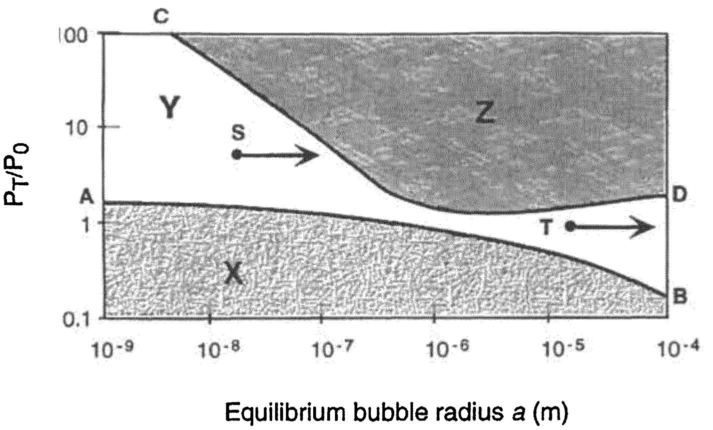

FIG. 4. Schematic representation of the domains of bubble growth via rectified diffusion for air-saturated water at 20 kHz (after Young, 1989). P_T is the peak negative pressure of the incident wave, P_0 is the ambient hydrostatic pressure (assumed to be 100 kPa), and *a* is the equilibrium bubble radius. In the region X delineated by curve A-B, acoustic forces cannot overcome surface tension and bubbles gradually dissolve. In the region Z delineated by curve C-D, bubbles collapse inertially. In region Y, bubbles grow via rectified diffusion until a boundary is crossed (e.g., *S* will grow and eventually collapse as it crosses C-D) or until buoyancy removes the bubble from the sound field (e.g., point *T*).

slowly around some mean size and never collapsing. Upon collapse, however, a bubble is likely to shatter into small fragments that can grow again by rectified diffusion, as shown schematically in Fig. 5.

During inertial cavitation, if a bubble is within one or two equilibrium radii of a solid surface, an asymmetrical collapse can occur. Because of the restriction of liquid flow on the side of the bubble closest to the solid surface, a liquid jet can form on the opposite side that penetrates the bubble and strikes the surface perpendicularly (Fig. 6).

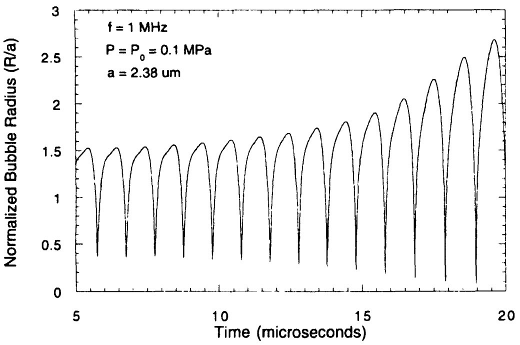

FIG. 5. Numerical calculations for a single CO_2 bubble in water exposed to continuous-wave ultrasound, showing growth via rectified diffusion and subsequent inertial collapse. Instantaneous bubble radius *R* divided by equilibrium radius $a = 2.38\ \mu m$ is plotted versus elapsed time for 1-MHz ultrasound at 0.1 MPa acoustic pressure amplitude (after Church, 1989).

Liquid jets have been observed at velocities of up to 200 m/s (Lauterborn and Bolle, 1975) and are thought responsible for pitting of foils (Coleman *et al.*, 1987), erosion of gallstones in lithotripsy (Vakil and Everbach, 1993), and ultrasonic cleaning of jewelry.

If the collapse of a bubble is symmetrical, the high temperatures, pressures, and shear forces that result can cause chemical and physical changes such as the fusing of metal particles (Doktycz and Suslick, 1990) and the formation of highly reactive free radicals (Riesz and Kondo, 1992), among other effects (see Sec. 6). The production of light (see SONOLUMINESCENCE) may also occur, although the precise mechanism for sonoluminescence is currently a matter of active research (Lepoint *et al.*, 1997).

In 1993, the U.S. Food and Drug Administration, in cooperation with the American Institute of Ultrasound in Medicine and the National Electronics Manufacturer's Association, took account of the potential for adverse bioeffects produced by inertial cavitation with a requirement for new output display on diagnostic ultrasound equipment (FDA, 1993). Diagnostic ultrasound devices must provide an on-screen descriptor of the likelihood of transient cavitation called the mechanical index (MI). The MI is defined as the derated peak rarefactional pressure in megapascals at the point of maximum pulse intensity integral, divided by the square root of the ultrasonic center frequency in megahertz (Meltzer, 1996). This descriptor was

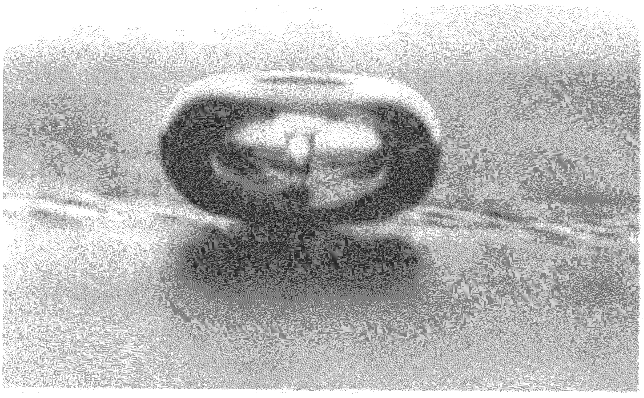

FIG. 6. As a result of the restriction of flow on the side of a collapsing bubble closest to a wall, a liquid jet can form that strikes the surface perpendicularly, causing pitting (from Coleman *et al.*, 1987; by permission).

adopted after reviewing the basic and theoretical research in cavitation inception available at the time (Apfel and Holland, 1991), which assumes that a population of cavitation nuclei of resonance size is always available (see BIOLOGICAL EFFECTS OF SOUND AND ULTRASOUND).

5. SHOCK WAVES

A shock wave in a gas or liquid is defined as a rapid discontinuity in pressure that travels as a wave with a speed faster than the small-signal sound speed of the medium. Shock waves can occur as a result of an abrupt source of pressure (e.g., an explosion), passage of an object traveling faster than the local sound speed (i.e., supersonic motion), or nonlinear wave steepening (see ACOUSTICS, NONLINEAR). Shock waves have physical effects on structures and materials due primarily to the energy they deposit and the forces they exert.

A derivation of the basic equations of shock theory, called the Rankine-Hugoniot shock relations (Lighthill, 1956), yields the following result for weak shocks:

$$v_{\text{shock}} \approx c_0 + \beta\left(\frac{u_1 + u_0}{2}\right), \tag{12}$$

where v_{shock} is the shock propagation speed, c_0 is the small-signal sound speed, $\beta = (\gamma + 1)/2$, γ is the ratio of specific heats of the medium, and u_1 and u_0 are the particle velocities behind the shock front and ahead of it, respectively. The above equation, valid to first order in the "shock strength" u_1/c_0, shows that a weak shock travels with the mean of the wavelet speeds just ahead of it and just behind it. For shocks in air, the spatial thickness of the discontinuity goes inversely as the shock strength, as Table 1 shows (Blackstock, 1982). Many applications of shock waves arise, but the most significant are those related to supersonic flight (sonic booms) and destruction of kidney stones (lithotripsy).

5.1 Sonic Booms

When an object moves faster than the local small-signal sound speed, sounds produced by the object (engine noise, wind turbulence noise) cannot propagate ahead of the object, and a conical shock is formed called a Mach cone. For supersonic aircraft,

Table 1. Shock thickness and SPL as a function of shock strength.

Shock strength u_1/c_0	Shock thickness (mm)	Equivalent SPL (dB)[a]
0.1	0.00524	174
0.01	0.0524	154
0.001	0.524	134
0.0001	5.24	114
0.00001	52.4	94

[a] Sound pressure level of a sinusoidal wave whose dimensionless amplitude is the same as the shock strength.

separate shocks occurring at cross-sectional discontinuities along the length of the aircraft are formed that merge into an "N"-shaped pressure discontinuity at large distances. Dissipation effects such as N_2 and O_2 molecular relaxation are strong at the vertical portions of the N wave, and so the rise time of the shock felt on the ground is strongly influenced by the altitude of the flight. Other important effects include relative humidity, wind turbulence aloft and near the ground, and pre-existing temperature gradients that serve to dephase the shock-wave frequency components.

By changing the length and shape of aircraft and by flying them as high as possible before supersonic flight occurs, the damage caused by sonic booms to windows and other structures on the ground can be minimized. So-called "shaped booms" have pressure signatures that deviate from N waves as a result of more streamlined aircraft designs (Maglieri, 1992). The trend to faster hypersonic flight, however, creates conditions that might reverse these advances. Such factors include a narrower Mach cone that produces more nearly vertical incident-ray angles and the potential for increased ground or water coupling (including shock waves launched into the ocean that are little affected by water depth).

5.2 Lithotripsy

Extracorporeal shock-wave lithotripsy (ESWL) is a medical procedure in which focused underwater shock waves impinge upon a kidney or gall stone, resulting in the pulverization of the stone into fragments that are subsequently passed by the patient. First introduced in the early 1980s (Chaussy *et al.*, 1980), the procedure has been used successfully on hundreds of thousands of patients worldwide. ESWL is considered much less traumatic and less expensive than abdominal surgery since it can be performed on an outpatient basis.

The precise mechanism by which the converging shock wave breaks the stone is unknown. However, stone breakage is thought to be governed either by the internal reflection of the compressional portion of the acoustic pulse (which becomes a tension wave) from the posterior of the stone (Ferrucci, 1989) or by the action of microscopic gas bubbles collapsing onto the stone surface in response to the rarefactional portion of the acoustic pulse (Coleman *et al.*, 1987). Both mechanisms may operate simultaneously or in combination, but each is dependent upon the temporal and spatial characteristics of the lithotripter pulse, as well as the material properties of the concretion (Vakil *et al.*, 1991).

Lithotripters of various designs produce acoustic shock waves using different techniques. Often an initial shock wave is created by an underwater explosion driven by a high-voltage spark discharge (Coleman and Saunders, 1989). The spark-gap electrodes are located at one focus of a hemi-ellipsoidal metal bowl so that the spherically expanding shock wave reflects from the bowl walls and converges at the opposite focus (Fig. 7). This second focus is placed (via ultrasound imaging or fluoroscopy) so as to coincide with the patient's kidney stone. Acoustic pulses can also be created via an electromagnetic device that is analogous to a loudspeaker, or via a piezoelectric crystal (or crystal array), but in these cases the waves produced are nearly sinusoidal and not shock waves. By focusing them with an acoustic lens or by placing the crystals on a spherical backing surface, the converging waves steepen and form shock waves *en route* to the stone. The "shape" of the lithotripter pulse varies from one lithotripter to another but shares the common characteristics of a rapid rise time (from ambient pressure to a maximum of nearly 1000 atmospheres in several nanoseconds) followed by a slower return to ambient pressure (in about 1 μs) and a longer negative tail (up to 200 atmospheres of tension lasting up to 10 μs).

6. SONOCHEMISTRY

Prior to 1940, investigators had established that certain chemical reactions could be accelerated in the presence of high-frequency sound waves. These reactions included the hydrolysis of dimethyl sulfate in basic aqueous solutions, the acceleration of the iodine clock reaction, the decomposition of certain pure organic liquids, the degradation of macromolecules in solution, and the production of free radicals (Riesz and Kondo, 1992). These and other effects are

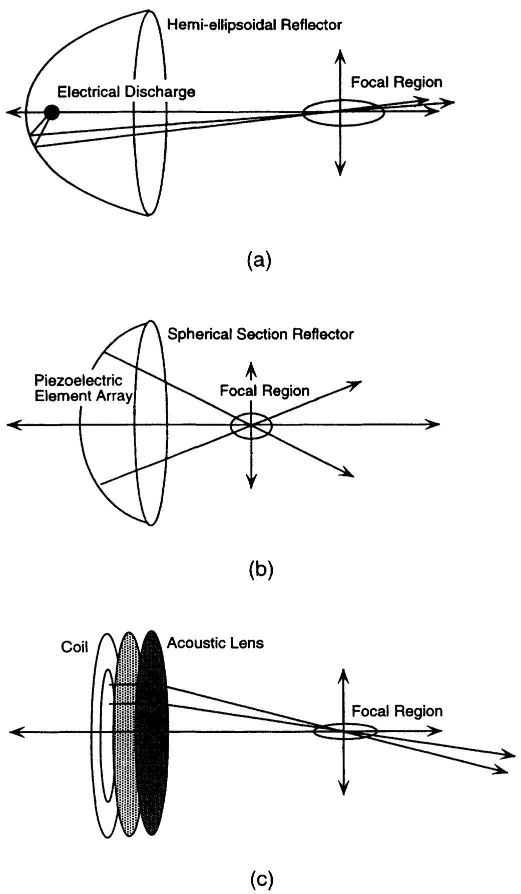

FIG. 7. Lithotripter designs: (a) underwater spark discharge is focused via hemi-ellipsoidal bowl, (b) piezoelectric mosaic mounted on spherical section causes convergence at center, and (c) electrodynamic coil or electrostrictive element launches pulse that is focused via a concave lens (after Coleman and Saunders, 1989).

thought by some researchers (Suslick, 1990; Suslick and Doktycz, 1991) to be due to the momentarily high temperatures (5000 K) and pressures (50 MPa) inside microbubbles undergoing inertial cavitation.

Reactions that take place inside the bubble include typical gas-phase pyrolysis reactions such as sonolysis of aqueous solutions. Unlike combustion pyrolysis, sonolysis can generate free oxygen inside the bubble by thermal dissociation of water, and so no external oxygen source is necessary for certain reactions. For example, in the sonolysis of aqueous solutions containing acetylene and argon, complex hydrocarbons such as benzene and naphthalene can be formed (Hart *et al.*, 1990). Reactions can also take place at the bubble wall in a region extending approximately 200 nm into the surrounding liquid (Suslick *et al.*, 1986), where temperatures reach approximately 2000 K. Here the concentration of OH radicals is the highest, however, and so the thermal decomposition of solutes may be affected by the scavenging of these radicals, depending upon the reaction. Finally, reactions can take place in the liquid away from the bubble wall as free radicals that have not been scavenged in the interfacial region react with solutes there (Riesz *et al.*, 1985). It is also the case that metal powder grains suspended in the solution may have their surface oxide layers removed by bubble jet formation or high-velocity interparticle collisions, and so increase their reactivity or catalytic function (Suslick, 1989).

ACKNOWLEDGMENT

This work was supported in part by a Presidential Faculty Fellowship of the National Science Foundation, MSS 92537777.

GLOSSARY

Cavitation Nuclei: Small pre-existing gas bubbles often stabilized in the cracks of dirt particles or by surfactants.

Derating: The procedure by which an acoustic field measurement in water is corrected to allow for the estimated attenuation caused by ultrasound propagation through tissue.

Deterministic Chaos: The family of characteristics of nonlinear systems that includes the following:

1. the system is governed by deterministic laws (i.e., not random), yet successive states appear random,
2. infinitesimal changes in initial conditions can produce wildly different final states, and
3. the dimensionality of a phase-space plot is of noninteger order.

Free Radicals: Unbound but highly chemically reactive ionic compounds such as OH^-.

Hypersonic: Faster than about Mach 4 (four times the local sound speed).

Mach Cone: The conical shock front, usually originating as a bow wave, from a supersonic object or aircraft.

Nuclear Spins: The rapid rotation of charged atomic nuclei that induces an effective magnetic field.

Particle Velocity: The speed and direction of fluid elements considered sufficiently small so that their properties may be considered uniform within them.

Pyrolysis: The breaking down, or the creation by rearrangement of bonds, of chemical compounds via heating.

Rarefaction: A region of negative gauge pressure and low density, in which the molecules of a medium are momentarily farther apart from one another than they are at equilibrium.

Resonance Size: The radius of a bubble at which an incident sound wave will cause maximum radial displacement oscillations.

Sonolysis: The breaking down, or the creation by rearrangement of bonds, of chemical compounds via action of ultrasound through the mechanism of inertial cavitation.

Wavelet: A single-frequency component of a wave, having infinitesimal amplitude.

INTRODUCTION

Underwater acoustics and atmospheric acoustics have many similarities. Both of these acoustic environments are often characterized by multipath or waveguide-type propagation (see ACOUSTICS, UNDERWATER; ATMOSPHERIC ACOUSTICS); the frequencies of interest are in the same regime, from a few hertz to tens of kilohertz; the media have many similar and analogous properties, such as stratification, currents or winds, internal waves, etc.; high-frequency attenuation results in band-limited propagation. Therefore, it is convenient to address many of the signal-processing issues for underwater and atmospheric acoustics in the same place.

In this article we discuss both temporal and spatial signal processing. We begin with a brief description of the atmospheric and underwater acoustic environment. Data acquisition and temporal and spatial processing are discussed with emphasis on ultimately taking advantage of digital signal processing. Both passive and active acoustic systems are treated. This article is a brief overview of a very large field. The references, therefore, provide much more detail.

1. THE ACOUSTIC ENVIRONMENT

Both the ocean and the atmosphere are nonhomogeneous fluid media in which the same general principles for acoustic sensing and signal processing apply, although differing boundary conditions, media parameters, and applications lead to variations in approaches and techniques. Descriptions of the media can be found in Clay and Medwin (1977) for the ocean and in ATMOSPHERIC ACOUSTICS and Panofsky and Dutton (1984) for the atmosphere. Characteristics that affect signal processing for the media are summarized here. For underwater acoustic propagation prediction models, see Jensen *et al.* (1994), and for a set of benchmark tests for propagation models in the atmosphere (excluding turbulence), see Attenborough *et al.* (1995).

Except in close proximity to the source, most sounds in the atmosphere and the ocean cause only small disturbances in the medium and propagate according to the linear wave equation for inhomogeneous media,

$$\rho\nabla\cdot\left(\frac{1}{\rho}\nabla p\right) - \frac{1}{c^2}\frac{\partial^2 p}{\partial t^2} = 0,$$

where p is the acoustic pressure, c is the sound speed, and ρ is the medium density. Both ρ and c may vary with position and time. For signals in this linear regime, particularly where moving sources and targets are concerned, sound propagation is treated as a time-varying, linear system. Higher-pressure sound waves in the nonlinear regime also occur, such as from explosions or sonic booms. They cause significant disturbances in the media, such as cavitation underwater, and require nonlinear models (see ACOUSTICS, NONLINEAR); however, nonlinear disturbances generally decay rapidly into the linear regime as they propagate.

Sound pressure levels are expressed in decibels relative to 1 μPa underwater and 20 μPa in the atmosphere. These different references result in sound pressure levels underwater being specified numerically as 26 dB above the equivalent level in the atmosphere. Sound pressure levels reported in the atmosphere are often weighted with frequency to account for human hearing characteristics. In the atmospheric acoustics literature, unweighted measurements are often referred to as being linearly weighted.

The acoustic energy flux, or acoustic intensity, for a plane wave is $\mathbf{I} = \mathbf{n}p^2/\rho c$, where $\mathbf{n}$ is a unit vector in the direction of propagation, p is the acoustic pressure, ρ is density (approximately 1.2 kg/m^3 for the atmosphere and 1000 kg/m^3 for the ocean), and c is the speed of sound (approximately 340 m/s for the atmosphere and 1500 m/s for the ocean). Accordingly, a plane wave with a given pressure amplitude will have an intensity in the atmosphere that is about 3500 times greater than that in the ocean.

A high sound pressure level within the linear regime in the atmosphere, such as a rocket launch measured at a few hundred meters, may exceed 140 dB re 20 μPa, linearly weighted. Background levels are often in the range of 40–60 dB re 20 μPa, linearly weighted. Background levels tend to increase at lower frequencies, as can be seen in Fig. 1, which shows an example of a background noise spectrum near the ground with a sound pressure level (linearly weighted) of about 60 dB re 20 μPa. Microphones outdoors must be protected by windscreens to reduce the noise generated at the sensor by wind. Rainfall generates high noise levels, making acoustic sensing difficult.

In the ocean, sound pressure levels are usually not weighted with frequency. A high

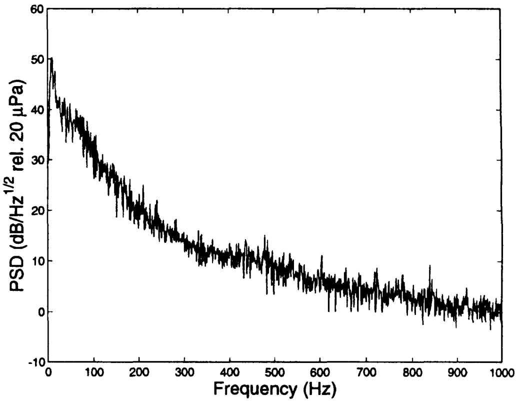

FIG. 1. An example power spectral density (PSD) for background noise in the atmosphere. The recordings were made near a hard ground in a rural environment. The PSD increases significantly at lower frequencies, although it declines below 10 Hz in the figure because of attenuation by the recording system.

sound pressure within the linear regime in the ocean, such as might be generated by sonar, is greater than 220 dB re 1 μPa. Background noise levels are of the order of 60–90 dB re 1 μPa, depending on frequency. As in the atmosphere, background noise level increases at lower frequencies.

Sound absorption loss is due primarily to molecular relaxation mechanisms (Piercy *et al.*, 1986), which involve the rate of exchange of energy between molecular states. In the atmosphere, there are two main relaxation mechanisms, which are catalyzed by water vapor and involve mechanical vibrational modes of O_2 and N_2 molecules. In the ocean, there are two chemical relaxation mechanisms, involving magnesium sulfate and boric acid. These absorption mechanisms exhibit a "resonance" sort of behavior, which results in humps in the spectral absorption curves. The locations of these humps are determined by the relaxation frequencies. While these frequencies change significantly for the atmosphere, because they are highly dependent upon the water-vapor content, they are relatively constant for the ocean. Figure 2 shows example sound absorption curves in the ocean and the atmosphere. The lower absorption of the ocean makes it possible to sense acoustic signals at much greater ranges than in the atmosphere. For long-range propagation in the atmosphere and in the ocean, frequencies of interest are constrained below about 1000 Hz on account of absorption. Although natural acoustic sources extend well into the infrasonic region, the greatest interest lies in the frequency ranges 10–1000 Hz because of the abundance of man-made and biological sources in this frequency range.

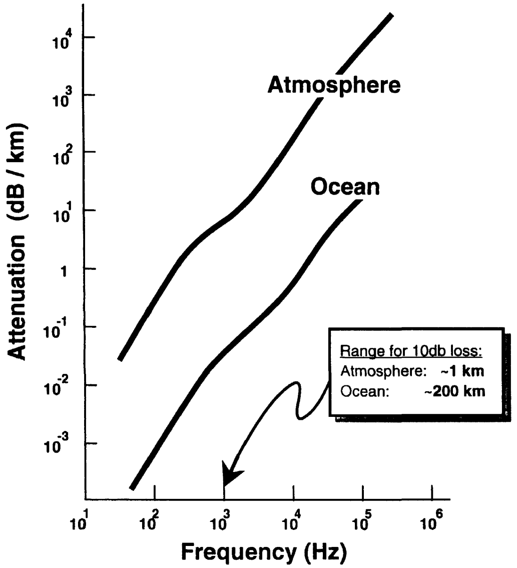

FIG. 2. Example absorption curves for sound propagating in the ocean and the atmosphere.

The speed of sound is nominally 1500 m/s in the ocean and 340 m/s in air; hence wavelengths are longer underwater, and larger arrays are needed for spatial processing.

The density, pressure, temperature, wind or currents, and salinity in the case of the ocean change with depth or height resulting in sound-speed variations that are expressed by *sound-speed profiles.* Typical sound-speed profiles for the ocean with their geographical disposition and a schematic of resulting ocean paths are shown in Figs. 1–3 of ACOUSTICS, UNDERWATER. An example of sound-speed profiles and propagation paths for the atmosphere are shown in Pierce (1989). Of particular interest is the existence of features such as a *surface duct,* the *deep-sea duct, acoustic shadow regions,* and periodic *convergence zones* in both the underwater and atmospheric sound propagation.

A surface duct is formed when sound is refracted toward the reflecting surface, thereby constraining propagation within the duct. Similarly, the deep-sea duct (or upper atmosphere duct) refracts sound back into the duct from its upper and lower extremities. Ducts may be cylindrically (azimuthally) symmetrical, as is typically the case underwater, resulting in cylindrical spreading, or they may be asymmetrical, as in the case of wind-induced profiles in the atmosphere. Sound pressure generally varies with range R as R^{-2} (spherical spreading), but when propagating through a duct, it varies as R^{-1} (cylindrical spreading).

For acoustic line-of-sight propagation there is at least one acoustic ray path between the source and receiver. For a receiver located within an acoustic shadow region, there are no ray paths between the source and receiver. Acoustic shadow regions can be generated by refraction patterns, often at a surface interface, or by masking due to large surface topographical features. At the edge of an acoustic shadow region, sound energy is present as a result of diffraction from the shadow boundary. Full wave propagation models are used to predict the sound field in these regions since the simpler ray-path models do not admit a ray path between the source and a receiver within an acoustic shadow region.

Deeper within the shadow region, sound energy is predominantly due to scattering from the turbulence in the surrounding ensonified regions. Sound pressure levels in acoustic shadow regions in the atmosphere near the ground can exhibit weak range dependence.

Convergence zones are regions of enhanced sound pressure levels at range intervals along a duct. They are caused by the coincidence, or focusing, of ray paths that are radiated (or launched) from the source at different elevation angles. Sound pressure levels in these convergence zones are well above that expected for cylindrical spreading and are determined by the shape of the sound-speed profile and the homogeneity of the medium.

Sound-speed profiles change considerably because of diurnal, seasonal, and weather system fluctuations, particularly near the ground in the atmosphere and near the surface underwater. An example of sound-speed profile fluctuations near the ground, and the corresponding short-range sound propagation, can be seen in L'Esperance *et al.* (1995).

Range dependence in the sound-speed profile complicates the structure (and prediction) of a propagating sound field. Atmospheric propagation and shallow-water propagation both exhibit significant range dependence in the sound-speed profiles. Winds in the atmosphere have a greater effect on propagation than do currents in the ocean.

Turbulence introduces random fluctuations in the index of refraction and fluctuations in the local velocity of the medium. These random perturbations generally moderate sound-level extremes that would be present in a nonturbulent, deterministic environment; sound levels in null regions, where interfering propagation paths would normally result in very low levels, are raised somewhat, and sound levels in regions of reinforcement, where constructive interference or convergence of ray paths would normally increase levels, are decreased somewhat.

Turbulence also distorts the propagating wave fronts and can cause mixing between propagation modes. In the presence of turbulence the sound field becomes a stochastic function of time and space with finite temporal and spatial coherence, limiting the achievable array processing gains. The effects of turbulence are more significant in the atmosphere than they are in the ocean. In the atmosphere, at frequencies of a few hundred hertz, temporal coherence is on the order of seconds and spatial coherence may be less than a meter (Daigle *et al.*, 1983; Havelock *et al.*, 1995). Coherence is greater in the ocean.

The fluctuations in the phase and magnitude of a pure tone propagating through turbulence increase with range, but the magnitude fluctuations reach a saturation level of approximately 6 dB at some distance, beyond which the magnitude fluctuations do not increase further. A 1000-Hz signal propagating in the atmosphere may reach saturation within a kilometer, whereas saturation will not be reached for hundreds of kilometers in the open ocean. Phase fluctuations, rather than magnitude fluctuations, are usually the main cause of spatial and temporal decorrelation of the sound field.

Acoustic sensing in the atmosphere is usually done near the ground, where the variable ground impedance, topology of the terrain, strong refraction, and surface structures such as buildings or forests play an important role. The frequent occurrence of acoustic shadow regions near the ground further complicates signal detection.

Deep-ocean measurements have a more stable environment than the atmosphere, but measurement near the ocean surface must contend with varying surface conditions, while measurements near the ocean floor or in shallow water must contend with a complex seafloor impedance and seafloor topography. The ocean seafloor typically consists of a sediment layer overlying a hard basement. Both types of materials are elastic media, which support shear waves as well as compressional waves. The shear-wave speed in sediments is typically of the order of 100 m/s (very slow). The existence of this wave acts as an additional degree of freedom to transport sound out of the water column; hence, it appears as a loss mechanism. On the other hand, the rock basement often has a shear-wave speed greater than the speed of sound in water and therefore acts as a good reflector (Jensen *et al.,* 1994). These layered structures combine to have complicated frequency-dependent properties. Accurate knowledge of the seafloor is difficult and expensive to ascertain but is important for many signal-processing applications.

2. SIGNAL ACQUISITION

2.1 Sensors

Signal acquisition begins at an acoustic transducer inserted into a sound field. Microphones (Wong and Embleton, 1995), used in the atmosphere, and hydrophones, used underwater, are capable of measuring wide ranges of signal frequencies and amplitudes; nevertheless, with acoustic signals of interest ranging over nine orders of magnitude in frequency and amplitude, the appropriate sensor type must be selected for the desired signals. Microphones can range in size from millimeters, for ultrasonic or insertion-type microphones, to several meters and beyond, for infrasonic microphones. In general, greater sensitivity and lower-frequency response is achieved with larger sensors.

In most cases, acoustic sensors are small relative to the signal wavelength and are considered to sample the sound field at a point. Acoustic sensors can measure the instantaneous acoustic amplitude, rather than just the envelope or intensity as is often the case with optical sensors. This capability allows multiple independent sensors to be used to construct an array that samples the sound field over a spatially distributed region and integrates the results coherently to obtain gains in sensitivity and directionality. The processing of signals gathered by such arrays occupies a large proportion of the subject of underwater and atmospheric acoustic signal processing.

2.2 Signals

A wide variety of signal sources are of interest in both underwater and atmospheric applications. The signals are broadly categorized as impulsive or continuous wave. Continuous-wave (cw) signals have fairly constant power levels over the signal monitoring interval and are generally easier to generate and detect than are impulsive signals. The term continuous wave is usually interpreted to mean pure sinusoidal tones, which have been studied extensively for detection, localization, and classification problems. Manmade equipment readily produces continuous-wave signals because of the periodicity of reciprocating mechanical parts.

Impulsive signals are characterized by short periods of high power interspersed with long periods of little or no signal power. The classical impulse signal is the Dirac delta function, which is not physically realizable. There are practical difficulties in generating and receiving pulses, due to the high instantaneous power required to obtain adequate signal-to-noise ratio. Active sonar systems utilize the high temporal resolution of impulsive signals to perform range estimation. Narrow-band short pulses, consisting of a tone that is amplitude modulated by short-duration pulses, are used for this purpose. Short pulse duration corresponds to wide frequency bandwidth, making pulses useful for examining system response. The time-varying environments of the ocean and the atmosphere are often probed with impulsive signals to determine the response at many frequencies simultaneously, before the environment changes.

Swept tones, which are generated by progressively increasing or decreasing the frequency of a pure-tone generator, are sometimes used to measure system response. These signals can provide high power in narrow frequency bands, but they have the disadvantage that the component tones do not propagate simultaneously. Periodic sequences, which are composed of combinations of harmonics of the repetition frequency, are better suited for this purpose. A repeated pulse is one example of such signals, and a repeated tone burst is another. Tone bursts are regularly spaced intervals of pure sinusoidal signal interspersed with silence.

An important parameter of test signals is the peak factor (or crest factor), which is a measure of the variations in the (instantaneous) power. It is defined as the ratio of the maximum signal amplitude to the rms signal amplitude. Techniques have been developed to adjust the phase and magnitude of harmonics so as to minimize the signal peak factor. (See Burgess, 1992 and the references therein.)

Maximum-length (ML) sequence signals can be efficiently generated by a feedback shift register (Kramer, 1965) and are well known for their low peak factor and constant power spectra. An ML sequence is a finite sequence of numbers, generated according to the principles of the theory of cyclic groups, with an autocorrelation function that approximates a delta function. Repetition of such a sequence results in a spectrum composed of the harmonics of the repetition frequency, and the envelope of the harmonics is reasonably flat. Binary ML sequences, which are widely used, are obtained from the high-order bit of the feedback shift register.

2.3 Spatial Distribution

Coherent detection with an array of sensors refers to adjusting the phase (and possibly the magnitude) of the signal received at each sensor so that they synchronously receive a specific signal. The spatial distribution of the signal sound field must be modeled for coherent detection. In many applications, when the source is a long distance from the receiver, the signal is modeled as a plane wave arriving at the receiver from a specific direction. Other models, based on ray propagation or modes, may be used in more complicated environments.

The sound field close to a source deviates significantly from a plane or spherical wave on account of nonpropagating modes arising from the specific geometry of the source. The *far field* refers to ranges sufficiently great that the sound field resembles the desired model (spherical spreading or plane-wave propagation, for example). Since the near field is complicated, acoustic measurement of the sound power output of a source is often made in the far field and the reported source levels are referred back to a standard range, such as 1 m, on the basis of a simple propagation model.

Refraction by the medium, reflection from boundaries, and diffraction from discontinuities can cause *caustics* and *nulls* in the sound field. Caustics are regions of intensification due to constructive interference of propagating wave fronts, and nulls are regions of rarefaction due to destructive interference of the wave fronts. An array of sensors spanning a significant portion of a null or caustic region will observe a sound field that may be significantly distorted from a plane wave. This problem is more acute in the atmosphere than underwater since wavelengths are shorter and the environment is generally more complicated. Modeling the received sound field under such conditions can be difficult.

Various models and computational implementations have been developed for sound propagation underwater (Jensen *et al.*, 1994) and in the atmosphere (Attenborough *et al.*, 1995; Gilbert and Di, 1993), for deterministic environments. Methods for including stochastic properties of the medium are only now beginning to emerge.

2.4 Noise and Distortion Characteristics

For signal-processing applications, noise is often modeled as a temporally uncorrelated, Gaussian process $n(t)$; that is, the random variable $n(t)$ has a Gaussian distribution for each t and the correlation $R_n(\tau) = E\{n(t)n(t + \tau)\}$ is zero for $\tau \neq 0$, where $E\{\cdot\}$ indicates the expected value in the ensemble sense. Such noise is referred to as *white Gaussian noise* because its power spectral density, given by the Fourier transform of $R_n(\tau)$, is flat in much the same way as white light is considered to contain all colors equally. When noise is temporally correlated, so that $R_n(\tau) \neq 0$ for some $\tau \neq 0$ and its spectrum is not flat, it is referred to as *colored noise.* The typical noise spectrum, both underwater and in the atmosphere, increases at lower frequencies, suggesting that the noise should be considered colored; however, in practical terms, when the signal bandwidth is narrow, the approximation to white noise within the signal bandwidth is often adequate.

If all statistics of the noise are independent of time (although they may depend upon time differences such as τ in the autocorrelation mentioned above), the noise is said to be *stationary,* or *strict-sense stationary.* The noise is *wide-sense stationary* if the mean and temporal correlations (but not necessarily other statistics) of the noise are independent of time. Noise in the ocean and in the atmosphere is not stationary, and some form of dynamic noise modeling may be required, depending upon the signal duration. The problem may be further complicated by the presence of impulsive noise sources (for example, from biological sources such as insects or marine mammals).

A noise field that has the same statistical distribution at all points in space is said to be *homogeneous*. When statistics of the noise are independent of the orientation of the frame of reference, the noise is said to be *isotropic*. In practical situations, the noise can often be assumed to be locally homogeneous but not necessarily isotropic. Knowledge of the noise anisotropy can be utilized to improve discrimination between signals and noise when using arrays of sensors.

Noise is usually considered to be additive, in that the received signal is the sum of a desired signal and a noise signal. However, there are various forms of signal distortion that are not additive. One example is *clipping*, which is the limiting of the system response to a maximum level for input signal levels that exceed the maximum receiver response. Another example of signal distortion is phase or amplitude modulation such as may be caused by sensor motion or variations in sensitivity. Signal perturbations due to turbulence are also a source of signal distortion.

Noise that is tonal in nature may be considered to be a jamming, or interfering signal. It is often treated in the spectral domain, where it can be localized within a small frequency band. Correspondingly, jamming that is impulsive may be treated best in the time domain. Repetitive impulsive noises may be treated with a combination of spectral and temporal processing. Spatial processing (beam forming) can be very effective for eliminating jamming. Reverberation is a signal-generated noise, or distortion, that is periodic in the spectral domain. It can be generated by the scattering of a probe signal from inhomogeneities in the medium and is a major cause of interference.

Noise sources underwater and in the atmosphere are discussed in ACOUSTICS, UNDERWATER and ATMOSPHERIC ACOUSTICS, respectively.

3. TIME-SERIES PROCESSING

The broad subject of digital signal processing for time-series data is treated in textbooks such as Marple (1987) Oppenheim and Schafer (1989), and Rabiner and Schafer (1978). Central to this subject is the discrete Fourier transform, implemented with a fast Fourier-transform (FFT) algorithm. Many of the tools used for signal processing of time series from underwater and atmospheric acoustics are generic, in that they are also used in other application areas. Prominent among the techniques that are more specific to our application are those that deal with constructing a complex-signal representation, with extracting narrow-band signals, and with reducing the large volumes of recorded time-series data that contain considerable amounts of noise power. Representative techniques for accomplishing these tasks are discussed in this section.

3.1 Complex-Signal Reconstruction

Analytical techniques of signal processing are often presented in the elegant framework of complex-signal theory. Acoustic sensors and digital data-acquisition equipment respond to the signal frequencies of interest to provide measured signals that are real valued, rather than complex. For direct implementation of the theoretical principles, it is common practice to reconstruct the complex acoustic signal from the measured real signal. While there is no perfect method for complex-signal reconstruction in practice, there are various techniques that are quite accurate if done correctly.

The simplicity and importance of the reconstructed complex signal is illustrated by an example in Fig. 3, which compares a real-valued pulse signal with its complex reconstruction. The location of the pulse peak is an important signal parameter that is more clearly determined in the complex signal than it is in the real signal.

3.1.1 *I-Q* Demodulation of Narrow-Band Signals The received signal $s_r(t)$ is real valued and often consists of a pure tone, called a carrier frequency, modulated by the signal of interest $x(t) = a(t)\exp[i\phi(t)]$:

$$\begin{aligned} s_r(t) &= \mathrm{Re}[x(t)\exp(2\pi i f_c t)] && (1)\\ &= a(t)\cos[2\pi f_c t + \phi(t)] && (2)\\ &= x_r(t)\cos(2\pi f_c t) - x_q(t)\sin(2\pi f_c t), && (3)\end{aligned}$$

where the bandwidth of $x(t)$ is assumed to be less than the carrier frequency. Equation (1)

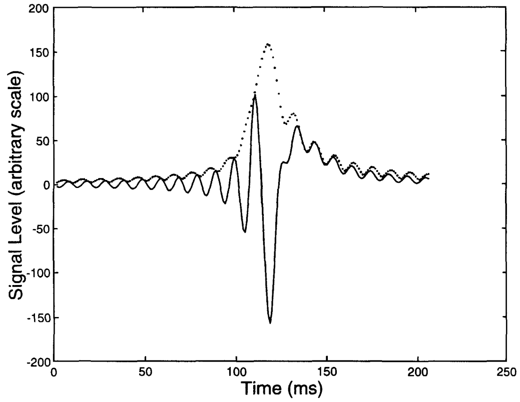

FIG. 3. The real-valued signal of a band-limited, distorted pulse (solid line) and the magnitude of the reconstructed complex signal (dotted line). The peak of the pulse is more easily located using the reconstructed signal.

is the *complex modulation* representation of the signal, Eq. (2) is the *envelope-phase* representation, and Eq. (3) is the *quadrature-carrier* representation. The frequency f_c is the carrier (center) frequency of the modulated signal $x(t)$. In the quadrature-carrier representation, the signal $x(t) = x_r(t) + ix_q(t)$ is the *complex envelope.* Interest in this signal characterization arises from a pure tone propagating through a perturbing ocean or atmosphere. In this situation, the perturbation $x(t)$, rather than the original carrier signal $\exp(2\pi i f_c t)$, is the main object of interest.

The real part of the complex envelope can be obtained by *I-Q* demodulation. In this method, a *quadrature filter* or *90° phase shifter* is first applied to the real received signal $s_r(t)$ to obtain the signal quadrature component $s_q(t)$, which is 90° behind the received signal, and then $x_r(t)$ is obtained using

$$x_r(t) = s_r(t)\cos(2\pi f_c t) + s_q(t)\sin(2\pi f_c t). \tag{4}$$

The accuracy of this method depends upon the accuracy in reconstructing $s_q(t)$, and on accurate knowledge of the value of f_c. The quadrature filter or a 90° phase shifter typically introduces a small error in either the magnitude or the phase, respectively (Bellanger, 1984, Chap. 9). Furthermore, the phase of the extracted signal $x(t)$ or $x_r(t)$ will depend upon the phase of the carrier signal at $t = 0$; we have assumed in the preceding that the carrier is of the form $\exp[2\pi i f_c(t + t_0)]$, where $t_0 = 0$. If the value of t_0 is shifted by $1/4f_c$, then the so-called in-phase component $s_r(t)$ and the quadrature component $s_q(t)$ are exchanged (with a sign reversal).

3.1.2 Heterodyne Demodulation of Narrow-Band Signals Equation (4) may be interpreted as the real part of the product of a complex version of the received signal, $s(t) = s_r(t) + is_q(t)$, and the complex exponential $\exp(-2\pi i f_c t)$. Multiplying by an exponential in this way is referred to as *heterodyning.* Heterodyning shifts the carrier frequency of the signal, and when the carrier frequency is shifted to dc (0 Hz), the process is called *homeodyning.* The bandwidth ω_x of $x(t)$ is assumed to be less than the center frequency f_c of the carrier frequency. The term *baseband* refers to the frequency band containing the signal of interest; thus, the baseband of $s(t)$ is $f_c \pm \omega_x/2$.

The mathematical description of the heterodyne process given above involves complex signals. Heterodyning can also be accomplished by multiplying real-valued signals by a real-valued sinusoid modulator, as is done in radio communications for example. This results in a spectrum that contains components at the sum and difference of the original signal frequencies. Suitable filtering can then be used to extract the desired component; extracting the difference component shifts the frequency down, and extracting the sum component shifts the frequency up.

3.1.3 Analytic Reconstruction of Complex Signals Complex-signal reconstruction can be treated as the analytic extension of a real function to the complex plane. This approach is not restricted to narrow-band signals and does not require knowledge of a carrier frequency. The real and imaginary components of an analytic complex signal are related by the Hilbert transform relationships, and these relationships also apply to discrete signals in the appropriate context (Oppenheim and Schafer, 1989). In the spectral domain, this has a particularly simple interpretation; a real-valued discrete signal $x_r(n)$ has a conjugate-symmetric discrete Fourier spectrum X_r [that is, $X_r(k) = X_r^*(N - k)$, where X^* is the complex conjugate of X and N is the length of the FFT], and the spectrum of the corresponding complex signal $x(n) = x_r(n) + ix_q(n)$ is obtained from just the lower half of X_r. More precisely, define the new spectrum $\tilde{X}$ by

$$\tilde{X}(k) = \begin{cases} X_r(k) & k = 0, N/2, \\ 2X_r(k) & 0 < k < N/2, \\ 0 & N/2 < k < N; \end{cases} \tag{5}$$

then the inverse Fourier transform of $\tilde{X}$, denoted $\tilde{x}$ (with the index suppressed), is complex and is equal to $x_r + ix_q$. The imaginary component $x_q = (\tilde{x} - x_r)/i$ is the *Hilbert transformation* of x_r. Discontinuity at the ends of the N-point FFT segment of x_r can result in large fluctuations in $x_q(n)$ near the ends of the segment. This problem can be overcome by using only the middle portion of each segment of the reconstructed signal. The segments must then be chosen so that they overlap to maintain continuity in the reconstructed signal.

Whereas Eq. (5) describes complex-signal reconstruction in the frequency domain, the same can be done in the time domain by convolving x_r with the impulse response obtained from the transfer function $\tilde{X}/X_r$.

3.2 Narrow-Band Signal Filtering

The processing of narrow-band signals is important in underwater and atmospheric acoustics because of the abundance of narrow-band signals that are generated by machinery and detectable at considerable range. Narrow-band digital filters are used to extract these narrow-band signals and reject noise outside of the signal baseband. Without this filtering, the noise power may be greater than the signal power and many sophisticated processing techniques would be ineffective. Computational efficiency is necessary to implement filtering for a multisensor (array) receiver that processes complicated signals in real time. Much of this efficiency is achieved by reducing the data volume (without losing signal information) as the data are processed.

3.2.1 FIR and IIR Filters Discrete time-series data are filtered using digital filters. The reader is directed to Oppenheim and Schafer (1989) and Rabiner and Gold (1975) for a more complete discussion of digital filters. Digital filters are often defined in terms of their response to an impulse. There are two principle types of digital filters: finite impulse-response (FIR) filters, for which there is zero response at the filter output beyond a finite time after the impulse, and infinite impulse-response (IIR) filters, for which the filter response remains nonzero (albeit diminishing) indefinitely.

Implementation of a digital filter is based on the constant-coefficient finite-difference equation

$$\sum_{k=0}^{N} a_k y(n-k) = \sum_{k=0}^{M} b_k x(n-k), \tag{6}$$

where $y(n)$ is the output sequence for an input sequence $x(n)$. The coefficients a_0, a_N, and b_M are always assumed to be nonzero. For an IIR filter, at least one of the coefficients a_k must be nonzero, besides a_0, so that $N > 0$. For a FIR filter, the coefficients a_k are all zero except a_0, so that $N = 0$. The order of the filter corresponding to Eq. (6) is the maximum of N and M.

The computational complexity of both the IIR and FIR filters increases with increasing order, and so it is important to achieve the desired filter characteristics with as few filter coefficients as possible. An IIR filter can often achieve, or approximate, a desired frequency response function using fewer coefficients than can a FIR filter; however, the FIR filter has several important advantages over the IIR filter. A FIR filter can be easily implemented in the frequency domain by multiplying the discrete spectrum of the signal with that of the impulse response of the FIR filter, on a point-by-point basis. The FFT algorithm makes this implementation very efficient. An IIR filter, on the other hand, must be implemented by a recursive algorithm in the time domain. Furthermore, FIR filters are easily designed to have a linear phase response, which is a desirable property for avoiding phase distortion.

An important class of filters consists of filters designed to reject frequencies outside of some frequency band. They are typically specified by the signal rejection in their *stopband,* the deviation from unity response in their *passband,* and the width of the *transition band* between the passband and stopband. Filters that have a very narrow passband and transition band, such as would be used to select a narrow-band signal as in Eq. (1), tend to be of high order.

3.2.2 Processing Long Records Processing of acoustic signals is often done over a long period of time relative to the rate at which data are being collected (the sampling rate). Efficient algorithms based on the FFT are inherently block oriented; that is, they process data in blocks of a specific size. Practical constraints on data storage and handling during computations places limits on the size of the data block that can be processed. Techniques to overcome these constraints are important in underwater and atmospheric acoustic signal processing.

One such technique is *overlap-save* (or its variation, *overlap-add*), which achieves the convolution of long sequences by breaking them into smaller, overlapping segments. The smaller segments are extended with a predetermined number of zeroes, their convolution is computed, and portions of the results are pieced together to recover the overall convolution of the long sequences.

This method is used to implement FIR filtering of long data sequences (Oppenheim and Schafer, 1989). A FIR filter with an impulse response $\{h_n\}$ of length $N + 1$ is convolved with a signal $\{x_n\}$ to obtain the filtered signal $\{y_n = \Sigma_{k=0}^{M} x_{n-k} h_k\}$. For a data record containing the samples x_k for $0 \leq k < N$, the convolution can be correctly calculated for y_n, where $M \leq n < N$, but not for $n < M$. The first M points can, however, be obtained from the previous record by arranging that the current record overlaps the previous record by M points.

3.2.3 Efficient Baseband Signal Extraction Reconstruction of a baseband signal using *I-Q* demodulation, as described in Sec. 3.1.1, can be applied to a discrete complex envelope signal $x(n)$ by filtering with a quadrature filter or a 90° phase shifter that is constructed as a FIR or an IIR filter and applying Eq. (4), with $t = nt_s$, where t_s is the sampling interval. Since the bandwidth of the envelope is much less than the carrier frequency f_c, and since the sampling rate t_s need only be twice f_c to prevent frequency aliasing, the reconstructed envelope time series x_r can be *decimated,* or subsampled by keeping only every kth sample. This greatly reduces the data volume in the reconstructed signal. The integer k is called the *decimation factor.* Decimation factors in excess of 100 are not uncommon.

As an alternative to *I-Q* demodulation, the baseband signal can be extracted by using a very narrow bandpass filter and homeodyning the filtered signal. If a FIR filter is used, with filtering implemented in the frequency domain, then the filtered signal is easily homeodyned by shifting the coefficients of its discrete Fourier transform. Computational efficiency and reduced data storage requirements are achieved by breaking the filter into several stages that are applied in series to reduce the width of the passband progressively. This approach requires lower-order filters because the passband of each stage does not need to be as narrow as that of the overall filter. Furthermore, by decimating the output of each stage of the filter, successive filter stages process less data and considerable computational savings are realized. This multistage approach to filtering is called *variable-rate filtering.*

The individual stages in a variable-rate filter can be designed to be very efficient. Modification or substitution of stages can provide an effective method for adjusting the overall filter characteristics. At each stage of the filter the signal may be examined, which provides an opportunity to analyze the signal at different frequency resolutions. The later stages of a variable-rate filter are sometimes referred to as *vernier modes.* Vernier modes may introduce a significant delay between the input signal and output response due to the block-processing nature of the FFT.

3.3 Zoom Filtering

Received signals, particularly those including multiple sources, can contain many narrow-band signals. The center frequencies of these signals may change as the source maneuvers or changes its operating conditions. Analysis of these signals involves isolating and possibly tracking each frequency with the use of very narrow passband filters. To make this task as computationally tractable and efficient as possible, various application-specific techniques are used. As an example of how the generic narrow-band signal extraction process can be made efficient, we discuss the *zoom filter* that is particularly well suited to processing complicated narrow-band signals. While alternative approaches exist, the zoom filter employs many of the basic principles in a compact algorithm.

The zoom filter procedure method utilizes a FIR filter that can be implemented particularly efficiently in the frequency domain. This is done by multiplying only a few bins of the signal spectrum by filter coefficients, corresponding to the filter response values in the transition bands. This is possible because the zoom FIR filter frequency response is designed to be zero at the spectral bins in the stopband and unity at the spectral bins in the passband.

Zoom filtering is an example of a variable-rate filtering technique. From an elemental building block, multiple parallel and sequential stages are combined to obtain the desired analysis bands and resolutions, as in Fig. 4. The building block of the zoom transform is implemented digitally by applying the following procedures in sequence.

1. The data $s_r(n)$ are segmented into records $s_r^m(n)$ of length N (usually a power of 2), with records overlapping by $N - M$ samples; $s_r^m(n) = s_r(mM + n)$ for $0 \le n < N$.
2. Each record is Fourier transformed, using a FFT.
3. The specialized zoom FIR narrow-band filter is applied, centered on a signal baseband of interest. This is done by zeroing the spectral bins that are in the filter stopband and multiplying the spectral bins in the transition bands by the optimally selected filter coefficients.
4. The filtered spectrum is shifted k_0 spectral bins so that an edge of the passband with flanking transition bands is near to zero hertz, thus heterodyning the signal baseband to a lower (but nonzero) frequency.
5. The signal is decimated by truncating the zero-valued, high-frequency portion of the shifted spectrum and applying an inverse FFT.
6. Nonoverlapping portions of the decimated time records are concatenated. A phase factor, which is constant over each record, must be applied to maintain phase continuity across data records. The phase factor $\exp(i\phi_m)$ for the mth data record is determined by the recursion $\phi_{m+1} = \phi_m - 2\pi M k_0/N$. For example, with 50% overlap the factor is -1 for a shift of an odd number of spectral bins and $+1$ otherwise.

The concatenated time series can be submitted to a second-stage zoom transform to obtain a narrower passband and finer spectral resolution. To extract more than one narrow-band signal, multiple narrow-band filters are applied to the same signal spectrum in parallel and their outputs processed separately (and possibly in parallel). The incremental computational cost for additional narrow-band signals or higher-resolution stages is small. With proper selection of the transition band coefficients, a multistage zoom filter can easily restrict aliasing artifacts and ripple in the stopband and the passband to less than -80 dB.

3.4 Power Spectral Density Estimation

The power spectral density (PSD) is an ensemble-averaged quantity describing the distribution of signal energy in the frequency domain. It is formally defined as the Fourier transform of the autocorrelation function $\rho(\tau) = \langle x(t)x^*(t + \tau)\rangle$ of a stochastic process $x(t)$ and is expressed in units of signal power per unit frequency interval.

In practice the power spectral density is

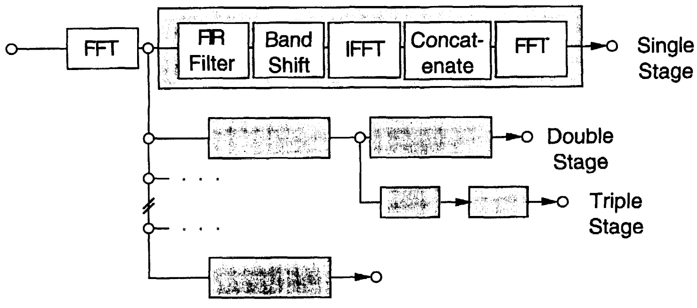

FIG. 4. Components of the zoom filter. The five basic components are FIR filter, heterodyne (band shift), inverse FFT, concatenate consecutive data segments, and FFT. These operations are grouped into a shaded box. Replicas of this box, operating with different spectral-resolution, bandwidth, and center-frequency parameters, are applied in series and parallel to achieve multiresolution processing in a computationally efficient and flexible manner.

estimated from the power spectra of windowed discrete data $y(n) = w(n)x(n\Delta t)$, as

$$\hat{P}(f/f_s) = \frac{2}{W_0}\left|\sum_{n=0}^{N-1} y(n)e^{-2\pi i n f/f_s}\right|^2, \tag{7}$$

where $\Delta t = 1/f_s$ is the sampling interval, the signal frequency f lies in the range $\pm f_s/2$, the window function $\{w(n)\}$ is zero outside the interval $0 \le n < N$, and $W_0 = \Sigma_{n=0}^{N-1} w(n)$. When the window function $w(n)$ is rectangular, with $w(n) = 1$ for $0 \le n < N$, the PSD estimate is called a *periodogram*. For a nonrectangular window function, $\hat{P}$ is called a *modified periodogram*.

The PSD estimate in Eq. (7) is typically calculated using a FFT and evaluates $\hat{P}$ at the normalized frequencies $f_k/f_s = k/N$. The numerical value of $\hat{P}(k/N)$ is the signal power in the kth bin (modulo N) relative to that of a unit discrete impulse. The PSD can be expressed in units of volts^2/hertz, as a function of conventional frequency, using

$$P_{\mathrm{Hz}}(f) = (\Delta V)^2 \Delta t \hat{P}(f/f_s), \tag{8}$$

where ΔV is the voltage quantization step of the digital data.

The variance, or uncertainty, in the power spectral density estimate $\hat{P}$ is independent of the duration $N\Delta t$ of the time record. In fact, the variance is approximately equal to the average value of the estimate. To obtain a better estimate of the PSD, that is, one with lower variance, it is necessary either to average adjacent frequency bins under the assumption that the PSD is approximately constant across these frequencies or to average multiple periodograms. The variance in the PSD estimate varies in proportion to $1/M$, where M is the number of adjacent bins or sequential periodograms being averaged. For individual PSD estimates to be accurate, the autocorrelation function of the signal must be small for lag times beyond $N\Delta t$.

A convenient technique for the display of time-varying signals is to plot the PSD as a function of frequency and time. This particular graphical data format has been widely used for the analysis of underwater acoustic data and is referred to as a *lofargram*, in reference to low frequency analysis and recording. The example lofargram in Fig. 5 shows time-varying frequency components from maneuvering small aircraft. Lofargrams for the analysis of underwater sources do not usually display such large variations in line frequency. Traditional lofargrams were recorded by a temperature-modulated hot needle that produced variable-density traces on long rolls of specially treated paper.

The visibility of lines in a lofargram is enhanced by techniques such as normalizing the spectrum with respect to the background noise. The lofargram has proven to be a valuable detector for narrow-band signals because the human visual system is effective at

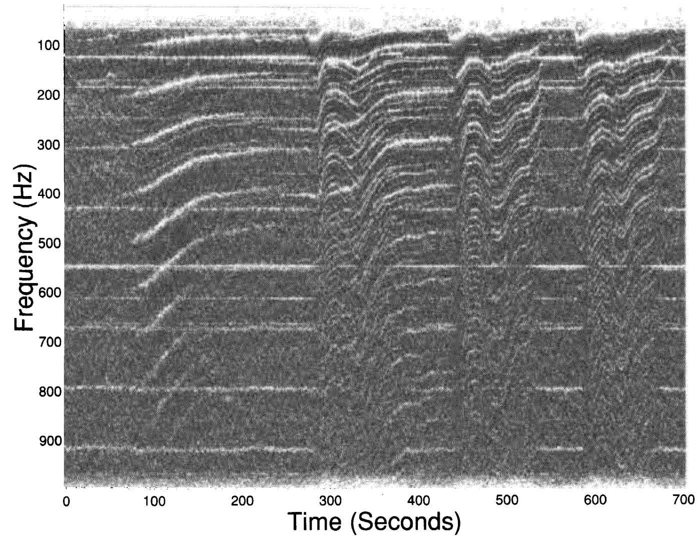

FIG. 5. An example lofargram of a maneuvering aircraft. White and black indicate high and low power spectral density, respectively. The density scale is arbitrary. The straight white lines correspond to stable tones. The wavy lines correspond to signals from aircraft, which exhibit frequency variations due to Doppler-shift and source variations. The signals are normalized with respect to the mean noise spectrum.

recognizing even faint narrow-band signals on long lofargram records. Furthermore, slight variations in line frequency and relationships between the line-frequency fluctuations of different lines are readily detected visually.

High-resolution spectral-estimation techniques are typically applied more for the purpose of frequency estimation and the resolution of closely spaced frequency components than they are for accurate PSD estimation. An overview of high-resolution spectral-estimation methods can be found in Marple (1987).

4. ARRAY PROCESSING

Spatial sampling of a sound field is usually done by an array of transducers, although the synthetic-aperture array, where a sensor is moved through space to obtain sequential measurements in both the time and space domains, is an important exception. Spatial sampling is analogous to temporal sampling with the sampling interval replaced by the sensor spacing vectors. The Nyquist criterion requires that the sensor spacing be at least twice the spatial wave number of the measured sound field. Aliasing and signal reconstruction for spatially sampled data follow the same principles as for temporal data, although there are some important differences such as the ambiguity that can arise in the reconstructed wave-number components due to symmetries in the array geometry.

Practical constraints associated with using multiple sensors make it necessary to minimize the number of sensors used; consequently, the conceptually simple uniformly spaced array distributed in three dimensions is seldom implemented in practice.

4.1 Linear Plane-Wave Beam Forming and Spatiotemporal Sampling

The simplest example of array processing is plane-wave beam forming, or delay and sum beam forming in the time domain. This processing is implemented by phase shading in the frequency domain or by sample delay in the time domain and is used to search for the bearing angle θ associated with a plane-wave signal as shown in Fig. 6 for a linear array.

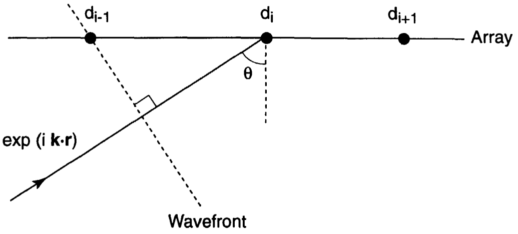

FIG. 6. Geometry for plane-wave beamforming.

4.1.1 Frequency-Domain Processing A plane wave with bearing angle θ and wave number $\mathbf{k}(\theta)$, observed at a position $\mathbf{r}$, can be represented as

$$s(\theta) = e^{i\mathbf{k}(\theta)\cdot\mathbf{r}}, \tag{9}$$

where we have suppressed the time dependence $\exp(-i\omega t)$, and $\omega = ck = c|\mathbf{k}|$ is the angular frequency of the signal. For an array of sensors at positions $\mathbf{d}_j$ the field is summed coherently (in phase) if the inputs r_j from the receiving elements (hydrophones or microphones) are first multiplied by the complex conjugate of the plane-wave phase factors (or *plane-wave replica*),

$$w_j = |w_j| e^{i\mathbf{k}\cdot\mathbf{d}_j} = e^{id(k\sin\theta_s)}, \tag{10}$$

where θ_s is a scanning angle (or *steering angle*) and $|w_j|$ are weighting factors (also called *tapers* or *array shading*) used to control sidelobes (Harris, 1978). The beam-forming process $B(\theta_s) = \Sigma w_j r_j$ will have a maximum when the scanning angle equals the incident angle of the signal.

Often it is the power (mean square of the magnitude) of the output of the beam former that is of interest:

$$\begin{aligned} |B(\theta_s)|^2 &= \left\langle \left| \sum_{i=1}^{m} w_i^*(\theta_s)(s_i(\theta) + n_i) \right|^2 \right\rangle \\ &= \sum_{i,j=1}^{m} w_i^*(\theta_s)(K_{s_{ij}} + K_{n_{ij}}) w_j(\theta_s), \end{aligned} \tag{11}$$

where the inputs are $r_i = s_i + n_i$, with s_i and n_i being the signal and noise at the ith receiving element, and where $K_{s_{ij}} + K_{n_{ij}}$ are elements of a *cross-spectral density matrix* (CSDM). The angle brackets indicate the expected (ensemble-averaged) value. The cross-spectral density matrix for the single-tone plane wave considered here corresponds to the signal covariance matrix of the array of receiving elements, but for more general signals it is obtained from the data using Fourier transforms and time averages, as discussed at the end of this section. To obtain the right-hand side of Eq. (11), the signal and noise fields are assumed to be uncorrelated.

We can write the above expression in matrix notation with boldface lower-case letters denoting vectors (in column form) and boldface upper-case letters denoting matrices. Define a *steering vector* $\mathbf{w} = \{w_i\}$ and a cross-spectral density matrix $\mathbf{K} = \{K_{ij}\}$ with $\mathbf{K} = \mathbf{K}_s + \mathbf{K}_n = \{K_{s_{ij}} + K_{n_{ij}}\}$ since the signal and noise are assumed to be independent.

In practice, to be precise, we cannot know the ensemble-average statistic **K**. Instead, we measure the *sample covariance*

$$\hat{\mathbf{K}} = \overline{\mathbf{q}^\dagger \mathbf{q}}$$

from time-averaged data **q**, where the dagger denotes the complex transpose operation and the overbar denotes time averaging, and assume ergodicity so that $\hat{\mathbf{K}}$ can be used to approximate the CSDM **K**. It is useful to note that the cross-spectral density matrix is Hermitian since it is constructed as the outer product of data vectors.

Equation (11) can be approximated as

$$|B(\theta_s)|^2 = \mathbf{w}^\dagger(\theta_s)\hat{\mathbf{K}}(\theta_{\text{true}})\mathbf{w}(\theta_s) \equiv \mathbf{w}^\dagger\hat{\mathbf{K}}\mathbf{w}, \qquad (12)$$

where the sample covariance of the field is composed of uncorrelated signal and noise covariances,

$$\hat{\mathbf{K}} = \hat{\mathbf{K}}_s + \hat{\mathbf{K}}_n. \qquad (13)$$

The data across the array, as represented in the matrix $\hat{\mathbf{K}}$, contain the information that the source is in the direction θ_{true}. Sometimes $\mathbf{w}(\theta_s)$ is referred to as a replica, and the above beam-forming process is viewed as matching the received data across the array with a replica. The type of beam former represented by Eq. (12) is called a *linear beam former,* or *Bartlett beam former,* as opposed to a nonlinear beam former, which utilizes data-dependent weights. We also mention that the beam-former process can also be considered as a wave-number–scanning process rather than an angle-scanning process.

For the sample covariance estimation we assume that we have an array with N sensors located at $\mathbf{d}_i$, $1 \le i \le N$, and a narrow-band model as illustrated in Fig. 7. While we assume in much of our discussion that the sample covariances are known, generally these covariances must be estimated from the data. For this estimation the signal is segmented into "snapshots," using a sampling window $w(t)$ that is unity for $0 \le t \le T_w$ and zero elsewhere, and then it is Fourier transformed to obtain the spectral estimates

$$R_i^l(f) = \int_{Tl}^{Tl+T_w} r_i(t)w(t - T_l)e^{-2\pi i f t}dt, \qquad (14)$$

where $0 \le i < M$ indexes the sensor and $0 \le l < L$ indexes the snapshot. We assume that window lengths and resolution bandwidths have been chosen so that bias errors are not an issue.

In most beam-forming algorithms these spectral estimates are used to obtain the sample covariance matrix

$$\hat{\mathbf{K}}(f) = L^{-1}\mathbf{R}(f)\mathbf{R}(f)^\dagger, \qquad (15)$$

where the matrix product sums across snapshots. We assume that there are L_{eff} "degrees of freedom" in the sample covariance matrix. (One can also average across frequency if relative phase constraints across the array are observed.) We assume that the data vectors have zero mean and that the expected value of the sample covariance is the ensemble covariance $\mathbf{K}(f)$. If we further assume that the statistics of the field are Gaussian, then the data vectors are Gaussian and the sample covariance matrix has a complex

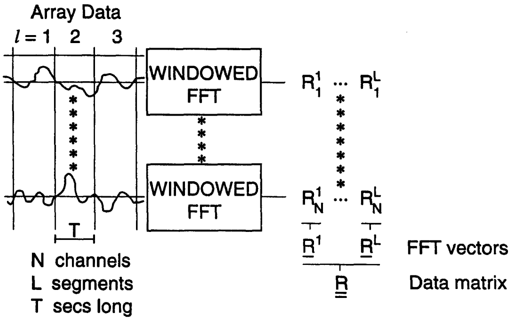

FIG. 7. Array, narrow-band model, sample matrix estimation, and data preconditioning for beam forming.

Wishart distribution of order N with L_{eff} degrees of freedom (Anderson, 1984).

4.1.2 Time-Domain Processing Time delay is the time-domain analogy to (linear) phase shading in the frequency domain. This can be derived formally by taking the Fourier transform of the beam-forming process. Using the property that the Fourier transform of a product of functions in one space is a convolution in the conjugate space, we can immediately write down from Eq. (11) that

$$B(t,\theta) = \sum_i \int w_i(t',\theta) r_i(t - t')dt', \tag{16}$$

where $r_i(t)$ is the signal plus noise time-domain data at the ith array element. The time-domain replica $w_i(t,\theta)$ is the Fourier transform of Eq. (10) [with the time dependence $\exp(-i\omega t)$ included],

$$w_i(t,\theta) = g_i\delta(t - (d_i/c)\sin\theta), \tag{17}$$

where δ is the Dirac delta function, and we have included the tapers g_i so that we can write the beam-former output as

$$B(t,\theta) = \sum_i g_i r_i\left(t - \frac{d_i}{c}\sin\theta\right). \tag{18}$$

This process is referred to as *delay and sum beam forming;* the delay is simply the time interval associated with the phase shift in the frequency-domain array processing. Here we note that we must now impose another requirement on the temporal sampling of the data in order to achieve the delay quantization consistent with the inherent angular resolution of the spatial array. The temporal sampling requirements for time-domain beam forming may be more than ten times the Nyquist requirements. Interpolation filters may be used to obtain samples between those obtained by the data acquisition system.

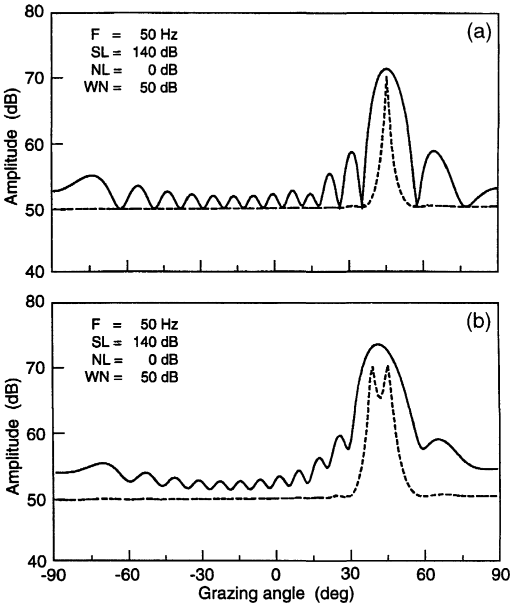

FIG. 8. Beam-former outputs. (a) Single source at a bearing of 45°. (b) Two sources with 6.3° angular separation. Solid line: linear processor (Bartlett). Dashed line: minimum-variance distortionless processor (MV).

4.1.3 Some Properties of Array Processors Figure 8 shows the output results of some plane-wave beam formers for the cases of one and two incident signals. To be noted are the sidelobes of a nontapered linear processor and the high-resolution performance of the adaptive processors (discussed in the next section). Some of the general attributes of an array processor are as follows:

- *The main response axis (MRA).* One often normalizes the beam-former output to have 0 dB, or unity, gain in the direction of maximum response, which under ideal conditions occurs when the array is steered in the direction of the signal.
- *Beamwidth.* An array with finite extent, or aperture, must have a finite beamwidth centered about the MRA that is termed the *main lobe.* A typical scale for the main-lobe beamwidth (in radians) of a line array is the reciprocal of the length of the array expressed in wavelengths. For linear arrays there is an extensive literature on weightings, often termed *tapers,* that produce desired main-lobe characteristics (see Harris, 1978, for example). For two-dimensional arrays, or those with an irregular sensor distribution, the situation is much more complicated, and adaptive processing (see below) plays a larger role in many contemporary applications.
- *Sidelobes.* Sidelobes are angular or wavenumber regions where the array has a

relatively strong response. Sometimes they can be comparable to the MRA, but in a well-designed array, they are usually -20 dB or lower; i.e., the response of the array is less than 0.1 to a signal in the direction of a sidelobe. Sidelobe performance is especially important in jamming situations where very strong signals entering through the sidelobes can overwhelm the desired signal. Again, for linear arrays there is a well-developed theory for sidelobe control (Harris, 1978); however, for more complicated arrays adaptive methods may be appropriate. It is also important to note that sidelobes are a function of frequency, and this can be exploited in many applications.

- *Wave-number processing.* Rather than scanning through incident angles, one can scan through wave numbers, $k \sin\theta_s \equiv \kappa_s$. Scanning through all possible values of κ_s results in nonphysical angles when $|\kappa_s| > k$, which correspond to waves not propagating at the acoustic-medium speed. Such waves may be associated, for example, with array vibrations. The beams associated with these wave numbers are sometimes referred to as *virtual beams.* An important aspect of these beams is that their sidelobes can be in the physical angle region, thereby interfering with acoustic propagating signals.
- *Array gain.* The array gain is defined as the ratio of the signal-to-noise ratio (SNR) of the array output to the SNR of a single-sensor output for a given ambient noise field. Array gain is expressed in decibels and, if the noise field is isotropic, the array gain is also termed the *directivity index.*

4.2 Adaptive Processors

The high-resolution methods to suppress sidelobes and perform main-lobe nulling are usually referred to as *adaptive methods* since the signal-processing procedure constructs weight vectors depending on the received data itself. We briefly describe one of these procedures: the minimum-variance distortionless processor (MV), sometimes also called the maximum-likelihood method (MLM) directional spectrum estimation procedure. The powerful tool of eigenvector analysis of beam formers is also presented. There are many other types of adaptive beam-forming algorithms (Johnson and Dudgeon, 1993). These adaptive methods are characteristically nonlinear functions of the received fields. As a matter of fact, these beam formers often have a signal-to-noise ratio threshold that must be exceeded for their desirable properties to appear. For this reason, nonlinear beam forming is often used interchangeably with adaptive beam forming. The processing described below is done in the frequency domain.

4.2.1 Minimum-Variance Distortionless Processor We seek a weight vector $\mathbf{w}_{\mathrm{MV}}$ applied to the matrix $\hat{\mathbf{K}}$ such that its effect will be to minimize the output of the beam former in Eq. (12) except in the "look" direction where we want the signal to pass through undistorted. Beam forming with such a weight vector is referred to as the *minimum-variance distortionless processor* (MV), which essentially optimizes the match to a signal in the "look" direction and therefore tries to reject signals and correlated noise from other directions. The weight vector is therefore chosen to minimize the functional

$$F = \mathbf{w}_{\mathrm{MV}}^{\dagger}\hat{\mathbf{K}}\mathbf{w}_{\mathrm{MV}} + \alpha[\mathbf{w}_{\mathrm{MV}}^{\dagger}\mathbf{w}(\theta) - 1]. \tag{19}$$

The first term is the mean square output of the array, and the second term incorporates the constraint of unity gain by means of the Lagrangian multiplier α. Note that for this complex-variable problem, there are two independent variables, which we can take as $\mathbf{w}_{\mathrm{MV}}$ and $\mathbf{w}_{\mathrm{MV}}^{*}$. Following the method of Lagrange multipliers, we obtain the MV weight vector,

$$\mathbf{w}_{\mathrm{MV}}(\theta) = \frac{\hat{\mathbf{K}}^{-1}\mathbf{w}(\theta)}{\mathbf{w}^{\dagger}(\theta)\hat{\mathbf{K}}^{-1}\mathbf{w}(\theta)}. \tag{20}$$

This new weight vector depends on the received data as represented by the estimate of the cross-spectral density matrix that is measured for a particular ambient noise field; hence, the method is "adaptive." Substituting back into the quadratic form of Eq. (19) (which is constructed so that the second term on the right-hand side will vanish) gives the output of our MV processor,

$$B_{\mathrm{MV}}(\theta_s) = [\mathbf{w}^{\dagger}(\theta_s)\hat{\mathbf{K}}^{-1}(\theta_{\mathrm{true}})\mathbf{w}(\theta_s)]^{-1}. \tag{21}$$

The MV beam former should have the same peak value at θ_{true} as the linear beam former in Eq. (12) but with the sidelobes suppressed and a narrower main beam, meaning that it is a higher-resolution beam former.

4.2.2 Eigenvectors and Beam Formers Eigenvector analysis provides a powerful tool to study and implement beam-forming algorithms. In principle, the estimate of the cross-spectral density matrix $\hat{\mathbf{K}}$ across a receiving array is made by taking an average over an appropriate time interval such that signals from sources are statistically independent of each other (uncorrelated) and of the background noise. For the set of source positions that the array can resolve, we can further interpret this to mean that the source position vectors are linearly independent, and, furthermore, that the noise subspace is orthogonal to the signal subspace. This linear independence of the source vectors, though, is not a necessary condition for implementing beam formers by utilizing the computational advantages of eigenvector methods.

We start by representing $\hat{\mathbf{K}}$ in terms of its M eigenvectors $\mathbf{v}_i$ and corresponding eigenvalues λ_i,

$$\hat{\mathbf{K}} = \sum_{i=1}^{M} \lambda_i \mathbf{v}_i \mathbf{v}_i^{\dagger}, \tag{22}$$

which satisfy the standard eigenvalue equation,

$$\hat{\mathbf{K}}\mathbf{v}_i = \lambda_i \mathbf{v}_i,\ i = 1, \ldots, M. \tag{23}$$

If there are p independent signal sources of strength σ_i with signal vectors $\mathbf{s}_i$, then $\hat{\mathbf{K}}_s$ of Eq. (13) can be expressed in terms of these signal vectors such that the sample covariance approximation to the total CSDM can be written as

$$\hat{\mathbf{K}} = \sum_{i=\mathrm{i}}^{p} \sigma_i \mathbf{s}_\mathbf{i} \mathbf{s}_\mathbf{i}^{\dagger} + \hat{\mathbf{K}}_n. \tag{24}$$

The simplest case is when the noise is spatially white (with strength σ_n at each sensor) for which the sample covariance of the noise is proportional to the identity matrix; then Eq. (24) becomes

$$\hat{\mathbf{K}} = \sum_{i=\mathrm{i}}^{p} \sigma_i \mathbf{s}_\mathbf{i} \mathbf{s}_\mathbf{i}^{\dagger} + \sigma_n \mathbf{I}. \tag{25}$$

It then follows that there are p eigenvectors that correspond to the signal vectors so that the remaining $M - p$ eigenvectors are orthogonal to the signal vector space. Note that the signal eigenvectors have eigenvalues $\sigma_i + \sigma_n$ that include the noise. We therefore have that

$$\hat{\mathbf{K}} = \sum_{i=1}^{M} (\sigma_i + \sigma_n) \mathbf{v}_i \mathbf{v}_i^{\dagger}, \tag{26}$$

and

$$\hat{\mathbf{K}}^{-1} = \sum_{i=1}^{M} (\sigma_i + \sigma_n)^{-1} \mathbf{v}_i \mathbf{v}_i^{\dagger}, \tag{27}$$

such that $\sigma_i = 0$ for $i > p$.

It is straightforward to simply use the eigenvalue decomposition of the CSDM to implement the linear and MV processors; however, there are some interesting additional variants of interest. For the linear processor, we might limit the eigenvector representation to the signal space. Alternatively, the eigenvector version of the MV processor suggests a direct application for the situation when eigenvectors can represent specific source vectors. In this case, we can eliminate signals by truncating the matrix representation so as not to include the signal subspace, and use as the CSDM

$$\hat{\mathbf{K}}_{\perp\text{sig}}^{-1} = \sum_{i=M-p}^{M} \lambda_i^{-1} \mathbf{v}_i \mathbf{v}_i^{\dagger}. \tag{28}$$

The replica scanning process produces a null for the source locations so that the MV prescription of the inverse of the process is infinite at source locations and finite otherwise. This provides an extremely high-resolution estimate of the source location. The *MUSIC* method (Schmidt, 1986) uses eigenvector decomposition where the eigenvalues of the (noise) subspace orthogonal to the signal subspace are set to unity by a "prewhitening" transformation of the CSDM. This kind of processor can estimate source direction but does not give a good estimate of source strength.

Finally we note that when the noise is

correlated so that the second term of Eq. (24) is not diagonal, then there is no one-to-one correspondence between eigenvectors and source location vectors. Nevertheless, one can expect that under certain conditions such as highly directional noise conditions or the existence of *a priori* knowledge about the noise field, eigenvector methods may prove beneficial. Examples of adaptive processing are shown in Fig. 8.

4.3 Matched-Field Processing

Matched-field processing (MFP) (Baggeroer *et al.*, 1993; Tolstoy, 1993) as first applied to ocean acoustics is the three-dimensional generalization of the conventional lower-dimensional plane-wave beam former. The one or two dimensions in the latter case correspond to bearing, and the matching is done to plane-wave replicas for these bearings. Localization in this case refers to determining a bearing direction. The generalized matched-field beam former matches the measured field at the array with replicas of the expected field for a point source. At each possible source location a replica of the expected field is derived from a propagation model, based on a specific ocean environmental model, as discussed in ACOUSTICS, UNDERWATER.

Localization in range, depth, and azimuth depends upon the degree of uniqueness of the spatial structure of the field, which in turn depends upon the array geometry and complexity of the ocean environment. The acoustic field generally has complex interference patterns that depend upon the source location and the ocean environment, thus allowing the field pattern to be *matched* to a source location and ocean environment. In terms of rays we can say that the refractive properties of the waveguide generate a pattern of arrival angles that can also be matched.

The process is shown schematically in Figs. 9 and 10. The process consists of systematically placing a test source at each point of a search grid, computing the acoustic field (replicas) at all the elements of the array, and then correlating this modeled field with the data from the real source whose location is unknown. When the test source is collocated with the true source, the correlation will be a maximum. The two main factors that limit performance of MFP are noise (both natural and man-made) and the ability to model the ocean acoustic environment accurately.

Using a specific ocean environment and an arbitrary (test) source location **a**, we construct a replica field **w** from one of the numerical solutions to the acoustic wave equation (see ACOUSTICS, UNDERWATER) to obtain a replica at each element of the array. Rather than finding just the direction of the source from the array, we can search for its actual location by matching the received data $\hat{\mathbf{K}}(\mathbf{a}_{\text{true}})$ from the true source location $\mathbf{a}_{\text{true}}$ against solutions of the wave equation based on the test source location **a**.

FIG. 9. Schematic of matched-field processing. The ocean is treated as a waveguide with a sound-speed profile *c*(*z*). Sound propagates from a source to an array of sensors. Ships and surface activity generate noise at the array. The source is located by systematically choosing test source positions and comparing the modeled data from the test positions with the actual signal on the array. When the test source position is at the true source position, correlation between modeled and real data is a maximum.

FIG. 10. Block diagram of MFP processor.

The output of this matched-field processor, denoted by $S(\mathbf{a})$ to indicate the generalization beyond plane-wave beam forming, at each point in space $\mathbf{a} \equiv (x,y,z)$ is, in analogy to Eq. (12),

$$S(\mathbf{a}) = \mathbf{w}^{\dagger}(\mathbf{a})\hat{\mathbf{K}}(\mathbf{a}_{\text{true}})\mathbf{w}(\mathbf{a}). \tag{29}$$

where the peak of the output of the beam former, $S(\mathbf{a})$, is at $\mathbf{a}_{\text{true}}$. The beam-former output $S(\mathbf{a})$ is also referred to as the *Bartlett ambiguity function* (or surface) of the matched-field processor because it also contains ambiguous peaks, some of which are analogous to the sidelobes of a conventional plane-wave beam former. However, there is the added feature that the acoustic field in a waveguide has cyclic properties, an obvious example being adjacent convergence zones (see ACOUSTICS, UNDERWATER) that have similar spatial structures. Hence the localization of a source in one convergence zone may be confused with another, ambiguous convergence zone. Suppression of sidelobes, including those that originate from the waveguide nature of propagation, can often be accomplished by using a nonlinear beam former such as the maximum-likelihood method (MV) beam former:

$$S_{\text{MV}}(\mathbf{a}) = [\mathbf{w}^{\dagger}(\mathbf{a})\hat{\mathbf{K}}_{-1}(\mathbf{a}_{\text{true}})\mathbf{w}(\mathbf{a})]^{-1}. \tag{30}$$

FIG. 11. The environment for the matched-field processing results shown in Fig. 12.

an example of the Bartlett and MV types of MFP processors for an ocean acoustic waveguide with a high signal-to-noise ratio; the results are shown in Fig. 12. Eigenvector versions of these processors can be implemented as described above.

Mismatch between the replica fields and the actual acoustic field in MFP, usually due to incomplete knowledge of the environment, is an important problem to which much attention has been devoted. The technique of *matched-field tomography* (MFT) searches for the environmental parameters controlling the propagation (for example, the index of refraction, which may be a spatially dependent coefficient of the wave equation) rather than source location. As with the case of plane-wave beam forming, there are an assortment of processors that can be used for MFP/MFT (Baggeroer *et al.*, 1993).

There have been two approaches to deal with environmental mismatch in MFP. The first has been to construct processors that are tolerant to environmental uncertainty (Schmidt *et al.*, 1990; Richardson and Nolte, 1991; Krolik, 1992). These processors trade resolution for lack of precise knowledge of the environment. The second approach is *focalization* (Collins, 1991), which uses nonlinear optimization methods to search simultaneously for the environment and the source position. All of these methods have limita-

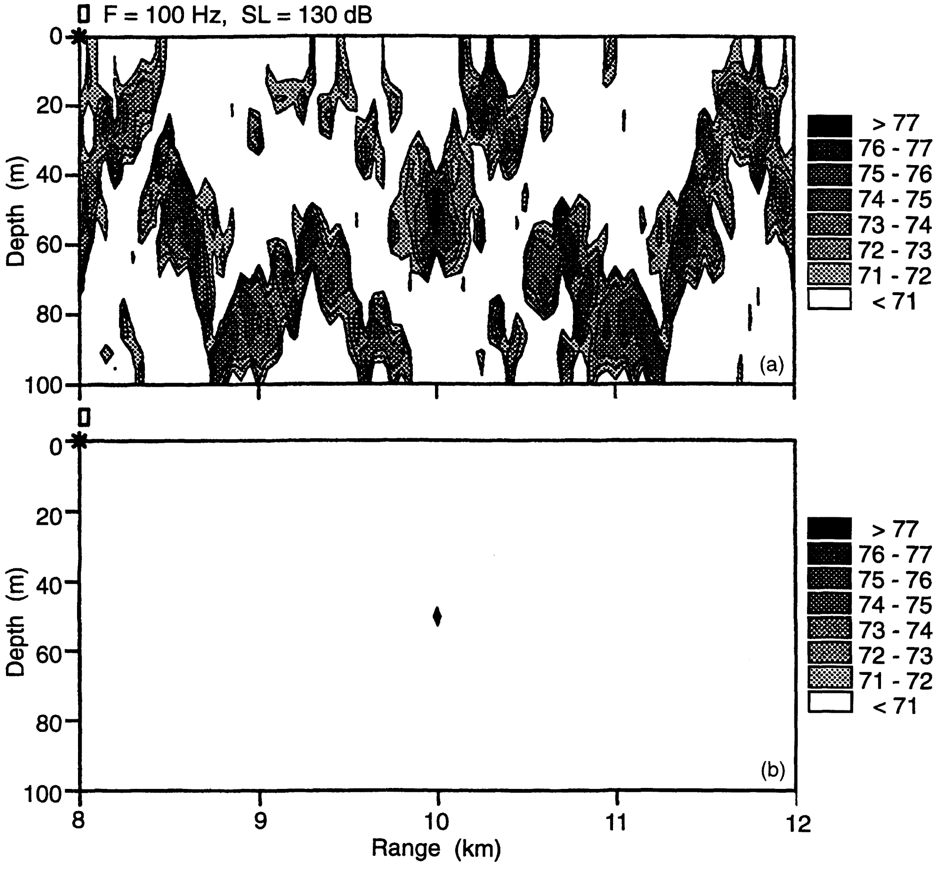

FIG. 12. Matched-field processing results. (a) Bartlett MFP ambiguity surface showing significant ambiguities (sidelobes) about the true location, which is at 10 km range and a depth of 50 m. (b) The MV processor with exact knowledge of the environment suppresses ambiguities.

tions, but under various conditions they have been successfully applied to experimental data.

5. ACTIVE SYSTEMS

Active systems (Baggeroer, 1978; Burdic, 1984) detect targets from reflections of a signal transmitted by the system and estimate their range (reflection travel time), speed (reflection Doppler), and bearing. They also can be used to infer environmental properties such as bottom bathymetry, currents and winds, particulate concentrations, etc. In an active system, a signal pulse with a known wave form is transmitted at known time and frequency. This contrasts to a passive system where the wave form is generally unknown and the transmission is asynchronous. This has two important signal-processing consequences. First, one can use coherent processing, in particular matched filtering, over the frequency band of the signal. Second, knowledge of the transmission time and carrier frequency enables one to estimate the travel times and Doppler shifts of the reflections, and hence the ranges and speeds of the targets producing the reflections.

The spatial-processing methods already discussed are applicable to the active problem, so that in this section we emphasize the temporal aspects of active signal processing. Here, two items that are of particular interest are target motion and signal design.

Wave forms are central to active sonar, where we are concerned with the complex envelope function [denoted here as $\tilde{s}(t)$] of a narrow-band real signal $s_r(t)$ with center frequency f_c and bandwidth $B < 0.5f_c$. The complex wave form and the envelope function can be reconstructed from the real signal by methods such as *I-Q* demodulation (see Sec. 3.1). Working with the complex envelope function provides considerable simplification in the mathematical notation for the signal processing, but it also has important practical consequences. Straightforward sampling of the original narrow-band signal requires a sampling rate of $2(f_c + B/2)$, where B is the bandwidth, whereas the complex envelope requires a sampling rate of only $2B$. Since the carrier frequency is usually much greater than the bandwidth, $f_c \gg B$, the reduction in data rate, and corresponding computational savings, can be considerable.

5.1 Active Sonar Signal Processing

Figure 13 schematically illustrates the basic elements of an active sonar: the (wave form) transmitter, the channel through which the signal, echo, and interference propagate, and the receiver. The receiver consists of some sort of matched filter, here a quadrature demodulated correlator, a square-law device, and possibly a threshold device for the detector and range, Doppler,

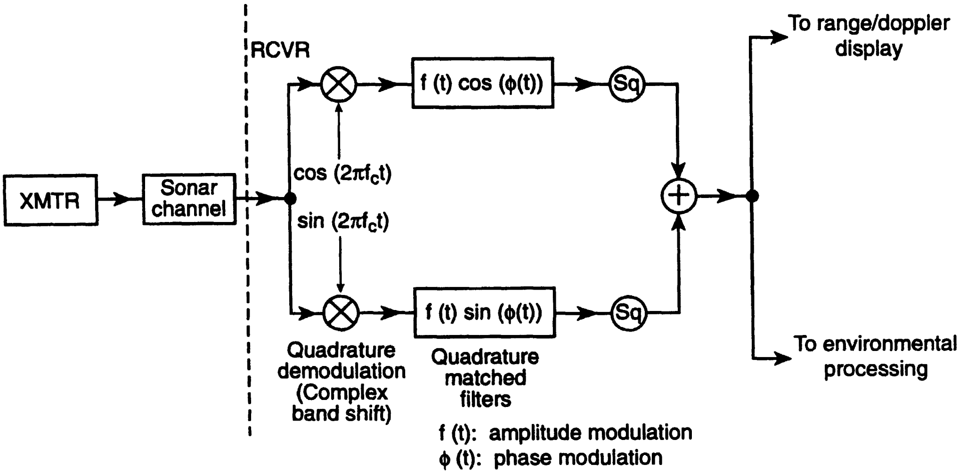

FIG. 13. Front-end processing structure for a quadrature-matched filtering of a sonar signal.

and bearing scanners for the estimator. (Some systems operate at the carrier or some intermediate frequency.)

The matched filter maximizes the ratio of the peak output signal power to the variance of the noise and is implemented by correlating the received signal with the transmitted signal. Implementing the narrow-band correlation process digitally with the complex signal, as suggested in Fig. 13, results in a lower sampling requirement than working with the original observed real signal. A simple description of the received signal, $r(t)$, is that it is an attenuated, delayed, and Doppler-shifted version of the transmitted signal, $s_t(t)$:

$$r(t) \approx \mathrm{Re}[\alpha e^{i\theta}\tilde{s}_t(t - T)e^{2\pi i f_c t}e^{2\pi i f_d t} + n(t)], \tag{31}$$

where α is the attenuation due to transmission loss and target cross section, θ is a random phase from the range uncertainty compared to a wavelength, T is the range delay time, and f_d is the Doppler shift caused by the target motion. The correlation process can be performed in either the frequency or time domain and will have an output related to the following process:

$$C(\mathbf{a}) = \left|\int \tilde{r}^*(t)\tilde{s}(t;\mathbf{a})dt\right|^2 \tag{32}$$

$$= \left|\int \tilde{R}^*(f)\tilde{S}(f,\mathbf{a})df\right|^2, \tag{33}$$

where $\tilde{s}(t;\mathbf{a})$ is a replica of the envelope of the transmitted signal as determined by a parameter set **a** that includes the propagation-reflection process. The parameter set may consist of the range delay and Doppler rate; a particular set of these parameters is called a *range–Doppler resolution* cell.

For the detection problem, the correlation receiver is used to generate a sufficient statistic that is the basis for a threshold comparison in making a decision whether a target is present. The parameters **a** determine the range and Doppler-shift value in the particular resolution cell of concern. If the range and Doppler shift are not known, this threshold must be generated over the entire plane of potential range–Doppler cells. The range–Doppler estimation problem has both global and local aspects. In the global aspect one simply wants to identify which range–Doppler resolution cell the target occupies. This yields an estimate with an accuracy of roughly the reciprocal of the bandwidth ($1/B$) for the range and the reciprocal of the duration ($1/T$) for the Doppler shift. At high SNR (signal-to-noise ratio) the accuracy can be further refined by finding the matched filter, or correlation, peak over a denser grid in the range–Doppler plane. This improves the accuracy by $1/\sqrt{\mathrm{SNR}}$ (where the SNR is expressed here in linear units, not in decibels).

For a matched filter operating in a background of white noise and detecting a point target in a given range–Doppler resolution cell, the detection SNR depends on the ratio of average energy to noise and not on the shape of the signal. The wave form becomes a factor when there is a reverberant environment and when one is concerned with estimating which range–Doppler resolution cell the target is in. The potential for range and Doppler resolution can be ascertained from the *ambiguity function* Θ of the transmitted signal,

$$\Theta(\tilde{T},T_t,\hat{f}_d,f_{d_t}) \propto \left|\int \tilde{s}_t^*(t - T_t)\tilde{s}_t(t - \hat{T}) \exp[2\pi i(f_{d_t} - \hat{f}_d)t]dt\right|^2 \tag{34}$$

where $\tilde{s}_t$ is the (complex reconstruction of the) transmitted signal, T_t and f_{d_t} are the true target range (time) and Doppler shift, and $\hat{T}$, $\hat{f}_d$ are the scanning estimates of range and Doppler shift. The ambiguity function is related to the correlation process of Eq. (32) for a transmitted signal scanned as a function of range and Doppler shift and can be used to design desirable wave forms for particular situations (VanTrees, 1971).

Figure 14 shows sketches of ambiguity functions of some typical wave forms. The range resolution is determined by the reciprocal of the bandwidth and the Doppler resolution by the reciprocal of the duration. The coded or pseudorandom sequence can attain good resolution of both by appearing as long-duration noise with a wide bandwidth.

Many environments and targets introduce travel-time and Doppler-shift spreading. The duration of the reflection of a short transmitted pulse is extended by travel-time spreading and the bandwidth of the reflection of a transmitted narrow-band tone is widened by

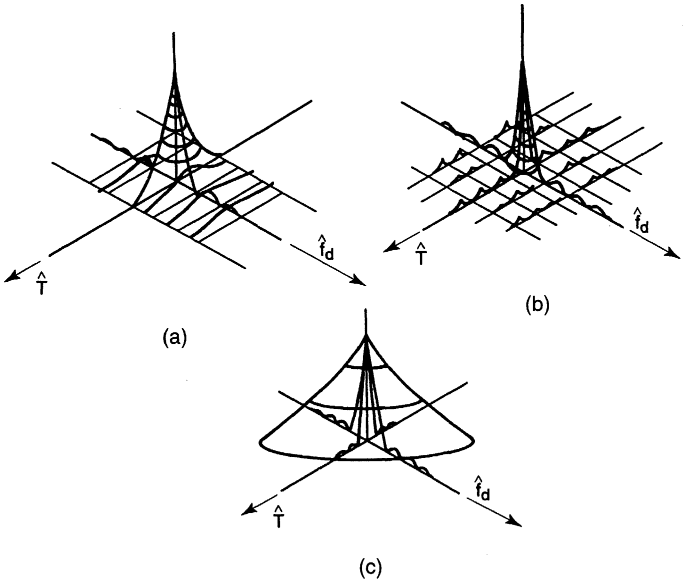

FIG. 14. Ambiguity function for several sonar signals: (a) rectangular pulse; (b) coded pulses; (c) chirped FM pulse.

Doppler-shift spreading. The *scattering function* (Westerfield *et al.*, 1960) describes how the energy of a transmitted signal is statistically redistributed in the reverberant ocean environment by multipath and Doppler-shift spread. This formulation leads to the result that the distribution of energy in the range–Doppler plane is given by the convolution of the ambiguity function of the transmitted signal and the scattering function of the reflection complex.

One of the important applications of scattering functions is for describing reverberation or clutter. This is signal-generated noise introduced by reflections and scattering not originating from the desired target. Increasing the signal energy in a reverberation-limited environment does not improve system performance, since it increases both the target and reverberation levels; consequently, good signal design is the only way to improve performance. For this, one can demonstrate that one wants to minimize the overlap of the result of convolution of the ambiguity function and the scattering function modeling the reverberation at the target range–Doppler location.

5.2 Communications and Seabed Mapping

Underwater acoustic telemetry is another type of active sonar system. The objective is to transmit a message, or a sequence of symbols, from a source to a user. Generally, one wants to do this at a maximum rate with a minimum number of errors. In acoustic telemetry this performance is limited by several characteristics of the underwater environment. First, the channel bandwidth is constrained by strong attenuation at high frequencies; second, the channel has both travel-time spreading due to the many different propagation paths and Doppler-shift spreading due to surface and internal waves and source-receiver motion. The power levels are often low because of restricted energy storage in typical applications, such as unmanned underwater vehicles and ocean-bottom sensors. These factors have made acoustic telemetry design a very challenging signal-processing problem.

In a communication or telemetry system, the input is a symbol sequence represented by a binary bit stream. These symbols may be encoded for cryptographic purposes, but, in any case, they are further encoded as a sequence of transmitted wave forms. The latter encoding algorithms are the subject of an extensive literature in communications theory (Proakis, 1989, 1990). Generally, there are two approaches: *block encoding,* where a fixed number of symbols are encoded together as a block, and *convolutional encoding,* where individual symbols are encoded using a linear, finite-field system. In both approaches additional (redundant) components are included in the encoded wave form for reliability, and the encoded signals, obtained from an alphabet of wave forms, are transmitted to the receiver.

The receiver design must accomplish several tasks. In the simplest, it must determine the sequence of blocks, for block encoding, or perform deconvolution to determine the system input, for the convolutional encoder. In practice, this is complicated by including

1. probing signals used to calibrate for the multipath propagation,
2. synchronization of the timing between source and receiver,
3. Doppler reference time for Doppler compensation, and
4. adaptive equalization for combatting multipath and intersymbol interference.

Communications in the undersea channel is especially challenging and depends a great deal on the acoustic environment. High-rate telemetry in shallow water where the range is much greater than the water depth is probably the most difficult; however, long-range telemetry at modest rates in deep water is certainly difficult as well. Presently, it is an area where a lot of signal-processing work is ongoing.

Maps and charts of the seabed are generated by plotting estimates of depths obtained by a sequence of reflections from the seabed (deMoustier, 1988). A single sounding does not convey an appreciable amount of information; a grid of soundings to determine the topographic relief is usually required. Systems can be as simple as plotting the matched-filter output for a sequence of transmissions as a ship steams a track, to very sophisticated multibeam systems that produce contour charts of bathymetry along a track. A variety of processing methods are used; some simply compensate for the finite beamwidth of the sounding system, while others compile the grid of points, interpolate the data, and contour the relief.

5.3 Travel-Time Tomography

Tomography generally refers to applying some form of inverse theory to observations in order to infer properties of the propagation medium (Munk, 1995). The received field from a source emitting a pulse is spread in time as a result of multipath structure in which different paths have different arrival times (or group speeds) that are determined by the sound-speed distribution in the ocean. Hence the arrival times sample the acoustic medium. (In contrast, medical tomography utilizes the different attenuation of the paths rather than arrival time for the inversion process.) Since the sound speed of the ocean is a function of temperature and other oceanographic parameters, the arrival structure can ultimately be related to a map of these oceanographic parameters. The same principle can be applied to the temperature and wind-velocity parameters in the atmosphere (Wilson and Thomson, 1994). In its most primitive form, the inversion can be described by an algorithm discretizing the ocean into cells, computing travel times from candidate acoustic paths through these cells, and solving a set of equations that equate these travel times to the measured travel times. Each cell is characterized by an unknown sound speed. Typically, some base-line oceanographic information is known so that one searches for departures from this base-line information. Tomographic experiments have been performed at ranges greater than 1000 km. Pulse-compression methods using sequences of signals are often employed in ocean tomographic experiments to enhance bandwidth and travel-time accuracy and received signal strength.

GLOSSARY

Array Gain: A measure of the effectiveness of a beam forming array. The response to a signal arriving on the main response axis relative to the response to isotropic noise.

Beam Forming: Combining signals from individual sensors in an array to obtain significantly greater response to signals that arrive from a specific direction. Beam forming takes into account the geometry of the array and the shape of the arriving wave front. By adjusting processing parameters the directional response of the array can be adjusted or steered without requiring that array elements be moved.

Beamwidth: The angular extent of the main lobe in the beam response pattern of a beamforming array, usually measured between points at which the response is 3 dB less than that of the main response axis.

Beam Response Pattern: The output of a beam-forming array as a function of the direction of arrival of the signal. The pattern generally exhibits a distinct maximum in the direction of the main response axis and a series of local maxima and minima that form a pattern of lobes. The lobe on the MRA is called the main lobe; all others are called sidelobes. It is usually desirable to achieve a narrow main lobe and small sidelobes.

Complex Signal: A signal containing both real and imaginary components. Generally, the real component is obtained from measurements, and the imaginary component is reconstructed from the real component.

Far Field: The sound field at distances from the source that are much greater than the signal wavelength and the source diameter.

Finite Impulse-Response (FIR) Filter: A linear time-invariant system whose response to an impulse has limited duration.

Frequency-Domain Beam Forming: Beam forming by applying a (complex coefficient) linear transformation to each frequency component output from the elements of an array.

Infinite Impulse-Response (IIR) Filter: A linear time-invariant system whose response to an impulse has infinite extent as a result of a feedback loop in the system.

***I-Q* Demodulation:** One of several methods for reconstructing a complex signal from its real component. This method is applicable to modulated pure tones.

Main Response Axis (MRA): The direction at which an array has its maximum response. The response is usually normalized to unity or 0 dB.

Matched-Field Processing (MFP): Simultaneous determination of source location and environmental parameters based on a propagation model and acoustic signals received at an array. Matched-field tomography is the application of this technique to estimating environmental parameters, as when the source location is known.

Matched Filter: A filter designed to maximize the signal-to-noise ratio of a receiver. For white noise, the filter impulse response is a time-reversed model of the signal.

Maximum-Length Sequence (or ML Sequence): A periodic signal with an autocorrelation function that is zero except at delays of zero or multiples of the signal period. These signals are generated by specialized pseudorandom-number generators that cycle through the entire output range in each period of the ML sequence.

MUSIC: An adaptive array-processing method for finding directional sources based upon a singular-value decomposition (SVD) of the sample spectral covariance matrix.

Minimum-Variance Distortionless Processor (MV): An adaptive processing method where the output variance in response to a noise field is minimized while the gain in the steered signal direction is unity producing no distortion of signal incident from the steered direction.

Power Spectral Density (PSD): The distribution of signal power in frequency. For practical measurements with finite record lengths the estimated signal power at each frequency is normalized to a unit spectral interval, such as 1 Hz. The power spectral density of white noise is independent of record length, but the peak in the PSD for a pure tone will increase in proportion to the record length.

Sample Spectral Covariance Matrix: An estimate of the spectral covariance matrix of a signal field on an array of sensors. It is a function of frequency.

Sidelobes: Angular regions away from the MRA where an array has relatively strong responses, e.g., -20 dB (or 0.1) compared to the maximum response of the MRA.

Singular-Value Decomposition (SVD): Representation of a linear transformation in terms of its eigenvectors. This technique is used to decompose the output of an array into mutually orthogonal signal and noise spaces. Beam formers employing SVD techniques are called eigenvector beam formers.

Sound Pressure Level (SPL): Mean acoustic pressure expressed in decibels relative to 20 μPa in the atmosphere and 1 μPa in the ocean.

Time-Domain Beam Forming: Beam forming by applying a time delay to the output of each array element and summing the result. Various gains may be applied to the individual elements prior to summing, these being referred to as tapers.

Tomography: A volumetric imaging technique using multiple planimetric views. In underwater and atmospheric acoustic signal processing, an array of sensors and an array of sources are used to determine the velocity of sound within a specific volume of the medium to investigate inhomogeneities.

White Gaussian Noise: Random noise that is temporally uncorrelated and has a Gaussian sample distribution.

Zoom Filtering: A variable-rate filtering technique used for high-resolution narrowband spectral analysis.

INTRODUCTION

The idea of unification is to look for a single theory from which all observed phenomena can be ultimately derived. Even though the idea appears unrealistically optimistic at first sight, it has a good grounding in the context of elementary-particle physics. In fact, history has shown us examples that many varied phenomena could be understood in terms of a single and simple theory. This article intends to explain historic examples, attempts at finding a unified description of different phenomena, and the most recent activities.

1. PROTOTYPE UNIFICATION

Maxwell's theory of electromagnetism has been regarded as one of the best examples of unification. Another good example is the unified theory of electromagnetism and weak interactions. In both cases, there were early experimental hints of a need for a unified description, theoretical progress toward such a direction, prediction of new phenomena based on unified theories, and experimental confirmation of the unified theories.

By the end of the 19th century, it was clear that Faraday's notion of the field is the most useful description of both electric and magnetic forces. This was probably the only theoretical similarity between these two apparently distinct forces. On the other hand, there were experimental indications that the two forces were related. An electric current creates a magnetic field around it. A change in the magnetic flux induces an electric potential.

Maxwell pushed it to the extreme. Since a change in the magnetic flux can induce an electric field, they might be two manifestations of a single force. If this is true, a change in the electric field must also induce a magnetic field. Even though there were no experimental indications of it by then, Maxwell postulated the existence of such a new phenomenon, which allowed him to formulate the theory of electric and magnetic fields on an equal footing. In particular, such a unified description predicted the existence of an electromagnetic wave, which consists of electric and magnetic fields without any sources, propagating in the vacuum by inducing each other. Finally, the existence of electromagnetic waves was confirmed and Maxwell's theory was established.

Furthermore, Maxwell's theory of electromagnetism lead to a further revolution in physics. Maxwell's equations happen to have a symmetry that was first recognized by Lorentz and Poincaré. The symmetry, known as Lorentz invariance, was later emphasized as a true symmetry of space-time by Einstein in

his special theory of relativity, which required us to change our basic notion of absolute time.

The Glashow–Weinberg–Salam theory of electromagnetic and "weak" forces is another example that provided a unified description of two different forces by a single theory that further predicted a new force, the neutral-current weak interaction, and a new particle, the Higgs boson. We will discuss the electroweak theory further in the next section, after briefly describing the four known forces in nature.

2. FOUR FORCES

There are at least four known basic forces in nature: gravity, electromagnetism, "weak," and "strong" forces. Here, weak and strong refer to the proper names of two kinds of forces, which reflect their strengths as well.

The four forces manifest themselves in quite distinctive ways. Below are their brief descriptions. See Table 1.

2.1 Gravity

The gravitational force was first formulated in Newton's theory of gravity. It has an infinite range with a potential $V(r) \propto 1/r$ and acts on any bodies with a mass. Its remarkable feature is that the motions induced by gravity do not depend on the composition or mass of the body. Any body follows the same trajectory. This is called the equivalence principle. Because of this property, Einstein proposed his theory of general relativity, which describes gravity as a curvature of four-dimensional space-time. According to this theory, moving bodies follow geodesics: they appear to fall because the space-time is curved. This is a natural explanation of why gravity exhibits the equivalence principle. The quantum theory of gravity is still not available; in such a quantum theory, gravity is supposed to be mediated by a spin-2 carrier, the graviton. There is a single coupling constant in the theory, Newton's constant $G_N = (M_{\text{Planck}})^{-2} = (1.2 \times 10^{19}\ \text{GeV})^{-2}$, which has dimensions of inverse mass squared in the natural units $\hbar = c = 1$.

2.2 Electromagnetism

The electromagnetic force also has an infinite range with a Coulomb potential $V(r) \propto 1/r$. It acts on any matter with electric charges. Like gravity, the form of the interaction is completely determined only by the charge of an object, irrespective of its composition. This universality is now understood on the basis of the gauge principle, which allows us to change the phase of quantum-mechanical wave functions or quantum fields locally. The coupling constant of the theory is the fine-structure constant, $\alpha = e^2/4\pi\epsilon_0\hbar c \simeq 1/137$, which is a dimensionless number. With only this one parameter, electromagnetism and especially its quantum version (quantum electrodynamics, or QED) are extraordinarily successful and are in agreement with experimental data at the precision of 10^{-11} (Kinoshita, 1995). As a result of quantum effects, the fine-structure constant actu-

Table 1. Comparison of four known forces in Nature. The existence of the graviton is not confirmed yet. See the text for the meanings of "Universality" and "Gauge invariance."

	Gravity	Electromagnetism	Strong	Weak
Range	∞	∞	10^{-13} cm	10^{-16} cm
Force carrier (spin)	Graviton (?) (2)	Photon (1)	Gluon (1)	W, Z bosons (1)
Gauge invariance	General coordinate tr.	U(1)	SU(3)	SU(2)
Universality	Equivalence principle	Electric charge	SU(3) rep.	SU(2) rep.
Source	Anything with energy	Charged particles	Hadrons	Left-handed quarks, leptons
Theory	General relativity (classical)	Maxwell's theory (classical/ quantum)	QCD (quantum)	Electroweak theory (quantum)
Phase	Coulomb(?)	Coulomb	Confinement	Higgs
Coupling constant	Newton's constant	Fine-structure constant	Strong-coupling constant	Weak-coupling constant

ally varies slowly with energy scales, growing for larger energies.

2.3 Strong Force

The strong force is an interaction among the hadrons, such as baryons (proton, neutron, hyperons, etc.) and mesons (π, K, ρ, etc.), and is responsible for various phenomena, which include nuclear α decay, fission, fusion, the nuclear binding force, and hadron resonances. It has a finite range $\simeq 10^{-13}$ cm and appeared completely different from the above two forces. Now the hadrons are understood as composites made up of quarks: baryons as bound states of three quarks, and mesons of a quark and an antiquark. The quarks come in three kinds, called "colors," and one can rotate three kinds of colors arbitrarily [SU(3) gauge invariance] analogous to the phase rotation in QED. The color quantum number is the source of the gluon field, just like the electric charges for the electric field. The theory is characterized by a dimensionless coupling constant, the strong-coupling constant α_s. The gluon mediates a long-range force, but with a much stronger variation with energy scales than the fine-structure constant. Experimentally, $\alpha_s(91 \text{ GeV}) = 0.118 \pm 0.003$, which is much stronger than the fine-structure constant. The strong-coupling constant is smaller at higher energies (asymptotic freedom), grows logarithmically at lower energies, and becomes practically infinite around 300 MeV. Because of this behavior of the coupling constant, the potential among colored particles is approximately $V(r) \propto r$ at large distances $r > 10^{-13}$ cm, and the quarks are "confined" in bound states; i.e., it requires an infinite amount of energy to separate a quark out from a bound state.

The observed strong interactions among hadrons are understood as residual force among the bound states similar to the van der Waals force (residual Coulomb force) among the atoms (electron–nucleus composites). Such a strong residual force exhibited highly nonuniversal (composition and mass dependent) and nonperturbative phenomena, which hindered the formulation of theory until the 1970s. The experimental discovery that there is an approximate scaling in the deep inelastic electron–nucleon scattering experiments at SLAC in the late 1960s by the SLAC-MIT group (Bloom *et al.*, 1969; Breidenbach *et al.*, 1969), and a theoretical discovery that a non-Abelian gauge theory can exhibit asymptotic freedom by Gross and Wilczek (1973) and Politzer (1973), enabled people to formulate quantum chromodynamics (QCD) based on SU(3) gauge invariance. Because QCD becomes perturbative at high energies, many quantitative tests of QCD were and are being performed at high-energy experiments successfully.

2.4 Weak Force

The weak force manifested itself in nuclear β decay first and was later observed in various meson decays, muon decays, and neutrino interactions. It has the smallest range among the forces observed, $\simeq 10^{-16}$ cm. Fermi formulated the first theory of weak force, which showed a remarkable universality. The β-decay lifetimes of many different nuclei and mesons could be described by a single Fermi constant $G_F = 1.1664 \times 10^{-5}$ GeV^{-2}. In particular, the strengths of the weak force acting on the muon and "up" quark are measured accurately and agree at the level of a permille. Glashow (1961) speculated that the weak force could also be a gauge force based on $SU(2)_L \times U(1)_Y$ group because of this universality. An important point here is that the β decay changes the electric charge of the parent nuclei ("charged-current weak interaction"). If the weak force is mediated by a gauge boson (named the W boson) similar to the photon or gluon, it must carry an electric charge. The only way a gauge boson (W) can interact with another gauge boson (photon) is when they belong to the same non-Abelian gauge group [SU(2) in this case]. Therefore, a gauge theory of the weak interaction needs also to incorporate the electromagnetic force on equal footing: a need for a unified description. To be consistent with the observed pattern of electric charges, Glashow needed another group, $U(1)_Y$, and predicted a new kind of weak force: the neutral-current weak interaction mediated by the Z boson. Such a new type of weak force was discovered later by neutrino experiments, first by the Gargamelle Collaboration (Hasert *et al.*, 1973), and is now tested at permille accuracies at LEP (an e^+e^- storage ring at CERN, Geneva) and SLC (a linear e^+e^- collider at Stanford Linear Accelerator Center) (for a review, see Particle Data Group, 1996, p. 85). One feature of the weak force that turns out to be crucial in building unified models is that it distinguishes the left-handed from right-handed helicity states of particles. Thus the weak force is said to be *chiral,* as opposed to the other three forces that do not distinguish the helicities of particles of particles: *vector-like.*

A puzzle in Glashow's theory is why the weak force mediated by the *W* or *Z* boson is short ranged, while the theory also contains the photon. The explanation to this question is the Higgs mechanism. In the Meissner effect in a superconductor, a condensation of charges (Cooper pairs) results in a finite range of a gauge force, namely, the finite penetration length of the magnetic field into a superconductor. In a similar fashion, a condensation of the yet-to-be-found Higgs boson causes a finite range of the weak force. This theory was formulated by Weinberg (1967) and Salam (1968), based on a spontaneous breakdown of the SU(2) × U(1) gauge group to the electromagnetic U(1) gauge group by the Higgs mechanism at the energy scale of 250 GeV. It was later summarized as the standard model of particle physics together with QCD, based on the gauge group SU(3) × SU(2) × U(1).

2.5 Similarities and Differences among Four Forces

To arrive at a unified description of these forces, we need to identify the similarities and differences among them. One notable fact is that all four forces are based on gauge principles: general coordinate transformation (gravity), Abelian gauge invariance (electromagnetism), or non-Abelian gauge invariance (strong and electroweak forces). It is this fact that led to the idea that all four forces may have a unified description. The ranges of forces are quite diverse, but they are understood as a consequence of different phases that each gauge theory has: Coulomb (gravity and electromagnetism), confinement (strong), and Higgs (electroweak) phases. There are, however, two major differences between gravity and the other three.

1. Gravity is related to the space-time geometry described by a spin-2 field, the space-time metric. On the other hand, the other gauge fields are related to internal spaces, such as phase [U(1)], weak isospin [SU(2)], or color [SU(3)] degrees of freedom, and are described by vector fields, which carry spin 1.
2. The strength of gravity is described by the Newton constant with mass dimension -2 while the other three are described by dimensionless constants, such as the fine-structure constant in the natural units $\hbar = c = 1$.

These two points lead to a profound difference in the quantum field theory. Theories with constants with negative mass dimensions are not renormalizable; *i.e.,* there are irremovable infinities in the theory; while the ones with dimensionless coupling constants are. This fact makes the unification of electromagnetic, strong, and weak forces relatively easy from the field-theoretical point of view while the incorporation of gravity is rather difficult.

It must be noted that there are other kinds of forces in the standard model of particle physics. There is a self-interaction of the Higgs boson that generates the mass of the Higgs boson by its own condensate, and many Yukawa interactions of the quarks and leptons with the Higgs boson that generate their masses. They are all characterized by dimensionless coupling constants. They are, however, not based on a gauge principle by any means, and such interactions can be introduced with arbitrary strengths as opposed to the universal character of the gauge forces. They are often not called "forces" because we have not yet detected the effect of such interactions experimentally. However, they are present in the standard model and need to be understood as well if there is to be a unified description of *all* forces. In particular, the Yukawa interactions have a rather baroque pattern of strengths in order to reproduce the wide range of quark and lepton masses, i.e., 0.511 MeV/c^2 for the electron to 175 GeV/c^2 for the top quark discovered in 1995 (Abe *et al.*, 1995; Abachi *et al.*, 1995). A truly unified theory must also explain the pattern of Yukawa interactions.

2.6 Hints for Unification

Finally, we list two puzzles in the standard model that suggest a need for a possible unified description. In the standard model, the quarks and leptons appear completely independent from each other, and the different forces [namely, SU(3), SU(2) and U(1) forces] are *a priori* not related to each other. However, then, it is not clear in the standard model why the electric charges of both quarks and leptons come in integer multiples of $\frac{1}{3}$. Such a quantization is essential to guarantee the electric neutrality of matter, which balances the charge of a proton made up of two up and one down quarks, with the charge $\frac{2}{3} \times 2 + (-\frac{1}{3}) = 1$, and the charge of an electron -1. This neutrality is tested at 10^{-21}. Second, as a result of quantum effects, the gauge invariance could be lost (called anomaly), which potentially spoils the unitarity or renormalizability of the theory. In the standard model, however, this does not occur because of a nontrivial cancellation. For instance, it is necessary that the sum of all electric charges vanish in the standard-model particle content, which is true only after adding the contribution of the quarks *and* leptons, *and* with the correct multiplicities of color [3 for SU(3)], *and* the correct multiplicities for left-handed particles [2 for SU(2)]. Other necessary conditions are also satisfied thanks to contributions of both quarks and leptons with the correct multiplicities among the various groups. This observation suggests that different gauge groups are related at a deep level, and so are quarks and leptons.

3. GRAND UNIFIED THEORIES

If one leaves out gravity, the unification of the other three forces is not difficult because one can maintain the renormalizability of the quantum theory (for a detailed treatment, see Ross, 1984).

3.1 Original GUTs

The earliest model toward the unification of the electromagnetic, weak, and strong forces is probably the one by Pati and Salam (1973), where a gauge group SU(4) × SU(2) × SU(2) was employed. Later, Georgi and Glashow (1974) proposed a model based on a simple group SU(5), which became the reference group in almost all subsequent efforts. It was a remarkable observation that all gauge forces and quite complicated quantum numbers of quarks and leptons in the standard model fit nicely into a single gauge group SU(5) (see Table 2). Subsequently, Georgi *et al.* (1974) showed that the strong force becomes weaker at higher energies while the electromagnetic force becomes stronger, so that they have the same strength at a certain high energy: around 10^{14} GeV in the simplest example. This observation leads to the following picture of a possible unification of forces. The gauge forces (except gravity) are ultimately described by a simple group such as SU(5) [or SO(10) or E_6, as described below] with a single coupling constant. It breaks spontaneously to the SU(3) × SU(2) × U(1) gauge group at an extremely high energy scale (unification scale) such as 10^{14} GeV, and the gauge coupling constants of different groups run differently between the unification scale and the weak scale 250 GeV. A simple calculation shows that if one follows the running from the unification scale down to the weak scale, the coupling constant of a larger gauge group becomes larger than that of a smaller gauge group. Therefore, this picture, called grand unified theory or GUT, explains why the strong force is strong and the electromagnetic force is weak simply on the basis of the size of the groups, 3 > 2 > 1. Furthermore, quantization of the electric charge is ex-

Table 2. The quantum numbers of the quarks and leptons under the standard-model gauge groups and the way they can be embedded into representations under the grand unified gauge groups. In the first row, the first number is the number of color degrees of freedom under QCD, the second whether the particle couples to the electroweak group as doublets (**2**) or not (**1**), and the last the charge under the U(1) hypercharge group. In the latter two rows, the numbers indicate the dimensionality of SU(5) or SO(10) representations. The subscripts *L*, *R* refer to left- or right-handed helicity states.

	Q_L	u_R	e_R	d_R	L_L	ν_R
SU(3) × SU(2) × U(1)	(**3**, **2**, 1/6)	(**3**, **1**, 2/3)	(**1**, **1**, −1)	(**3**, **1**, −1/3)	(**1**, **2**, −1/2)	(**1**, **1**, 0)
SU(5)		**10**			**5***	**1**
SO(10)				**16**		

plained as a simple consequence of the group theory.

An interesting feature of SU(5) unification is that the quarks and leptons belong to the same multiplets under SU(5), so that they can transform into each other by the exchange of SU(5) gauge bosons, in the same way that an up quark and a down quark can transform into each other through the charged-current weak interaction mediated by the exchange of the *W* boson. Therefore, the SU(5) unification predicts that a quark can turn into a lepton, which allows a proton to decay (*e.g.*, $p \rightarrow e^+\pi^0$ in the simplest model), a new phenomenon that can be looked for by experiments. Such a violation of baryon number may explain the reason why the universe contains matter (protons, neutrons, and electrons) but no antimatter (antiprotons, anti-neutrons, and positrons) as a result of baryon-number nonconserving interactions that occurred when the universe was as hot as the unification energy scale (baryogenesis) (Yoshimura, 1978; Ignatiev *et al.*, 1978). Finally, it was also pointed out that the masses of the bottom quark and tau lepton, which differ roughly by a factor of 3 in laboratories, also become the same size when extrapolated up to a similar high energy scale. This observation led to a hope that the pattern of quark and lepton masses could be understood also in the context of unified theories.

Unfortunately, the original SU(5) unified model is now excluded for two reasons. First, the nonobservation of proton decay, especially by the IMB and Kamiokande experiments, has put lower limits on the proton lifetime that exceed the prediction of the model. Second, the LEP and SLC experiments measured the size of the three gauge coupling constants for three gauge groups SU(3) × SU(2) × U(1) accurately, which did not agree with the predicted pattern in the model. There were other problems pointed out concerning the original SU(5) unified model. The assumption that there are two very disparate energy scales (hierarchy), the unification scale and the weak scale, appears unnatural, as is discussed more below. The cancellation of the anomaly is still not obvious because one needs to add contributions of two multiplets (**5*** and **10**) under SU(5). The theory predicts the existence of magnetic monopoles of a mass higher than the unification scale, which have never been detected. The unification of quark and lepton masses works for the third generation (bottom and tau) but not so well for the first and second generations.

The question of anomaly cancellation led people to consider yet larger groups whose irreducible multiplet contains the whole generation that belonged to two irreducible multiplets under SU(5). One such candidate is SO(10), which carries certain unique features (see Table 2). It is the smallest group that allows chiral fermions while being automatically anomaly free. It predicts another particle, the right-handed neutrino, for each generation. If the right-handed neutrinos are allowed to acquire masses at a high scale, such as the unification scale, they become irrelevant to typical experiments. However, the diagonalization of the neutrino mass matrix leads to small but finite masses for the left-handed neutrinos, given approximately by $m_\nu \sim m_u^2/M$, where M is the mass of the right-handed neutrinos and m_u is the mass of the up-type quark in the same generation. Therefore, a large M results in a small m_ν well below 1 eV/c^2 (Yanagida, 1979; Gell-Mann *et al.*, 1979), which may explain the observed deficit in the solar neutrino flux, a part of the missing mass in the universe (hot dark matter), or various other observations in neutrino experiments (see Fukugita and Yanagida, 1994, for a review on neutrino physics). People discussed other anomaly-free gauge groups along the same line, such as E_6, or $[SU(3)]^3$.

3.2 Supersymmetric GUTs

The existence of a huge hierarchy between the unification scale and the weak scale posed a serious theoretical challenge. In particular, it was found that the correction to the Higgs boson mass squared from higher orders in perturbation theory is quadratically divergent, and either tends to bring the weak scale up to the unification scale or restores the electroweak group SU(2) × U(1) (no Higgs mechanism). A mechanism to stabilize the hierarchy in energy scales seemed necessary (see Murayama, 1995, for a review on this discussion). Supersymmetry (see Wess and Bagger, 1983, for a textbook) was postulated as such a mechanism. It is well known that the electron acquires a linearly divergent Coulomb self-energy in classical electrodynamics. If one extrapolates the electrodynamics to a much shorter distance scale, the Coulomb self-energy grows linearly with the distance scale and so does the electron mass. However, the existence of the positron and its appearance as a part of quantum fluctuation of the vacuum cancels the linearly divergent Coulomb self-energy, and the result is only logarithmically divergent for small distances. A symmetry, called chiral symmetry, which interchanges an electron with a positron, is responsible for the cancellation of wild behavior of the self-energy. After such a cancellation, quantum electrodynamics can be applied to much shorter distance scales, or, equivalently, much higher energy scales, without ruining the smallness of the electron mass. In a similar fashion, supersymmetry introduces a *superpartner* to each particle in the standard model, whose spins differ by $\frac{1}{2}$ and have opposite statistics (Bose vs Fermi). And their contribution in the quantum fluctuation cancels the quadratically divergent contribution to the Higgs boson mass squared and makes the standard model applicable up to the unification scale without spoiling the smallness of the weak scale.

Therefore, grand unified theories are often discussed with a supersymmetric extension (Dimopoulos and Georgi, 1981; Sakai, 1981). The precise determination of the three gauge coupling constants at LEP and SLC experiments running from 1989 revealed that they seem to unify remarkably well at an energy scale of 2 × 10^{16} GeV if we assume the minimal supersymmetric extension of the standard model, while they do not unify at all with a nonsupersymmetric standard model (see Fig. 1). This observation led to a renewed enthusiasm for supersymmetric grand unified theories. Superpartners of the standard-model particles are currently under intensive searches at various collider experiments, such as the upgraded LEP and Tevatron, and are expected to be found at latest at the LHC experiments that should begin data taking in 2005 (Baer *et al.,* 1996). The proton lifetime is expected to be within the reach of the Super-Kamiokande experiment that started in 1996, in the simple models (Murayama, 1997). Other experimental signatures of supersymmetric grand unified theories have been pointed out, such as $\mu \to e\gamma$ (Barbieri and Hall, 1994). They are under active experimental efforts as well. If the superparticles are found, there are numerous other tests possible on grand unified theories. The mass spectrum of superparticles has a definite pattern if the forces are grand unified. By measuring the masses of superparticles, one can either verify or exclude grand unified theories, which is possible at a percent level at future collider experiments (Tsukamoto *et al.,* 1995; Hinchliffe *et al.,* 1997).

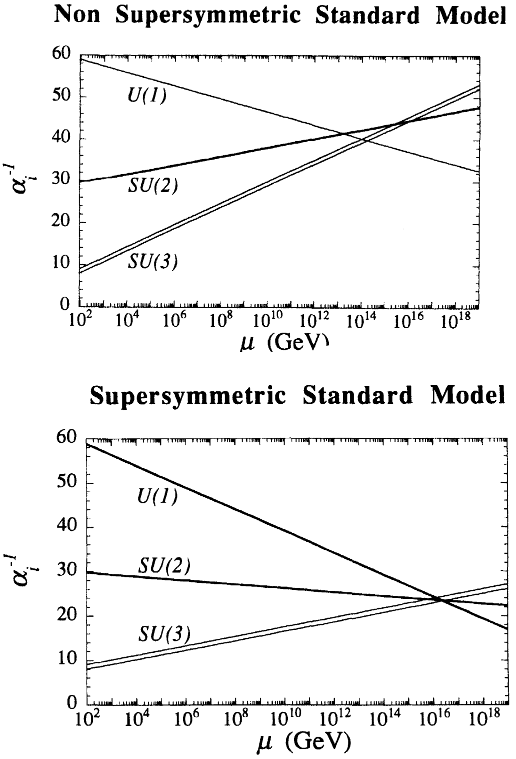

FIG. 1. The running of three gauge coupling constants in the standard model, assuming the minimal nonsupersymmetric standard model or its supersymmetric extension.

The supersymmetric grand unified theories are not without problems, however. Most importantly, supersymmetry *stabilizes* the hierarchy between the unification scale and the weak scale but does not explain why such a hierarchy exists to begin with. One common scheme assumed in literature is that supersymmetry is broken by a strong dynamics of a gauge theory, analogously to the chiral symmetry breaking due to the strong QCD dynamics, which is the origin of the masses of proton and neutron. Such a scheme naturally generates spontaneous supersymmetry breaking at an energy scale $\simeq M_{\text{Planck}}e^{2\pi/\alpha b_0}$ much lower than the unification scale or Planck scale, if the gauge coupling constant α is perturbative at the Planck scale, and if the gauge theory is asymptotically free implying $b_0 < 0$. Furthermore, the effect of broken supersymmetry is mediated to the standard-model particles only by gravitational interactions (Chamseddine *et al.*, 1982; Hall *et al.*, 1983). Therefore, incorporation of gravity into a unified theory appeared necessary.

Supersymmetry actually suggests a possibility to relate the gauge forces to gravity, whose force carriers have spin 1 and 2, respectively. Since supersymmetry relates particles with different spins, they may be related as well. Furthermore, supersymmetry can be promoted to a gauge invariance, *local* supersymmetry, which necessarily incorporates gravity (supergravity). Finally, supersymmetry makes the theory behave more reasonably at high energies, so that gravity, which has a severe problem of divergences at high energies and hence is nonrenormalizable, may be better behaved at the quantum level once it is made supersymmetric.

Supergravity itself does not make the quantum theory of gravity fully consistent. It still is nonrenormalizable. In the early 1980s there was a speculation that supergravity with the maximal supersymmetry (de Wit and Freedman, 1977; Cremmer and Julia, 1978, 1979; de Wit, 1979) (called $N = 8$ because it possesses eight times more supersymmetries than the smallest supergravity theory) may be finite and hence consistent. It also had a large internal symmetry that allowed 28 gauge bosons (de Wit and Nicolai, 1981, 1982; Hull, 1984), and, people hoped, it may contain the standard-model gauge groups. Unfortunately, neither of the expectations turned out to be true, and this direction of research has been basically abandoned. Possible counter terms were found at the seven-loop level (Howe and Lindstrom, 1981), which indicated that the theory has ultraviolet divergences. It was difficult to embed the standard-model gauge groups into the internal symmetry of the theory. And people could not embed chiral matter content into the theory. Supergravity is now regarded as an effective description of a true quantum theory of gravity valid only up to the energy slightly below the Planck scale.

Recently, a mechanism to mediate the effect of supersymmetry breaking to the standard model particles by usual gauge forces has attracted interest (Dine and Nelson, 1993; Dine *et al.*, 1995, 1996). In such a case, supergravity does not appear crucial for the purpose of generating supersymmetry-breaking effects that are phenomenologically necessary. The mechanism has a phenomenologically appealing feature that the quantum contribution of superparticles to rare phenomena are naturally suppressed below the experimental limits. There is ongoing active research to understand the phenomenological consequences of this mechanism (Dimopoulos *et al.*, 1996; Babu *et al.*, 1996). It appears, however, relatively contrived at the moment, and a substantial effort is being devoted to simplify it. Discussion of the phenomenology of grand unified models with this mechanism has just started (Carone and Murayama, 1996).

4. KALUZA–KLEIN THEORIES

Soon after Einstein's general theory of relativity, people tried to formulate electromagnetism on an equal footing. One possible direction is to obtain the electromagnetic gauge invariance [U(1)] as a part of the general coordinate transformation, which requires the extension of our four-dimensional space-time to higher dimensions. Such theories are called Kaluza–Klein theories according to the authors of early works (Kaluza, 1921; Klein, 1926). In general, theories of this class start with a higher-dimensional space-time with a certain theory of gravity and try to obtain other gauge forces in the standard model upon "compactifying" extra dimensions.

The simplest example by Kaluza and Klein starts with a five-dimensional space-time. One "compactifies" the extra spatial direction to a small circle, and the remaining large four dimensions are identified with our ordinary space-time. The metric tensor of the five-dimensional space-time $G_{\mu\nu}$, $\mu, \nu = 0, 1, 2, 3, 4$, now decomposes into the four-dimensional metric $g_{\mu\nu}$ ($\mu, \nu = 0, 1, 2, 3$), a vector $A_\mu = g_{4\mu}$, and a scalar $S = g_{44}$. The original five-dimensional general coordinate transformation acts as an ordinary gauge transformation on the vector A_μ. In general, an isometry of the compactified space generates an effective gauge invariance in the remaining four-dimensional space-time. Much later, it was found that such a space-time could be a solution to the (modified) Einstein's equation that could be regarded as a "spontaneous" compactification of a high-dimensional space-time.

This simple and beautiful idea suffers from all the difficulties that the Einstein's general relativity has, and more. First of all, quantum theory is not well-defined because the quantum theory of gravity is yet to be understood. Second, electromagnetism, which can be quantized and studied as a renormalizable quantum field theory, becomes nonrenormalizable in higher dimensions. Third, the five-dimensional theory cannot generate gauge fields for strong and weak forces (see, for a review and a collection of articles, Appelquist *et al.*, 1985).

Witten proposed a "realistic" version of the Kaluza–Klein theory (Witten, 1981). In order to incorporate all known forces, strong, weak, and electromagnetic, the space-time dimension has to be equal to or larger than 11. On the other hand, supersymmetry, as explained in the previous section, is probably an essential ingredient in unified theories. A space-time higher than 11 dimensions generates too many supersymmetry generators in four dimensions after compactifications, which results in theories with unwanted higher-spin fields, such as spin $\frac{5}{2}$ or 3, whose existence would make the theory even worse behaved at high energies. Therefore, 11 is the only dimensionality that may be realistic. In fact, solutions to Einstein's equation were found that allow compactified seven-dimensional space with SU(3) × SU(2) × U(1) isometry (Castellani *et al.*, 1984). This observation aroused a great enthusiasm in 11-dimensional supergravity theories (Cremmer *et al.*, 1978). However, the uniqueness of the dimensionality posed a serious difficulty in pursuing the direction further. Witten later (1985) showed that such a theory can never produce chiral fermions in four dimensions. Therefore, at least some extra ingredients (i.e., gauge fields) are needed before compactification to incorporate fully all known forces on equal footing. The apparent absence of the cosmological constant in our four-dimensional space-time was also very difficult to obtain in this framework. Finally, it did not solve the problem concerning the nonrenormalizability of the theory.

The Kaluza–Klein theories, at least with the original framework, do not seem to offer a successful unified description of all four forces. It is noteworthy, however, that 11-dimensional supergravity theories have renewed interest in the context of string duality, which is discussed later.

5. SUPERSTRING THEORY

The (partial) success of supersymmetric grand unified theories led to optimism on the basic concept of unification. There is no compelling and aesthetically appealing concrete model at hand, but the concept itself appears promising. On the other hand, the incorporation of gravity has been a serious challenge even with supersymmetry because of bad behavior of the quantum gravitational effects at high energies.

The string theory (see Green *et al.*, 1987, for a textbook) replaces particles by small strings with a typical size of the Planck length, $\sim 10^{-33}$ cm. The ordinary particles, with masses much less than the Planck mass, are identified with the lowest excitation modes of the string. Historically, the string model of particles was developed by Nambu and Goto to explain properties of hadrons that were not understood by then (see Scherk, 1975, for a review). Later, however, it became clear that the string theory contains massless spin-1 and spin-2 excitations that can potentially be identified with gauge bosons and the graviton. In particular, the equations of motion for spin-2 field derived from the string theory agreed with Einstein's theory of general relativity in low-energy approximation. Therefore, the focus of string theory changed to a consistent framework of quantum gravity (Scherk and Schwarz, 1974).

Green and Schwarz (1984, 1985) found that certain classes of string theory are free from anomalies and are ultraviolet finite. This observation aroused the hope that the string theory provides a consistent framework of quantum gravity. They were classified into the following categories: type I, type

IIA, type IIB, and heterotic. The heterotic string theory (Gross *et al.*, 1985) allowed only two choices for the gauge group, SO(32) or $E_8 \times E_8$, and the latter can incorporate the standard model or grand unified groups such as SU(5), SO(10), or E_6. The other E_8 can act as the sector that breaks supersymmetry well below the Planck scale. The theories could be formulated only in ten-dimensional space-time. It was further shown, however, that the extra six dimensions can be compactified as a solution to the equations of motions, on so-called Calabi–Yau manifolds or orbifolds, such that the remaining four-dimensional space-time has minimal supersymmetry and realistic gauge groups and chiral matter content (Candelas *et al.*, 1985). Furthermore, a string theory contains only a single coupling constant. If the theory is supposed to describe particle physics, it is supposed to explain *all* coupling constants by a single parameter. Therefore, if string theory is correct, it must be the "Theory of Everything."

There are a number of problems in string theory, however, at the moment. One of the major problems is that the string theory allows too many solutions to its equations of motion, which give different matter content, different gauge groups, different coupling constants, and even different space-time dimensions. It was hoped that nonperturbative effects would eliminate most of the solutions and could pick the unique solution that describes our universe. It requires a nonperturbative formulation of string theory, which is still not available. String theory is formulated only in the context of perturbation series at this moment. Phenomenological issues, such as whether the string theory is consistent with the observed pattern of gauge coupling constants (for a recent compilation of discussions, see Dienes *et al.*, 1996), are discussed mostly within perturbation theory.

The invention of string duality (Hull and Townsend, 1995; Witten, 1995) is changing the situation drastically. The behavior of string theory in the nonperturbative regime is now understood much better by using the duality transformation, which maps a strongly coupled regime of one string theory to a weakly coupled regime of another string theory. This is a generalization of electric-magnetic duality in electromagnetism or the duality in the two-dimensional Ising model, which interchanges small and large coupling constants. A much more nontrivial situation was revealed in supersymmetric gauge theories (for a review, see Intriligator and Seiberg, 1996). Similar techniques were employed in string theory, which led to discoveries of string duality. In particular, the heterotic string theory with $E_8 \times E_8$ gauge group, which appears to be the most promising one phenomenologically, is now believed to be dual to the 11-dimensional supergravity with a rather peculiar topology of the 11th direction (called M-theory) (Horăva and Witten, 1996). The theory contains no parameters at the Lagrangian level. The eleventh dimension is compactified on a finite interval $x^{11} \in [0,\rho]$, and the interval ρ plays the role of the coupling constant of the theory. All the gauge and matter fields live only inside the ten-dimensional hyperplanes at the boundaries $x^{11} = 0$ and $x^{11} = \rho$, while the supergravity multiplet can propagate both in ten-dimensional and 11th directions. Since there are gauge fields already present before the compactification to four dimensions, the theory is free from the problem of chiral fermions discussed before in the context of Kaluza–Klein theories. There are indications that the M-theory description is the most appropriate one for quantum gravity and the gauge forces among the elementary particles. Yet many problems are left unsolved, especially on the uniqueness of the solution.

6. SUMMARY

There have been many attempts to have a unified description of all observed forces in nature. Different attempts have different levels of success. Among them, supersymmetric grand unified theories appear to be the most promising phenomenological models that offer us a unified description of electromagnetic, strong, and weak forces. Many experimental efforts are being devoted to detect either superparticles or rare phenomena predicted by grand unified theories, and some of them are within the reach of near-future experiments. The incorporation of gravity, however, requires a formulation of quantum gravity, which is impossible within the standard quantum field theory. The most promising candidate formulation of quantum gravity is the string theory, and its nonperturbative dynamics has just begun to be understood. Concrete phenomenological predictions are yet to be worked out.

Sloan Foundation.

GLOSSARY

Anomaly: Suppose a theory defined at the level of classical Lagrangian has a symmetry. It sometimes happens that the symmetry is broken once the theory is quantized. This phenomenon in quantum field theory is called anomaly. For instance, the scale invariance of the QCD Lagrangian is broken quantum mechanically and the coupling constant runs as a function of energy; i.e., the theory is no longer scale invariant. This anomaly is needed to explain the asymptotic freedom of strong interaction and does not lead to any inconsistencies. On the other hand, the gauge invariance of a theory may also be broken quantum mechanically in chiral theories, which makes the theory inconsistent; it cannot maintain renormalizability and unitarity simultaneously. Therefore, one has to check that all gauge anomalies are canceled in chiral theories. This requirement puts a stringent constraint on the matter content of the theory.

Chiral: The word means handedness in Greek. A theory is called chiral if the right-handed and left-handed helicity states of a single particle interact differently with gauge fields at relativistic energies. A chiral theory necessarily breaks parity. The Glashow–Weinberg–Salam theory of electroweak forces is chiral.

Compactification: Suppose the true dimensionality of space-time is not four but is larger, such as ten in superstring theory. One assumes that extra dimensions ($10 - 4 = 6$ in this case) have very small spatial volume so that they are not visible in the current experiments. In this case, the extra dimensions are said to be compactified. The compactification can occur as a solution to the equations of motion of Einstein's equation with matter generalized to higher-dimensional space-time.

Supersymmetry: A hypothesized symmetry that interchanges bosons and fermions, whose spins differ by $\frac{1}{2}$. If supersymmetry exists, every particle in the standard model of particle physics, such as quarks, leptons, gauge bosons, and Higgs bosons, must have its superpartner.

Unified Theories: Theories of elementary particles and forces among them that attempt a unified description of many forces as different manifestations of a single force.

2.1
Introduction

The use of units is omnipresent in our daily life. Everywhere in trade, manufacturing, and science, measurements are quantified or compared with each other by the use of units.

Already James Clerk Maxwell (1873) stated that every expression of a quantity consists of two factors or components. In today's notation, this is expressed by the relation

$$Q = \{Q\} \times [Q] \tag{2.1}$$

where $\{Q\}$ denotes the numerical value and $[Q]$ is the unit of a physical quantity. The unit is a reference magnitude.

In other words, any quantitative measurement can be imagined as a comparison of a property of an object such as its mass, length, or temperature, with the same property of an object that represents the unit.

To ensure the correctness of this reference, it must be compared with a "higher order" reference. This is called *calibration*. Primary standards are the highest order references. They cannot be calibrated. Comparisons of different primary standards for the same unit, in many cases operated in different countries, are used to achieve highest confidence in the comparability of measurements.

When a measurement is referenced to a primary standard, directly or via an unbroken chain of references, it is called *traceable*. The trustworthiness of a measurement needs to be quantified by stating the uncertainty associated with measured value.

The choice of a unit is, in principle, quite arbitrary. Historically, units have been represented by artifacts. The magnitude of the quantity had been chosen for the sake of convenience or, in case of length, had been set by the length of cells or feet of pharaohs, kings or in later times by the average obtained from a group of people. This led to a variety of units for one and the same quantity that made comparison of measurement results across borders difficult and acted as a barrier for trade and later also for science.

The Convention du Mètre, signed by 17 states in Paris in 1875 was the first international agreement on metrology with the aim to use the same units worldwide. This furthers international trade and cooperation in science and is the basis for international standardization. Presently, there is a multitude of quantities that needs to be measured in the context of trade, manufacturing, the protection of life and environment, and science. Fortunately, virtually all of these quantities can be expressed as a product of powers of few basic quantities, forming a "system of base quantities." The units used to express

Handbook of Metrology. Edited by Michael Gläser and Manfred Kochsiek
Copyright © 2010 WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim
ISBN: 978-3-527-40666-1

numerical values of base quantities are then termed *base units*.

The choice of the base quantities is to a certain degree arbitrary. The present worldwide convention is the International System of Quantities (ISQ). It is based on the seven base quantities of length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity (BIPM, IEC, IFCC, ILAC, ISO, IUPAC, IUPAP, and OIML, 2008). The symbols for the dimensions of the base quantities are **L** for length, **M** for mass, **T** for time, **I** for electric current, **Θ** for thermodynamic temperature, **N** for amount of substance, and **J** for luminous intensity. Thus, the dimension of a quantity Q is denoted by

$$\mathrm{Dim}Q = \mathbf{L}^{\alpha}\mathbf{M}^{\beta}\mathbf{T}^{\gamma}\mathbf{I}^{\delta}\boldsymbol{\Theta}^{\varepsilon}\mathbf{N}^{\zeta}\mathbf{J}^{\eta} \qquad (2.2)$$

where the exponents, named *dimensional exponents*, are positive, negative, or zero.

Requirements that must be met in order to make the system acceptable for all users are as follows:

1. Consistency with the laws of physics: a measurement of pressure, for example, through a simultaneous measurement of force and area must not lead to different results when obtained by comparison with a realization of the unit of pressure.
2. Flexibility for modifications due to new needs, while being reliable and stable.
3. Practicability in all intended uses and simplicity.

The International System of Units (SI) represents such a system (BIPM, 2006). It is described in the following sections.

2.2
The International System of Units (SI)

In 1948, the Ninth Conférence Générale des Poids et Mesures (GCPM) adopted a draft for a system of units, which was originally based on six and meanwhile on seven base units. All other units are related with these base units just through multiplication and division. In 1960, the GCPM named the new system as *Système International d'Unités*, abbreviated as SI, and it decided that this abbreviation was to be used in all languages. All member states of the Meter Convention have adopted the metric system and have taken steps to eliminate most uses of traditional measurements.

The Bureau International des Poids et Mesures (BIPM) was entrusted to ensure worldwide uniformity of measurements and their traceability to the SI and publish a Brochure about the SI. The latest edition of the Brochure was published in 2006.

2.2.1
SI Base Units

The base units of the International System are listed in Table 2.1, which relates the base quantity to the unit name and unit symbol for each of the seven base units.

Sections 2.2.1.1–2.2.1.7 present the presently adopted definitions in italics followed by additional clarifications provided in the SI-brochure. Only brief remarks on history and realization are given as details can be found on the BIPM homepage (see Section 2.4).

For practical and economic reasons, the units are in many cases realized by reference standards optimized to the practical needs. In order to harmonize these realizations of units, the Comité international des poids et mesures (CIPM) drew up recommendations, which are generally referred to as the *mise en pratique* for the definition. The first *mise en pratique* was given in 1983 at the time of the adoption of the present definition of the

Tab. 2.1 SI base units.

Base quantity		SI base unit	
Name	Symbol	Name	Symbol
length	$l, x, r, \ldots$	metre	m
mass	m	kilogram	kg
time, duration	t	second	s
electric current	I, i	ampere	A
thermodynamic temperature	T	kelvin	K
amount of substance	n	mole	mol
luminous intensity	I_v	candela	cd

meter. In 1992, the CIPM acting on the advice of its Consultative Committee for the Definition of the Metre (CCDM), approved a revised *mise en pratique* for the definition of the meter (Quinn, 1994). Thereafter, it was decided to publish *mises en pratiques* on the homepage of the BIPM. The page is regularly updated if new significant progress has been achieved. Presently, *mises en pratiques* are available for the definition of the meter and the definition of the kelvin; see *http://www.bipm.org/en/publications.*

2.2.1.1 **The Meter**

The meter, unit of length, was redefined in 1983 by the 17th Conférence Générale des Poids et Pesures (CGPM) that specified the current definition, as follows: *The metre is the length of the path travelled by light in vacuum during a time interval of* 1/299 792 458 *of a second*.

It follows that the speed of light in vacuum is exactly 299 792 458 metres per second, $c_0 = 299\,792\,458$ m s.[1]

The first definition of the meter by the first CGPM in 1889 was based on the international prototype of platinum–iridium. This prototype is still kept at the BIPM under the conditions specified in 1889. The 11th CGPM replaced this first definition in 1960 and selected the wavelength of a well-defined transition in krypton 86 as a basis for defining the meter as a multiple of this wavelength. This was an important step toward defining units via fundamental constants.

The definition of the meter allows to use either the relation $l = c_0 t$, where l is the length of the path traveled by a plane electromagnetic wave in vacuum and t is the measured time of flight, or the relation $\lambda = c_0/f$, where λ is the wavelength and f the frequency of electromagnetic radiation. Both relations reflect that the unit of length depends on the unit of time.

The first of these relations is well suited for large distances, whereas the second relation is practical for small distances. In practice, laser radiation is used for realization of the unit of length.

For example, the distance between the earth and the moon is measured by directing a short pulse of a high-power laser beam at the moon where it is reflected from a mirror. The distance can be calculated from the time which the laser pulse needs to travel from the earth to the moon and back to the earth. The Global Positioning System (GPS), too, is based on time-of-flight measurements of electromagnetic radiation. The relative uncertainties associated with measured values of length using $l = c_0 t$ are determined by the uncertainty of the associated time measurement.

---

[1] This and the following definitions are cited from the 8th edition of the SI Brochure, BIPM 2006. With regard to the spelling of English-language words beside the quotations, we refer to the *United States Government Printing office Style Manual*, Which follows *Webster's Third New International Dictionary*. Form example, "meter" "liter," and "deka" are used instead of "metre," "litre," and "deca"

The use of the relation $\lambda = c_0/f$ requires the establishment of frequency standards representing reciprocal time realizations.

2.2.1.2 **The Kilogram**

The kilogram, unit of mass, is the only unit that is still explicitly based on an artifact, the international prototype of the kilogram that is made of platinum–iridium and kept at the BIPM since it was sanctioned by the first CGPM in 1889. The third CGPM confirmed this in 1903 by the definition: *The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram.*

It follows that the mass of the international prototype of the kilogram is always 1 kilogram exactly, $m(\mathcal{K}) = 1\,\text{kg}$.

The masses of 1 kg secondary standards of the same alloy as the international prototype are compared in air with the mass of the international prototype by means of balances with a relative uncertainty approaching 1 part in 10^9.

2.2.1.3 **The Second**

The second, unit of time, was redefined in 1967/1968 by the 13th CGPM that specified the current definition, as follows: *The second is the duration of* 9 192 631 770 *periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium* 133 *atom.*

It follows that the hyperfine splitting in the ground state of the cesium 133 atom is exactly 9 192 631 770 hertz, $\nu(\text{hfs Cs}) = 9\ 192\ 631\ 770\,\text{Hz}$.

As affirmed by the CIPM at its 1997 meeting, this definition refers to a cesium atom at rest at a temperature of 0 K.

This note clarifies that the definition of the SI second is based on a cesium atom unperturbed by black body radiation, that is, in an environment whose thermodynamic temperature is 0 K. The frequencies of all primary frequency standards should therefore be corrected for the shift due to ambient radiation, as stated at the meeting of the Consultative Committee for Time and Frequency (CCTF) in 1999.

Presently, the best primary standard produced the SI second with a relative standard uncertainty of some parts in 10^{16}.

2.2.1.4 **The Ampere**

The ampere, unit of electric current, was proposed by the CIPM in 1946 and, after replacing the expression "MKS unit of force" by "newton," adopted by the ninth CGPM in 1948: *The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed* 1 metre *apart in vacuum, would produce between these conductors a force equal to* 2×10^{-7} newton per metre *of length.*

It follows that the magnetic constant, μ_0, also known as the *permeability of free space*, is exactly $4\pi \times 10^{-7}$ henries per metre, $\mu_0 = 4\pi \times 10^{-7}\,\text{H/m}$.

Note that this definition implies the value of the electric constant, ε_0 (permittivity of vacuum), is also fixed, since $\varepsilon_0 = (\mu_0 c_0^2)^{-1}$.

2.2.1.5 **The Kelvin**

The kelvin, unit of thermodynamic temperature, was adopted in its present form by the 13th CGPM in 1968:

The kelvin, unit of thermodynamic temperature, is the fraction 1/273.16 *of the thermodynamic temperature of the triple point of water.*

It follows that the thermodynamic temperature of the triple point of water is exactly 273.16 kelvins, $T_{\text{tpw}} = 273.16$ K.

As affirmed by the CIPM at its 2005 meeting, this definition refers to water having the isotopic composition defined exactly by the following amount of substance ratios: 0.00015576 mol of ^{2}H per mol of ^{1}H, 0.000 379 9 mol of ^{17}O per mol of ^{16}O, and 0.002 005 2 mol of ^{18}O per mol of ^{16}O.

Already the 10th CGPM selected the triple point of water in 1954 as the fundamental fixed point and assigned to it the temperature of 273.16 K, so defining the unit.

Because of the manner in which temperature scales used to be defined, it remains common practice to express a thermodynamic temperature, symbol T, in terms of its difference from the reference temperature $T_0 = 273.15$ K, the ice point. This difference is called the *Celsius temperature*, symbol t, which is defined by the quantity equation: $t = T - T_0$.

The unit of Celsius temperature is the degree Celsius, symbol °C, which is by definition equal in magnitude to the kelvin. A difference or interval of temperature may be expressed in kelvin or degree Celsius, the numerical value of the temperature difference being the same.

The kelvin and the degree Celsius are also units of the International Temperature Scale of 1990 (ITS-90).

The *mise en pratique* for the definition of the kelvin (last update in 2006) is available on *http://www.bipm.org/en/publications/*.

2.2.1.6 **The Mole**

The mole, the unit for the amount of substance was adopted in its present form by the 14th CGPM in 1971:

1. *The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in* 0.012 kg *of carbon* 12; *its symbol is "mol."*
2. *When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.*

It follows that the molar mass of carbon 12 is exactly 12 grams per mole, $M(^{12}\text{C}) = 12$ g/mol.

This definition refers to unbound atoms of ^{12}C at rest and in their ground state.

The definition of the mole also determines the value of the universal constant that relates the number of entities to amount of substance for any sample. This constant is called the *Avogadro constant*, symbol N_A or L. If $N(X)$ denotes the number of entities X in a specified sample, and if $n(X)$ denotes the amount of substance of entities X in the same sample, the relation is $n(X) = N(X)/N_A$.

Note that since $N(X)$ is dimensionless, and $n(X)$ has the SI unit mole, the Avogadro constant has the coherent SI unit reciprocal mole.

2.2.1.7 **The Candela**

The candela unit of luminous intensity was adopted in its present form by the 16th CGPM in 1979.

The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz *and that has a radiant intensity in that direction of* 1/683 Watt per steradian.

It follows that the spectral luminous efficacy for monochromatic radiation of frequency of 540×10^{12} hertz is exactly 683 lumens per Watt, $K = 683\ \text{lm/W} = 683\ cdsr/W$.

The units of luminous intensity based on flame or incandescent filament standards in use in various countries before 1948 were replaced initially by the "new candle" based on the luminance of a Planck radiator (a black body) at the temperature of freezing platinum. This modification was then ratified in 1948 by the ninth CGPM, which adopted a new international name for this unit, the *candela*. In 1979, the present definition was given because of the difficulties in realizing a Planck radiator at high temperatures, and the new possibilities offered by radiometry, that is, the measurement of optical radiation power.

2.2.2
SI Derived Units

The unit of any quantity can be expressed by the relation

$$[Q] = \mathrm{m}^{\alpha}\ \mathrm{kg}^{\beta}\ \mathrm{s}^{\gamma}\ \mathrm{A}^{\delta}\ \mathrm{K}^{\varepsilon}\ \ \mathrm{mol}^{\zeta}\ \mathrm{cd}^{\eta}.$$

Units obtained by this relation are coherent derived SI units. The base and coherent derived units of the SI form a coherent set, designated the set of *coherent SI units*.

For convenience, certain coherent derived units have been given special names and symbols. There are 22 such units (see Table 2.2).

These units and symbols can be used in forming other coherent derived units. As an example, the unit of dynamic viscosity is expressed in terms of SI base units $\mathrm{m}^{-1}\,\mathrm{kg}\,\mathrm{s}^{-1}$, it can also be expressed in terms of coherent derived SI units pascal and the base unit second, it has then the unit symbol Pa. This convention allows to express the physical meaning of a given quantity.

2.2.3
SI Prefixes

The CGPM adopted, in 1960, a series of prefix names and prefix symbols to form the names and symbols of the decimal multiples and submultiples of SI units, ranging from 10^{12} to 10^{-12}. This range was increased in several steps. The presently approved prefix names and prefix symbols range from 10^{24} to 10^{-24}, and they are listed in Table 2.3. The prefixes are used to keep the numbers giving the values of a quantity in a practical order of magnitude. Names and symbols for decimal multiples and submultiples of the unit are generally formed by attaching prefix names to the unit name. However, one important exception is the base unit of mass, the kilogram, whose name and symbol, for historical reasons, already includes a prefix. For the unit of mass, decimal multiples and submultiples are formed by attaching a prefix to the gram, *g*.

The following points are noted:

- Units with a prefix are not coherent.
- SI prefixes refer strictly to powers of 10, and cannot be used for powers of 2. For example, 1 kilobit should not be used to represent 1024 bits (2^{10} bits), which instead is 1 kibibit (BIPM, IEC, IFCC, ILAC, ISO, IUPAC, IUPAP, and OIML, 2008). When SI prefixes are used, attention should be paid to the rules listed in Section 2.4.

2.2.4
SI on the BIPM-homepage

The BIPM issues the SI-brochure, which can be downloaded from its homepage *http://www.bipm.org*. The official version is the French text. The site allows both, online browsing and downloading of the entire brochure.

Tab. 2.2 Coherent derived units in the SI with special names and symbols.

		SI coherent derived unit		
Derived quantity	**Name**	**Symbol**	**Expressed in SI units**	**Expressed in SI base units**

pressure, stress	pascal	Pa	N/m^2	$m^{-1}\ kg\ s^{-2}$
energy, work, amount of heat	joule	J	N m	$m^2\ kg\ s^{-2}$
power, radiant flux	watt	W	J/s	$m^2\ kg\ s^{-3}$
electric charge, amount of electricity	coulomb	C	–	s A
electric potential difference, electromotive force	volt	V	W/A	$m^2\ kg\ s^{-3}\ A^{-1}$
capacitance	farad	F	C/V	$m^{-2}\ kg^{-1}\ s^4\ A^2$
electric resistance	ohm	Ω	V/A	$m^2\ kg\ s^{-3}\ A^{-2}$
electric conductance	siemens	S	A/V	$m^{-2}\ kg^{-1}\ s^3\ A^2$
magnetic flux	weber	Wb	V s	$m^2\ kg\ s^{-2}\ A^{-1}$
magnetic flux density	tesla	T	Wb/m^2	$kg\ s^{-2}\ A^{-1}$
inductance	henry	H	Wb/A	$m^2\ kg\ s^{-2}\ A^{-2}$
Celsius temperature	degree Celsius	°C		K
luminous flux	lumen	lm	cd sr[a]	cd
illuminance	lux	lx	lm/m^2	$m^{-2}\ cd$
activity referred to a radionuclide(f)	becquerel[b]	Bq		s^{-1}
absorbed dose[d], specific energy (imparted), kerma	gray	Gy	J/kg	$m^2\ s^{-2}$
dose equivalent[d], ambient dose equivalent, directional dose equivalent, personal dose equivalent	sievert	Sv	J/kg	$m^2\ s^{-2}$
catalytic activity	katal	kat	–	$s^{-1}\ mol$

[a] The *radian* and *steradian* are special names for the number one that may be used to convey information about the quantity concerned. In practice, the symbols rad and sr are used where appropriate, but the symbol for the derived unit one is generally omitted in specifying the values of dimensionless quantities. However, in photometry, the name steradian and the symbol sr are usually retained in expressions for units.

[b] The *hertz* is used only for periodic phenomena, and the *becquerel* is used only for stochastic processes in activity referred to a radionuclide.

[c] Activity of a radionuclide is sometimes incorrectly called *radioactivity*.

[d] For details on quantities and units for ionizing radiation, see ICRU 1998a, 1998b.

Tab. 2.3 SI prefixes.

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^1	deca	da	10^{-1}	deci	d
10^2	hecto	h	10^{-2}	centi	c
10^3	kilo	k	10^{-3}	milli	m

10^{24}	yotta	Y	10^{-24}	yocto	y

Note that Appendix 2 of the brochure, titled "Practical realizations of the definitions of some important units" is published in electronic form only, as this allows updating in the course of advances in experimental realizations of units. This decision underlines the strict distinction between the definition and the realization of a unit.

Furthermore, this webpage features links to a "Brief history of the SI," a concise visualization of "Linking SI base units to fundamental and atomic constants" and to "Unit conversions" (see also Appendix).

2.3
Units Outside the SI

The consequent use of SI units and the few non-SI units that are accepted for use with the SI promotes communication in pure and applied science.

However, in nearly all countries traditional units are still in use, for example, units for time, such as minute, hour, and day, and there are also some fields of science that use non-SI units. The exclusive use of SI units cannot always be enforced; rather it is a process that is accelerated by evidencing its advantages. Along this line, the policy of the Consultative Committee for Units is to advocate the use of the SI instead of deprecating units that are still widely used. The eighth edition of the brochure promotes this process by providing listings of units accepted for use with the SI and tables for converting some units that are still widely used but not accepted to SI units and by referring to complete conversion table on the BIPM homepage.

2.3.1
Non-SI Units Accepted for Use with the SI

It is distinguished between
- non-SI units accepted for use with the SI (Table 2.4(a) and notes below);
- other non-SI units (Table 2.4(b));
- non-SI units whose values in SI units must be obtained experimentally (Table 2.5); and
- non-SI units associated with the CGS and the CGS-Gaussian system of units (Table 2.6).

Notes on Table 2.4(a):
- ISO 31 recommends that the *degree* (angle) be divided decimally rather than using the minute and the second. For navigation and surveying, however, the minute has the advantage that 1 minute of latitude on the surface of the Earth

Tab. 2.4a Non-SI units accepted for use with the International System of Units.

Quantity	Name of unit	Symbol for unit	Value in SI units
time	minute	min	$1\,\text{min} = 60\,\text{s}$
	hour	h	$1\,\text{h} = 60\,\text{min} = 3600\,\text{s}$
	day	d	$1\,\text{d} = 24\,\text{h} = 86\,400\,\text{s}$
plane angle	degree	$^\circ$	$1^\circ = (\pi/180)\,\text{rad}$
	minute	$'$	$1' = (1/60)^\circ = (\pi/10\,800)\,\text{rad}$
	second	$''$	$1'' = (1/60)' = (\pi/648\,000)\,\text{rad}$
area	hectare	ha	$1\,\text{ha} = 1\,\text{hm}^2 = 10^4\,\text{m}^2$
volume	liter	L, l	$1\,\text{L} = 1\,\text{l} = 1\,\text{dm}^3 = 10^3\,\text{cm}^3 = 10^{-3}\,\text{m}^3$
mass	tonne[a]	t	$1\,\text{t} = 10^3\,\text{kg}$

[a] In English-speaking countries, the unit tonne is usually called *metric ton*.

corresponds (approximately) to one nautical mile.

- The *gon* (or grad, where grad is an alternative name for the gon) is an alternative unit of plane angle to the degree, defined as $(\pi/200)$ rad. Thus there are 100 gons in a right angle. The potential value of the gon in navigation is that because the distance from the pole to the equator of the Earth is approximately 10 000 km, 1 km on the surface of the Earth subtends an angle of one centigon at the center of the Earth. However, the gon is rarely used.
- For applications in *astronomy*, small angles are measured in *arcseconds* (i.e., seconds of plane angle), denoted as milliarcseconds, microarcseconds, and picoarcseconds, denoted mas, μas, and pas, respectively, where arcsecond is an alternative name for second of plane angle.
- The unit *hectare*, and its symbol ha, were adopted by the CIPM in 1879. The hectare is used to express land area.
- The *liter*, and the symbol lowercase l, were adopted by the CIPM in 1879. The alternative symbol, capital L, was adopted by the 16th CGPM (1979, Resolutions 6; CR, 101) in order to avoid the risk of confusion between the letter l (el) and the numeral 1 (one).

2.3.2
Other Non-SI Units Not Recommended for Use

There are many more non-SI units. Some are of historical interest and others are still used for specific applications such as the barrel of oil, or used in particular countries, for example, inch, gallon, and pound.

Although the advantages of a consequent use of SI units appear obvious, it is expected that some of these non-SI units will be used in future. The CIPM has therefore decided to compile a list of the conversion factors to the SI for such units and to make this available on the BIPM home page.

For the convenience of the reader, some more often needed conversion factors are provided in the Appendix.

2.4
Rules for Expressing Quantities

The compliance with rules and conventions enhances the readability of technical and scientific papers.

Tab. 2.4b Other non-SI units.

Quantity	Name of unit	Symbol for unit	Value in SI units
pressure[a]	bar	bar	1 bar = 0.1 MPa = 100 kPa = 10^5 Pa
	millimeter of mercury	mmHg	1 mmHg = 133.322 Pa
length	ångström[b]	Å	1 Å = 0.1 nm = 100 pm = 10^{-10} m
distance	nautical mile[c]	M	1 M = 1852 m
area	barn[d]	b	1 b = 100 fm^2 = 100 × $(10^{-15}\ \text{m})^2$ = 10^{-28} m^2
speed	knot[c]	kn	1 kn = (1852/3600) m/s
logarithmic ratio quantities	neper[e,g]	Np	[see footnote[h] regarding the numerical value of the neper, the bel, and the decibel]
	bel[f,g]	B	
	decibel[f,g]	dB	

[a] Since 1982 1 bar has been used as the standard pressure for tabulating all thermodynamic data. It replaced the *standard atmosphere*, equal to 1.013 25 bar, or 101 325 Pa. The *millimeter of mercury* is a legal unit for the measurement of blood pressure in some countries.

[b] The *ångström* is widely used by x-ray crystallographers and structural chemists because all chemical bonds lie in the range 1–3 ångströms. However, it has no official sanction from the CIPM or the CGPM.

[c] The *nautical mile* is employed for marine and aerial navigation to express distance. As yet there is no internationally agreed symbol, but the symbols M, NM, Nm, and nmi are all used. One nautical mile on the surface of the Earth subtends approximately 1 minute of angle at the center of the Earth. The *knot* is defined as one nautical mile per hour. There is no internationally agreed symbol, but the symbol kn is commonly used.

[d] The *barn* is a unit of area employed to express cross sections in nuclear physics.

[e] The statement $L_A = n$ Np (where n is a number) is interpreted to mean that $\ln(A_2/A_1) = n$. Thus when $L_A = 1$ Np, $A_2/A_1 = \mathrm{e}$. The symbol A is used here to denote the amplitude of a sinusoidal signal, and L_A is then called the *neperian logarithmic amplitude ratio*, or the *neperian amplitude level difference*.

[f] The statement $L_X = m$ dB $= (m/10)$ B (where m is a number) is interpreted to mean that $\lg(X/X_0) = m/10$. Thus when $L_X = 1$ B, $X/X_0 = 10$, and when $L_X = 1$ dB, $X/X_0 = 10^{1/10}$. If X denotes a mean square signal or power-like quantity, L_X is called a *power level* referred to X_0.

[g] In using these units it is important that the nature of the quantity be specified, and that any reference value used be specified. These units are not SI units, but they have been accepted by the CIPM for use with the SI.

[h] The numerical values of the neper, bel, and decibel (and hence the relation of the bel and the decibel to the neper) are rarely required. They depend on the way in which the logarithmic quantities are defined.

Tab. 2.5 Non-SI units whose values in SI units must be obtained experimentally.

Quantity	Name of unit	Symbol for unit	Value in SI units[a]
Units accepted for use with the SI			
energy	electronvolt[b]	eV	1 eV = 1.602 176 53 (14) × 10^{-19} J

Natural units (n.u.)			
speed	n.u. of speed (speed of light in vacuum)	c_0	299 792 458 m s^{-1}(exact)
action	n.u. of action (reduced Planck constant)	$\hbar$	1.054 571 68 (18) × 10^{-34} J s
mass	n.u. of mass (electron mass)	m_e	9.109 382 6 (16) × 10^{-31} kg
time	n.u. of time	$\hbar/(m_e c_0^2)$	1.288 088 667 7 (86) × 10^{-21} s
Atomic units (a.u.)			
charge	a.u. of charge, (elementary charge)	e	1.602 176 53 (14) × 10^{-19} C
mass	a.u. of mass, (electron mass)	m_e	9.109 382 6 (16) × 10^{-31} kg
action	a.u. of action, (reduced Planck constant)	$\hbar$	1.054 571 68 (18) × 10^{-34} J s
length	a.u. of length, bohr (Bohr radius)	a_0	0.529 177 210 8 (18) × 10^{-10} m
energy	a.u. of energy, hartree (Hartree energy)	$E_\hbar$	4.359 744 17 (75) × 10^{-18} J
time	a.u. of time	$\hbar/E_h$	2.418 884 326 505 (16) × 10^{-17} s

[a] The values in SI units of all units in this table, except the astronomical unit, are taken (Mohr, P.J. and Taylor, B.N. (2005) *Rev. Mod. Phys.*, 77, 1–107). The standard uncertainty in the last two digits is given in parenthesis (see Section 2.4, below).

[b] The *electronvolt* is the kinetic energy acquired by an electron in passing through a potential difference of 1 V in vacuum. The electronvolt is often combined with the SI prefixes.

[c] The *dalton* and the *unified atomic mass unit* are alternative names (and symbols) for the same unit, equal to 1/12 times the mass of a free carbon 12 atom, at rest and in its ground state. The *dalton* is often used with SI prefixes to express the masses of large molecules or small mass differences of atoms or molecules.

[d] The astronomical unit is approximately equal to the mean Earth–Sun distance. It is the radius of an unperturbed circular Newtonian orbit about the Sun of a particle having infinitesimal mass, moving with a mean motion of 0.017 202 098 95 radians per day (known as the *Gaussian constant*). The value given for the astronomical unit is quoted from the International Earth Rotation and Reference Systems Service (IERS) Conventions 2003 (McCarthy, D.D. and Petit, G. (eds) (2004) *IERS Technical Note* 32, Verlag des Bundesamts für Kartographie und Geodäsie, Frankfurt am Main, p. 12). The value of the astronomical unit in meters comes from the Jet Propulsion Laboratory (JPL) ephemerides DE403 (Standish, E.M. (1995) Report of the IAU WGAS Sub-Group on Numerical Standards, in *Highlights of Astronomy* (ed. Appenzeller), Kluwer Academic Publishers, Dordrecht, pp. 180–184).

The rules for quantity calculus are independent from the language used; however, the usage of names for quantities, dimensions, and units in a text does depend on the language used. For the rules discussed below, numbers in brackets refer to the examples given in Table 2.7.

Names for quantities and units are ordinary nouns. Therefore, in English, they are declined and start with a lowercase letter, even units named after person [1]. The plural is formed regularly, for example, "lengths" and "henries" are the plurals of "length" and "henry." However for lux, hertz, and siemens the plural is identical with the singular. The names of multiples or submultiples of a unit are written without a hyphen or a space [2]. Derived units that are products of units are written with a hyphen or a space as "multiplication sign" [3], those representing ratios are written using the word "per" to indicate the division [4]. Modifiers such as "squared" or "cubed" are placed after the unit name. However, for area and volume the words "square" and "cubic" may be used and are then placed before the corresponding unit [5].

Symbols for quantities, dimensions, and units are mathematical entities. The normal rules of algebra apply and one must neither use the plural nor mix symbols and names within one expression [6].

Symbols for quantities are generally single letters of the Latin or Greek alphabets, printed in an *italic* font. Symbols for quantities are *recommendations* [7].

Symbols for units are printed in roman (upright) type regardless of the type used in the surrounding text. Symbols for units are mandatory [8]. Unless they are named after a person, unit symbols begin with lowercase letter [9]. However, for the accepted non-SI unit liter the symbol L or l is allowed; L should be used to avoid that l is interpreted as the Arabic numerical for one [10].

The *symbols* for derived units reflect a product of base units with integer exponents, that are negative, zero, or positive, see Section 2.2. Base units with negative exponents are divisors, those with zero as exponents are omitted and those with positive exponents are multipliers. Multiplication must be indicated a half space () or a half-high centered dot (·), but never by a cross (×) [11] and division is indicated by a horizontal line (—), a solidus (/), or by the negative exponent [12].

SI *prefixes* and the unit again form a unit; therefore, they are also printed in roman (upright) type without a multiplication sign between prefix symbol and unit symbol and their names are also written as one word [13]. They can be raised to a positive or negative power [14]. Compound prefixes, that is, prefixes formed by juxtaposition of two or more SI prefixes are not permitted [15] as prefixes are not stand-alone abbreviations for $10^{\pm n}$, n being an integer. Names of decimal multiples or submultiples of the unit of mass are formed by attaching prefixes to the name "gram" and the symbols are formed by attaching prefixes to the unit g [16]. SI prefixes should only be used in stating results and not in calculations in order to preserve coherence.

When multiplying or dividing the values of quantities, brackets should be used to exclude any ambiguities [17]. The terms *ppm*, *ppb*, or *ppt* should not be used to express relative values in the SI. In most English-speaking countries, 10^6, 10^9, 10^{12}, and 10^{15} are named *million*, *billion trillion*, and *quadrillion*, respectively. In French, German, and other languages, however, they are named *million*, *milliard*, *billion*, and *billiard*. On the other hand, the internationally recognized symbol % (percent) may be used with the SI to

Tab. 2.6 Non-SI units associated with the CGS and the CGS-Gaussian system of units.

Quantity	Name of unit	Symbol for unit	Value in SI units
energy	erg[a]	erg	$1\,\text{erg} = 1\,\text{g cm}^2\,\text{s}^{-2} = 10^{-7}\,\text{J}$
force	dyne[a]	dyn	$1\,\text{dyn} = 1\,\text{g cm s}^{-2} = 10^{-5}\,\text{N}$
dynamic viscosity	poise[a]	P	$1\,\text{P} = 1\,\text{g cm s}^{-1} = 0.1\,\text{Pa s}$
kinematic viscosity	stokes	St	$1\,\text{St} = 1\,\text{cm}^2\,\text{s}^{-1} = 10^{-4}\,\text{m}^2\,\text{s}^{-1}$
luminance	stilb[a]	sb	$1\,\text{sb} = 1\,\text{cd cm}^{-2} = 10^4\,\text{cd m}^{-2}$
illuminance	phot	ph	$1\,\text{ph} = 1\,\text{cd sr cm}^{-2} = 10^4\,\text{lx}$
acceleration	gal[b]	Gal	$1\,\text{Gal} = 1\,\text{cm s}^{-2} = 10^{-2}\,\text{m s}^{-2}$
magnetic flux	maxwell[c]	Mx	$1\,\text{Mx} = 10^{-4}\,\text{cm}^2\,\text{T} = 10^{-8}\,\text{Wb}$
magnetic flux density	gauss[c]	G	$1\,\text{G} = 1\,\text{cm}^{-2}\,\text{Wb} = 10^{-4}\,\text{T}$
magnetic field	œrsted[c]	Oe	$1\,\text{Oe} \mathrel{\hat{=}} (10^3/4\pi)\,\text{A m}^{-1} \cong 7.957\,747 \times 10\,\text{A m}^{-1}$

[a] This unit and its symbol were included in Resolution 7 of the 9th CGPM (1948; CR, 70).

[b] The gal is a special unit of acceleration employed in geodesy and geophysics to express acceleration due to gravity.

[c] These units are part of the so-called electromagnetic three-dimensional CGS system based on unrationalized quantity equations, and must be compared with care to the corresponding unit of the International System, which is based on rationalized equations involving four dimensions and four quantities for electromagnetic theory. The magnetic flux, Φ, and the magnetic flux density, B, are defined by similar equations in the CGS system and the SI, so that the corresponding units can be related as in the table. However, the unrationalized magnetic field, $H(\text{unrationalized}) = 4\pi \times H(\text{rationalized})$. The equivalence symbol $\hat{=}$ is used to indicate that when $H(\text{unrationalized}) = 1$ Oe, $H(\text{rationalized}) = (10^3/4\pi)\,\text{A m}^{-1}$.

represent the number 0.01, and a half space separates number and % [18].

Multiplication or division of several quantities again leads to a quantity; however, addition or subtraction is only physically meaningful for quantities with the same dimension and equivalent units. Equations involving physical quantities must have the same dimensions on both sides, and the dimensions must be the correct ones for the quantity calculated.

For a complete statement of the result of a measurement, it is required

- to indicate the measurand;
- to provide the numerical value and the unit; and
- to state a measure for the trustworthiness of the result.

The measurand should be defined in sufficient detail. For instance, the quantity ''temperature at the triple point of water'' is not well defined, unless the isotopic composition of water is given (cf. Section 2.2.1.5).

Even if in a given field, one and only one unit is used, it must be given explicitly and a prefix should be used, such that the leading digits range from 0.001 to 1000. If a result has many digits, it enhances the legibility to group them in blocks of three, separated by a half space [19]. However, within a column of a table, the same unit should be used. In stating the values of quantities of dimension one, powers of 10 are used.

The most informative measure for the trustworthiness of a numerical value is the expanded uncertainty.

The Guide to the expression of uncertainty in measurement (GUM) ISO

Tab. 2.7 Examples for demonstrating rules.

1	Several kelvins, *not* Kelvins or Kelvin
2	milligram, *neither* milli-gram *nor* milli gram

17	$(0.5\,\mathrm{m\,s^{-2}})(2.0\,\mathrm{s}) = (0.5\,\mathrm{m\,s^{-2}} \times (2.0\,\mathrm{s}) = 1\,\mathrm{m}^{-1})$ in some countries × is used for expressing areas $a = 5\,\mathrm{m} \times 5\,\mathrm{m} = 25\,\mathrm{m}^2$ or volumes $(a/b)/c \neq a(b/c)$, unless $c = 1$; $a/b/c$ is undefined
18	$w\ (x) = 0.032\%$, and $w(x) = 0.032\%$
19	$l = 1000$ mm is appropriate, $l = 1\,000000$ µm is *less* appropriate, $l = 987.654\ 32$ mm *or* $l = 0.987\ 654\ 32$ m, but *neither* $l = 0.000\ 987\ 654\ 32$ km *nor* $l = 987\ 654.32$ µm are easy to read

(1993) denotes the standard uncertainty associated with the best estimate x of the value of a quantity X by $u(x)$. The GUM provides rules for the evaluation of the uncertainty and for the determination of the so-called coverage factor. The product of the coverage factor k and the uncertainty is called *expanded uncertainty* for which the symbol U is used. For example, the following statement would be complete:

The measured value of the nominal 50-mm *gauge block is* (49.999 926 ± 0.000 073) mm. *The reported expanded uncertainty of measurement is stated as the standard uncertainty of measurement multiplied by the coverage factor* $k = 2$, *which corresponds to a coverage probability of approximately* 95% *for a normal distribution.*

In some literature, the uncertainty is often given by adding two digits in parenthesis. For the result given above, it is 49.999 926 (73) mm. Here, too, the used coverage factor is to be stated.

Finally, there are no rules on choosing a unit for a given nonbase quantity. However, if possible, the unit should reflect the physics of the addressed quantity, for example, for torque, one would use newton and not joule.

2.5
International Metrology

2.5.1
Convention du Mètre

International metrology aims at global comparability of measurements. The first international agreement on metrology is the Convention du Mètre, signed by 17 states in Paris in 1875. It is still effective and currently has (2008) 51 signatory states and 27 associated states and economies. This treaty gives authority to the

- CGPM;
- the CIPM; and the
- BIPM.

to act in matters of world metrology, particularly concerning the demand for measurement standards of ever-increasing accuracy, range, and diversity, and the need to demonstrate equivalence between national measurement standards.

Table 2.8 visualizes the structure of international metrology under the authority of the Convention du Mètre.

The CGPM is the highest authority. Representatives of all member states and observers from the associate states meet every four years, last in 2007. The CGPM is responsible for

- discussing and instigating the arrangements required to ensure the propagation and improvement of the SI;
- confirming the results of new fundamental metrological determinations and the various scientific resolutions of international scope, mainly prepared by the CIPM; and
- adopting the important decisions concerning the organization and development of the BIPM.

Principal task of the CIPM is to promote worldwide uniformity in units of measurement and this is done by direct action or by submitting draft resolutions to the CGPM. The CIPM meets annually at the BIPM. It has 18 members from different member states of the Meter Convention and the director of the BIPM is a member *ex officio*.

The BIPM was established by the Convention du Mètre. It operates under the exclusive supervision of the CIPM and has the task to ensure worldwide uniformity of measurements and their traceability to the SI. The BIPM carries out measurement-related research, takes part in and organizes international comparisons of national measurement standards, and carries out calibrations for National Metrology Institutes (NMIs).

In view of the extension of the work entrusted to the BIPM, the CIPM has set up Comités Consultatifs (CC) since 1927. These CCs are responsible for coordinating the international work carried out in their respective fields and they advise on matters of the system of units. At present, 10 CCs exist (see Table 2.8).

The BIPM also forms Joint Committees with other international organizations, for particular tasks of common interest (see Table 2.8).

2.5.2
Mutual Recognition Arrangement

The Comité International des Poids et Mesures Mutual Recognition Arrangement (CIPM-MRA) (CIPM, 1999), is an agreement of NMIs with the following objectives:

- to establish the degree of equivalence of national measurement standards;

Consultative committees			
CCEM	Electricity and Magnetism, 1927 CCE (d'électricité), renamed in 1997.	**CCPR**	Photometry and Radiometry , 1933 CCP (de photométrie), renamed in 1971.
CCT	Thermometry, 1937.	**CCL**	Length, 1952 CCDM (definition of the metre), renamed in 1997.
CCTF	Time and Frequency, 1956 CCDS (definition of the second), renamed in 1997.	**CCRI**	Ionizing Radiation, 1958 as CEMRI (étalons de mesure des rayonnements ionisants), renamed in 1997.
CCU	Units, set up in 1964.	**CCM**	Mass and Related Quantities, 1980.
CCQM	Amount of Substance, 1993, in 2001 the qualifier "metrology in chemistry" was added.	**CCAUV**	Acoustics, Ultrasound and Vibration, 1998.

Joint Committees of the BIPM and other international organizations

JCDCMAS:	Joint committee for the coordination of technical assistance to developing countries in metrology, accreditation and standardization.
JCGM:	Joint committee for guides in metrology. It has two working groups (WG). WG 1 promotes the use of the guide to the expression of uncertainty in measurement (GUM), prepares supplemental guides for its broad application. WG 2 revises and promotes the use of the International vocabulary of metrology (VIM), the acronym stands for it French version "Vocabulaire international de métrologie"
JCRB:	Joint committee of the regional metrology organizations and the BIPM. Its most important tasks is the coordination of the activities among the RMOs in establishing confidence for the recognition of calibration and measurement certificates, according to the terms of the CIPM MRA. It reports annually to the CIPM and to the signatories of the CIPM MRA.
JCTLM:	Joint committee for traceability in laboratory medicine. The goal of the JCTLM is to provide a worldwide platform to promote and give guidance on internationally recognized and accepted equivalence of measurements in laboratory medicine and traceability to appropriate measurement standards.

For more details see http://www.bipm.org/en/committees/

- to provide for the mutual recognition of calibration and measurement certificates; and
- thereby to provide governments and other parties with the metrological basis for wider agreements negotiated for international trade, commerce, and regulatory affairs.

The NMIs, one per country, are signatories of the CIPM-MRA. However, in many countries also, other institutes hold national standards. These institutes can be designated by the signatory NMI and participate in the CIPM-MRA. These institutes are referred to as designated institutes (DIs).

The CIPM-MRA was introduced in the year 1999 at the 21st General Conference on Weights and Measures (CGPM). Presently (2008), it has been signed by the representatives of 74 institutes – from 45 member states, 27 associates of the CGPM, and 2 international organizations – and covers a further 121 DIs.

The objectives of the CIPM-MRA are reached by the following key elements:

- peer review of the declared Calibration and Measurement Capabilities (CMCs);
- international comparisons of measurement standards (key comparisons or supplementary comparisons); and
- peer review of the quality systems.

International comparisons take many forms. Some are carried out by the BIPM; others are organized by a Consultative Committee and may or may not include the BIPM; many more are organized and carried out, usually as part of the activities of a regional metrology organization, by the NMI and other institutes. Most BIPM comparisons are among the key comparisons chosen by the Consultative Committees to establish the *degree of equivalence* between national measurement standards.

The *degree of equivalence* of a measurement standard is a quantified expression of the consistency of the value of a measurement standard with the *key comparison reference value*. This is expressed quantitatively by the deviation from the key comparison reference value and the uncertainty associated with that value. The degree of equivalence between two measurement standards is expressed as the difference between their respective deviations from the key comparison reference value and the uncertainty associated with the value of this difference.

A *key comparison* is a set of comparisons selected by a Consultative Committee to test the principal techniques and methods for measuring quantities they are concerned with. Since only a limited number of participants is technically feasible in a given key comparison, key comparisons are also carried out by Regional Metrology Organisations (RMOs):

- APMP: Asia Pacific Metrology Programme;
- COOMET: Euro–Asian Cooperation of National Metrological Institutions;
- EURAMET: European Association of National Metrology Institutes;
- SADCMet: Southern African Development Community Cooperation in Measurement Traceability;
- SIM: Sistema Interamericano de Metrologia.

The results of key comparisons are accessible from a database maintained by the BIPM. Only key comparisons carried out by a Consultative Committee or the BIPM lead to a key comparison reference value. For a key comparison carried out by a regional metrology organization the link to the key comparison reference value is obtained by reference to the results from those institutes that have also taken part in the CIPM key comparison. For procedures to evaluate key comparisons see, for instance, Cox [2002a, 2002b].

2.6
Further Development of the SI

The SI is, and must be, a stable and reliable system because it affects almost all aspects of human life. However, the specific definitions of the units eventually need to be revised, since the levels of uncertainties, which can be achieved with the primary standards built to realize the units for practical use, depend on the specific definition of the units.

In fact, a quantum-based definition of the volt and ohm through the Josephson and the Quantum-Hall effect enables the realization of these units with smaller uncertainties than those possible through the classical SI definition. This led to a parallel use of these quantum-based units since 1990. In addition, an unsatisfactory relative drift of national kilogram prototypes versus each other and versus the international prototype kept at BIPM, was observed.

These and other arguments motivated the CIPM at its 94th meeting in 2005 to ask the metrology community to take preparative steps toward a redefinition of the kilogram, ampere, kelvin, and mole so that these four base units are linked to fixed values of fundamental constants.

It was advised that a possible redefinition should not introduce a discontinuity in the value of the unit. Furthermore, a significant benefit for one or more units must be achieved. Indeed, even an increased uncertainty in one specific unit may be tolerated, depending on the practical demands, if it is obviously outweighed by a related benefit of reduced uncertainty of another unit or of the system as a whole.

In the following, options that are currently being discussed but have not been decided yet are described. Some papers concerned with that discussion are cited below (see Further Reading) and briefly summarized there. The selection mirrors the main ideas and propositions, but not claimed to be exhaustive.

The possible redefinitions are such that one or more of the following fundamental constants are fixed: the elementary charge e, Avogadro's number N_A, Boltzmann's constant k_B, and Planck's constant h.

For instance, the definition of the ampere could refer to the number of electrons per second carrying the elementary charge. Approaches to realize the ampere according to such a definition are the single-electron transport (SET) using a chain of tunnel contacts, quantum dots, or nanostructured semiconductor channels.

The definition of the mole could refer to the amount of substance that contains N_A elementary entities.

The kelvin could refer to a change of temperature such that the thermodynamic temperature and the thermal energy E expressed in Joule are linked via $E = k_{\mathrm{B}}T$.

For the definition of the kilogram, essentially two options are discussed: the first is the so-called Watt-balance experiment, in which the weight of a test body (which then represents a reference mass) is balanced by an electromagnetic force, thus effectively relating the mass to a measurement of a current and a voltage. If the voltage is measured via Josephson effect with the Josephson constant $K_{\mathrm{J}} = 2e/h$, the current is measured via Quantum-Hall effect with the von Klitzing constant $R_{\mathrm{K}} = h/e$, and applying

Ohm's law, the kilogram would be linked to Planck's constant h. As an alternative, the kilogram could refer to the atomic mass unit m_e or to Avogadro's constant N_A, as realized in the so-called Avogadro experiment.

Any definition of a system of units is based on the definition of a certain set of values of constants or material parameters. In the present SI, exact values are defined for the speed of light in vacuum c_0, the mass of the international prototype of the kilogram $m(K$, the triple-point temperature of water T_{tpw}, and the magnetic constant μ_0. All other constants, if not automatically exact by definition such as the electric constant ε_0 via $\varepsilon_0 = 1/(c_0^2\mu_0)$, are quantities that need to be measured with a particular uncertainty given by the experiment.

The possible redefinitions as outlined before that are based on defining exact values of e, N_A, k_B, h (and c_0), would require to measure the values of $m(\mathcal{K})$, $M(^{12}C)$, T_{tpw}, and μ_0 and nonvanishing uncertainties would inevitably be associated with those values. As one of the most prominent benefits, however, the quantum-based definitions of volt and ohm through Josephson constant K_J and the von Klitzing constant R_K would become part of SI. In addition, the definition of the kelvin would become independent of possible drifts in water triple point cells and the kilogram would become independent of drifts of the mass of the international kilogram prototype.

Some fundamental constants such as e, N_A, k_B, and h are linked by fundamental laws of nature. Thus, one is not free to choose their values. Any redefinition of units that defines an exact value of one or more of these fundamental constants requires the consistency of the current experiments on them. This is not yet satisfactorily the case for the Watt-balance and Avogadro experiments. Values for h can be deduced from both experiments, which differ significantly. This disagreement needs to be solved before the CGPM may adopt redefinitions as outlined earlier.

Acknowledgment

We wish to thank Professor A. J. Wallard, Directeur du Bureau International des Poids et Mesures. With his kind permission, passages and tables from the brochure "Le Systeme International d'Unites (SI)," 8th edition 2006, have been used. We are also grateful to the BIPM for their generous access to publications on its home page.

Appendix: Conversion Factors for Some Non-SI Units

This appendix provides a list of some more frequently used non-SI units (Table 2.9). For a complete list, the reader is referred to *http://www.bipm.org/en/si/si_constants.html* and to Appendix B in the National Institute of Standards and Technology (NIST) Special Publication 811, (Thompson and Taylor, 2008). Bold printing indicates *exactly defined* conversion factors.

Glossary

The glossary lists scientific terms of relevance to units. Main sources are the Guide to the Expression of Uncertainty in Measurement (GUM) (ISO, 1993), the Mutual Recognition Arrangement (MRA) (CIPM, 1999) and the Vocabulaire International de Métrologie (VIM) (JCGM, 2008).

Base Quantity: Quantity in a conventionally chosen subset of a given system of

Rad (rad)	**10^{-2} Gy**	1 rad = 10^2 ergs/g (CGS-unit)
Rem (rem)	**10^{-2} Sv**	absorbed dose × radiation quality
Motor vehicle efficiency		
Is expressed in the US by miles per gallon (mi gal^{-1}) and in metric countries by liter per 100 km. Upon introducing x mi gal^{-1} and y L/(10^2 km), one obtains $y = (2.352\,145 \times 10^2)/x$ or $x = (4.251\,437 \times 10^{-3})/y$.		

quantities, where no subset quantity can be expressed in terms of the others. The following amy be noted:

- The subset mentioned in the definition is termed the *Set of Base Quantities.*
- Base quantities are referred to as *being mutually independent* since a base quantity cannot be expressed as a product of powers of the other base quantities.
- *Number of entities'* can be regarded as a base quantity in any system of quantities.

Base Unit: Measurement unit that is adopted by convention for a base quantity.

Coherent Derived Unit: Unit that is defined as product of the number 1 and powers of the base units with at least two nonvanishing exponents. For example, kg/m is a coherent derived unit for the quantity mass density.

Degree of Equivalence of a Measurement Standard: The degree to which the value of a measurement standard is consistent with the key comparison reference value. This is expressed quantitatively by the deviation from the key comparison reference value and the uncertainty of this deviation. The degree of equivalence between two measurement standards is expressed as the difference between their respective deviations from the key comparison reference value and the uncertainty of this difference.

Derived Unit: Unit that is defined as product of a number and powers of the base units with at least two nonvanishing exponents. For example, g/cm is a derived unit for the quantity mass density, but it is not coherent.

Dimension: See quantity dimension.

International System of Units (SI): System of units, based on the International System of Quantities, their names and symbols, including a series of prefixes and their names and symbols, together with rules for their use, adopted by the General Conference on Weights and Measures (CGPM), see Sections 2.2 and 2.4 and Table 2.8.

Key Comparison: One of the set of comparisons selected by a Consultative Committee to test the principal techniques and methods in the field (note that key comparisons may include comparisons of representations of multiples and submultiples of SI base and derived units and comparisons of artifacts).

Key Comparison Database: The database maintained by the BIPM, which contains Appendices A, B, C, and D of the Mutual Recognition Arrangement (CIPM, 1999).

Key Comparison Reference Value: The reference value accompanied by its uncertainty resulting from a CIPM key comparison (Source: BIPM).

Measurement Unit: Real scalar quantity, defined and adopted by convention, with which any other quantity of the same *kind* can be compared to express the ratio of the two quantities as a number. Also called *unit of measurement or unit*.

Multiple of a Unit: Unit that is formed from a given unit according to a scaling convention and is larger than that unit; see also prefix.

Numerical Value of a Quantity: Ratio of that quantity to the unit used.

Prefix: SI-prefixes (see Table 2.3) are used to form a multiple or submultiples of a unit.

Quantity: Property of a phenomenon, body, or substance, where the property has a magnitude that can be expressed as a number and a reference.

Quantity Dimension: Expression of the dependence of a quantity on the base quantities of a system of quantities as a product of powers of factors corresponding to the base quantities, omitting any numerical factor.

Set of Base Quantities: Mutually independent quantities such as, for instance, the International System of Quantities (ISQ).

Submultiples of a Unit: Unit that is formed from a given unit according to a scaling convention and is smaller than that unit; see also prefix.

Symbol of a Unit: Conventional sign designating a unit.

System of Quantities: Set of quantities together with a set of noncontradictory equations relating those quantities.

Uncertainty (of Measurement): Parameter, associated with the result of a measurement, that characterizes the dispersion of the values that could reasonably be attributed to the measurand (ISO, 1993).

Unit: See measurement unit.

Value of a Quantity: Number and reference together expressing magnitude of a quantity; see also numerical value of a quantity.

INTRODUCTION

Universality is a rather general term. Its uses in the sciences have been broad and varying. Strictly speaking, any scientific law implies at least a certain measure of universality. Indeed, in writing scientific relations, equations, and definitions, our aim is to provide description of the world in terms of the laws of nature. But any such description usually involves extrapolation; the laws of physics, in particular, are usually based on theoretical deductions suggested by, and checked through, analysis of experimental data. However, no matter how large the experimental data set is, the use of the equations of physics always assumes that they apply universally to all similar data. Thus, the widest use of universality in physics is in the context of extrapolation.

More "constructive" uses of the concept of universality are encountered in those applications where our knowledge of the underlying physical system is incomplete because of the size, cost, or complexity of the setup required to obtain experimental data sufficient to serve as a foundation for theoretical modeling, or because of difficulty with direct theoretical analysis of a complex system. Perhaps the most familiar approach is dimensional analysis (Schmidt and Housen, 1995) in which the number of independent variables is reduced by forming dimensionless combinations. A more definitive idea is that of *scaling*. In its broad sense, scaling consists of grouping physical variables according to some criteria in an attempt to reduce the number of independent combinations beyond that suggested by the simplest dimensional analysis. The scaling criteria usually refer to spatial or temporal scales (that is the source of the term "scaling") in the system. For instance, variables reflecting system behavior on macroscopic scales might be separated from variables corresponding to variation on the microscopic scales, in forming scaling combinations. Further discussion can be found in the article PHASE TRANSITIONS: RENORMALIZATION AND SCALING.

Universality then augments dimensional analysis and/or scaling in that the same relations are applied to different systems. Presumably, simpler systems, or numerical models appropriate for computer simulations, are used to determine the forms of the functional relations among the appropriate variable combinations. The results are then extended to more complex systems.

An elaborate use of universality and scaling ideas has developed during the past two to three decades in strongly fluctuating systems, near critical points and more generally at phase transitions. These effects are termed *critical phenomena* (*q.v.;* Domb and Green, 1976). Based on the renormalization-group ideas, formulation of scaling and universality for these systems has been developed, relat-

ing diverse systems in the regime of critical behavior. One of the most striking examples comprises the critical points of the liquid–gas phase transitions and of phase separation in certain binary mixtures, and the Curie points of uniaxial ferromagnets and of lattice models of ±1 "spins" (Ising models). All four systems fall in the same *universality class* in the sense that they are described by the same scaling relations. The Ising model, however, is much simpler than the other, experimental systems, and it has been used extensively in numerical simulations.

The rest of this article is devoted to universality in critical phenomena. Sections 1 through 4 introduce various aspects of the theoretical description of universal properties at phase transitions. Section 5 surveys the main calculation methods as well as selected results for the most familiar models. Additional topics are described briefly in Sec. 6.

1. CRITICAL PHENOMENA AT PHASE TRANSITIONS

Phase transitions are usually associated with singular or discontinuous behavior of thermodynamic quantities. As an illustration, in Fig. 1 the magnetization M of a ferromagnet is shown as a function of the temperature T. If there is no applied field, $H = 0$, then at low temperatures the system is spontaneously ordered. The magnetization is then nonzero, and in fact several directions of the magnetization can coexist. Some systems are *uniaxial* with "up" and "down" magnetization directions (termed Ising ferromagnets); others have vector magnetization pointing in an arbitrary direction in a plane (*XY* ferromagnets) or in three-dimensional space (Heisenberg ferromagnets), etc. In Fig. 1, two spin orientations are shown, thus assuming the simplest, uniaxial, Ising case. For temperatures above a certain transition point T_c, spontaneous magnetization disappears.

At the transition point, there may be a singularity, which is power-law in the leading order, $M \propto (T_c - T)^{\beta}$, as T approaches T_c from below. In that case we identify the critical or second-order phase transition, and the associated singular properties are termed critical phenomena. Figure 1 also illustrates a first-order phase transition for which the

(c)

FIG. 1. Variation of the magnetization with temperature for a uniaxial (Ising) ferromagnet. In zero applied field, two directions of the magnetization are possible at low temperatures; see solid and dashed curves in (a) and (b). The magnetization vanishes singularly, (a), or discontinuously, (b), at the transition point, for second-order and first-order phase transitions, respectively. For nonzero applied field, the magnetization is nonsingular and it is aligned with the field; see (c).

variation of the magnetization across the transition point is discontinuous. The magnetization is termed the *order parameter* of the transition. Of course, the type and location of phase transitions for various substances, as well as the symmetry and the identification of the appropriate order-parameter variable, depend on the nature of the interactions of the microscopic particles (such as spins, atoms, and molecules) that are the constituents of the macroscopic thermodynamic system. In fact, singular or discontinuous behavior in equilibrium is normally associated with the *thermodynamic limit* of an infinite number of such particles, i.e., with a macroscopically large sample.

Other quantities are also singular at second-order phase transitions, and in fact they can actually diverge according to some power laws; expressions for quantities such as the susceptibility or the specific heat are introduced later. In a larger parameter space, the point of a second-order phase transition is usually a special point, termed *critical point*. For instance, Fig. 2 illustrates variation of the magnetization for an Ising ferromagnet near its critical point as a function of the applied field. We note that for each temperature $T < T_c$ the applied field actually drives the system through a first-order phase transition, i.e., discontinuous magnetization. The behavior is analytic for $T > T_c$. However, only for $T = T_c$ and at $H = 0$ do the singularities of the power-law type occur. Thus the ferromagnetic critical point is a special point at $(T,H) = (T_c,0)$.

Figure 3 shows phase diagrams of (a) ferromagnetic and (b) gas–liquid–solid phase coexistences. Large fluctuations develop only in a limited part of the parameter space. Specifically, for a uniaxial ferromagnet in applied field H and at temperature T, the line of coexistence of positive and negative magnetization M extends from $T = 0$ to the critical or Curie point at $T = T_c$. In the close vicinity of the critical point, i.e., for small field H and small dimensionless temperature deviation

$$t = (T - T_c)/T_c, \tag{1}$$

large regions of correlated fluctuations develop, and various thermodynamic quantities behave in a singular fashion. We note that the line of coexistence of positive and negative spontaneous magnetizations, at $H = 0$ and $T < T_c$, also corresponds to large-scale heterophase fluctuations. This first-order phase transition also has certain universal scaling properties, which are mentioned in Sec. 5. The main emphasis here is on the critical-point behavior.

The gas–liquid–solid phase diagram, Fig. 3(b), is more complicated. However, second-order–transition type singular behavior is only observed near the critical (or cloud) point at which the liquid–gas coexistence (evaporation) line ends. The other end of that line is the triple point, at which the melting and sublimation lines of first-order phase transitions meet with the evaporation line. In the vicinity of the critical point, one can define a temperature-like deviation variable "along" the coexistence line, analogous to t of the ferromagnet, as well as a fieldlike deviation variable in the direction "perpen-

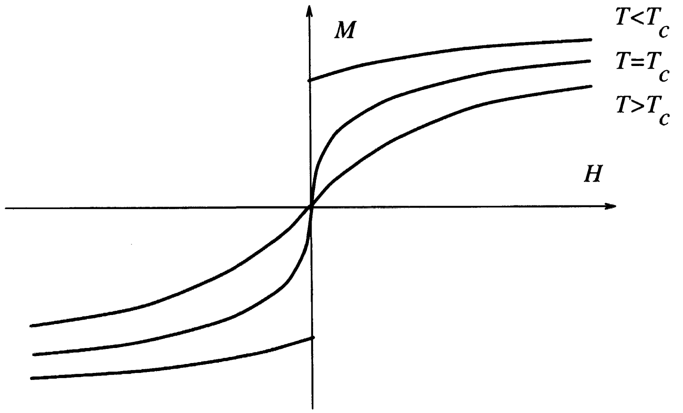

FIG. 2. Variation of the magnetization with applied field for a uniaxial (Ising) ferromagnet with a second-order phase transition point at $(T,H) = (T_c,0)$, at different temperatures.

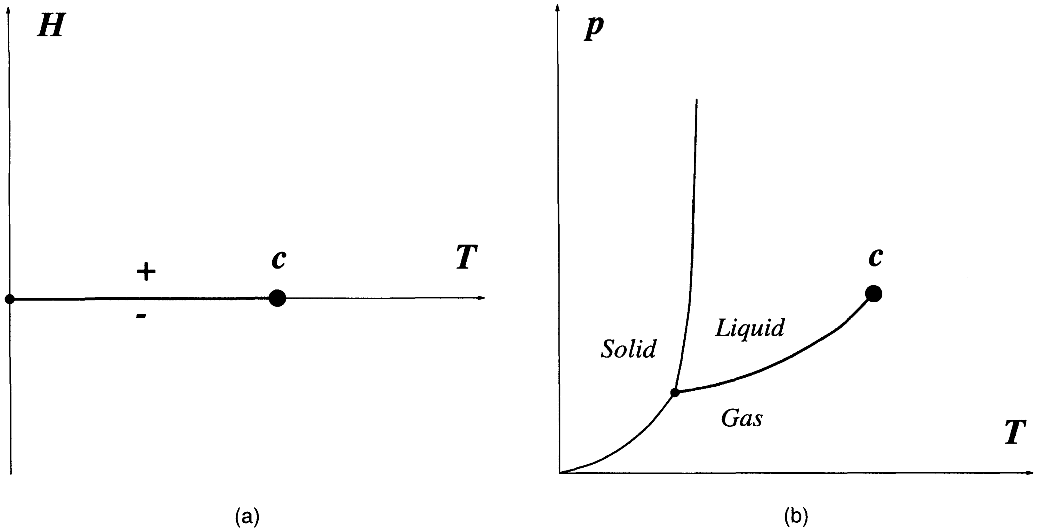

FIG. 3. (a) The ferromagnetic phase diagram showing the phase coexistence line for temperatures $T < T_c$, with the critical point (marked ***c***) at T_c; H denotes the magnetic field. (b) The gas–liquid–solid phase diagram with the liquid–gas phase coexistence line ending at the critical point (marked ***c***) at (T_c,p_c), where p denotes the pressure.

dicular" to the coexistence line. These are usually linear combinations of the temperature and chemical-potential deviations from their critical-point values (Privman *et al.*, 1991).

Let us also consider the nearest-neighbor Ising model defined by placing spins

$$s_i = \pm 1 \tag{2}$$

at sites i of a regular D-dimensional lattice. The energy of the spin configuration is

$$E\{s_i\} = -J \sum_{\text{pairs } m,n} s_m s_n - H \sum_k s_k. \tag{3}$$

Here the first sum is over all nearest-neighbor pairs. The coupling constant J is positive for the ferromagnetic behavior, while the applied field H can be positive or negative. For definiteness, we will use the dimensionless "magnetic field" variable of the Ising model,

$$h = H/k_B T, \tag{4}$$

where k_B is the Boltzmann constant. We note that this model has the phase diagram of Fig. 3(a). Similar dimensionless "applied field" variables analogous to H/k_BT can be defined for other systems.

2. SCALING AND UNIVERSALITY IN CRITICAL PHENOMENA

Near a critical point, singular behavior of thermodynamic quantities can be represented in the scaling form. In the limit $t \to 0$ and $h \to 0$, we have for the singular part of the free-energy density measured per k_BT

$$f_{\text{sing}}(t,h) \approx c_f |t|^{2-\alpha} Q_{\pm}(c_h h |t|^{-\Delta}), \tag{5}$$

where the scaling function $Q_{\pm}$ is different for $t > 0$ (+) and $t < 0$ (−). Both the scaling function $Q_{\pm}$ and the power-law exponents α and Δ are universal. The former is universal only provided we allow for the system-dependent constants c_f and c_h, frequently termed the *metric factors*. The origin of this universality is discussed in the next section.

Consider now various thermodynamic functions that can be derived from the free-energy density by differentiation. To be specific, we note that for the Ising model energy, Eq. (3), the free energy is given by

$$f(T,H) = -V^{-1} \ln \Lambda, \tag{6}$$

where V is the system volume (taken to infinity in the thermodynamic limit). The partition function Λ is defined as

$$\Lambda = \prod_i \left[\sum_{s_i=-1}^{1} \exp\left(-\frac{E}{k_B T}\right)\right]; \tag{7}$$

i.e., the Boltzmann factor $\exp(-E/k_B T)$ is summed over all system configurations. Then the thermodynamic average $\langle \mathbb{O} \rangle$ of any function $\mathbb{O}$ of the microscopic variables s_i can be calculated as

$$\langle \mathbb{O} \rangle = \Lambda^{-1} \prod_i \left[\sum_{s_i=-1}^{1} \mathbb{O} \exp\left(-\frac{E}{k_B T}\right)\right]. \tag{8}$$

Thus the magnetization,

$$M = \langle s_i \rangle, \tag{9}$$

is obtained as

$$M = \frac{\partial f}{\partial h}, \tag{10}$$

and similarly the specific heat, susceptibility, etc., are obtained as various derivatives of the free energy. We note that the choice of the free energy to "generate" the thermodynamic quantities depends on the physical system and on the independent variables selected; see Privman *et al.* (1991). For instance, for magnetic systems one could also use (T,M) as independent variables. The scaling expressions can then be written in terms of powers of t and M (Privman *et al.*, 1991).

Differentiation of Eq. (5) yields the singular behavior of the magnetization,

$$M \approx c_f c_h |t|^{\beta} W_{\pm}(c_h h |t|^{-\Delta}); \tag{11}$$

here

$$W_{\pm} = Q'_{\pm} \tag{12}$$

and

$$\beta = 2 - \alpha - \Delta. \tag{13}$$

Note that the symmetry $h \leftrightarrow -h$ implies that $W_{\pm}(w)$ are odd functions of their argument w. The meaning of the scaling relations is as follows. We consider behavior in the critical region, in the limit $t \to 0$, $h \to 0$, which corresponds to the vicinity of the critical point. While both t and h must be small for the scaling relations to apply (we mention corrections to scaling briefly in Sec. 5), the scaling combination $h/|t|^{\Delta}$ can be actually of order 1. Of course, the scaling function must correspond to the generally expected behavior of the appropriate quantity, here magnetization, outside the critical region. Specifically, we expect

$$W_{\pm}(w \gtrless 0) \gtrless 0, \tag{14}$$

$$W_{+}(0) = 0, \tag{15}$$

and

$$\lim_{w \to \pm 0} W_{-}(w) \gtrless 0, \tag{16}$$

where the latter property corresponds to spontaneous magnetization for $T < T_c$.

It is clear from the above discussion that exponents of the singular behavior, termed "critical exponents," and amplitudes entering scaling relations for various quantities derivable from the free-energy density are related. Indeed, they are expressed in terms of the exponents α and Δ and the metric factors c_f and c_h as well as the values of the universal functions $Q_{\pm}$ and their derivatives. For instance, for the magnetization, susceptibility χ (given by $\partial M/\partial h$), and specific heat C (proportional to $\partial^2 f/\partial t^2$), the leading-order zero-field critical behavior in the limit $t \to 0^-$, i.e., for temperatures below the critical point, is traditionally written as

$$M \approx B(-t)^{\beta}, \tag{17}$$

$$C \approx (A'/\alpha)(-t)^{-\alpha}, \tag{18}$$

$$\chi \approx \Lambda'(-t)^{-\gamma}. \tag{19}$$

Similarly, for $t \to 0^+$ we use the notation

$$C \approx (A/\alpha)t^{-\alpha}, \tag{20}$$

$$\chi \approx \Lambda t^{-\gamma}, \tag{21}$$

while $M \equiv 0$. Relations among exponents (termed *scaling relations*) then follow, such as

$$\Delta = \beta + \gamma, \tag{22}$$

$$\alpha + 2\beta + \gamma = 2. \tag{23}$$

Furthermore, universal amplitude combinations can be identified—for instance,

$$A/A', \tag{24}$$

$$\Gamma/\Gamma', \tag{25}$$

and

$$R_C = A\Gamma/B^2. \tag{26}$$

As emphasized, scaling relations are universally applicable to large classes of systems (see the next section for further explanation, as well as CRITICAL PHENOMENA and PHASE TRANSITIONS: RENORMALIZATION AND SCALING). Specifically, the scaling laws just defined apply not only to uniaxial ferromagnets but also to the liquid–gas and binary-mixture critical points. For instance, the $h = 0$ relations (17)–(21), etc., correspond to the liquid–gas critical isochore ($t > 0$) and phase boundary ($t < 0$). Other critical-point power-law singular behavior applies, for instance, along the critical isotherm. As an example, we consider $M(0,h)$; see Privman *et al.* (1991) for other quantities. The relation between M and h at $t = 0$ is written as

$$h \approx D_c M|M|^{\delta-1}. \tag{27}$$

In order to derive such a relation, we assume that the scaling functions $W_{\pm}(w)$ in Eq. (11) both have the same leading large-w asymptotic behavior,

$$W_{\pm}(w \text{ large}) \simeq \mathcal{W}_{\infty}\, \text{sign}(w)|w|^{\beta/\Delta}, \tag{28}$$

where the power law was selected to cancel out the $|t|$ dependence in the limit $t \to 0$. From this form, the exponent relation

$$\delta = \Delta/\beta \tag{29}$$

follows. Furthermore, since $\mathcal{W}_{\infty}$ is a universal coefficient, the nonuniversal factors in D_c follow as

$$D_c \propto c_f^{-\delta} c_h^{-\delta-1}. \tag{30}$$

The appropriate universal amplitude combination can then be identified as

$$R_\chi = AD_c B^{\delta-1}. \tag{31}$$

Behavior of other quantities along the critical isotherm, and the appropriate universal amplitude combinations, were reviewed by Privman *et al.* (1991).

Finally, let us mention the scaling of the two-point order-parameter correlation function. For ferromagnets, this is the spin–spin correlation function, while for liquid–gas systems, etc., it must be defined in terms of the local (microscopic) densities. The scaling of the correlation function $\mathcal{G}(\mathbf{r},t,h)$ is usually expressed in terms of its spatial Fourier transform $\hat{\mathcal{G}}(\mathbf{q},t,h)$ as follows:

$$\hat{\mathcal{G}} \approx c_{\mathcal{G}}|\mathbf{q}|^{-(2-\eta)}U(c_h h|t|^{-\Delta}, c_\xi|\mathbf{q}||t|^{-\nu}). \tag{32}$$

Note that new exponents were introduced as well as new metric factors. However, since the susceptibility can be obtained as the spatial integral of the correlation function (i.e., the $\mathbf{q} = 0$ value of its Fourier transform), two of the exponents and two of the amplitudes entering relation (32) are not independent (we already used the same Δ and c_h to simplify the notation). Specifically, we have the relation

$$2 - \eta = \gamma/\nu; \tag{33}$$

and, up to universal factors, $c_{\mathcal{G}}$ can be replaced by $c_f c_h^2 c_\xi^{-(\eta-2)}$.

The critical-point $\mathbf{q}$ dependence is frequently written as

$$\hat{\mathcal{G}}(\mathbf{q}, t = 0, h = 0) \approx D_\infty/|\mathbf{q}|^{2-\eta}. \tag{34}$$

Much attention has been paid to the quantity that scales the "inner" $\mathbf{q}$ dependence in relation (32), termed the *correlation length*, ξ. Actually, various correlation lengths can be identified, defined via the asymptotic fall-off of the correlation function with distance or via various spatial moments of its $\mathbf{r}$ dependence. The zero-field critical behavior is of the form

$$\xi = \xi_0 t^{-\nu} \quad (t > 0), \tag{35}$$

and

$$\xi = \xi_0'(-t)^{-\nu} \quad (t < 0), \tag{36}$$

with the obvious generalization to a scaling form for $h \neq 0$. Actually, for models with continuous symmetry of the order parameter, such as the O(N)-symmetric spin models with $N \geq 2$, the longitudinal and transverse correlation lengths must be identified separately for $t < 0$ (see Privman *et al.*, 1991).

Since $D_\infty \propto c_{\mathcal{G}}$ up to universal factors, while ξ_0 and ξ_0' are both proportional to c_ξ, these coefficients can be used to form universal amplitude combinations—for instance,

$$\xi_0/\xi_0' \tag{37}$$

and

$$Q_3 = D_\infty \xi_0^{2-\eta}/\Gamma. \tag{38}$$

However, a more direct relation between the "correlation" and "thermodynamic" amplitudes requires concepts of hyperscaling and hyperuniversality, discussed in the next section.

3. RENORMALIZATION, TWO-SCALE-FACTOR UNIVERSALITY, AND FINITE-SIZE SCALING

Universality in critical phenomena is described by the renormalization-group theory (Domb and Green, 1976; Phase Transitions: Renormalization and Scaling). Review of the renormalization-group theory is outside the scope of this article; see Critical Phenomena and Phase Transitions: Renormalization and Scaling. The renormalization-group transformations relate a system with correlations on the scale ξ to another system with correlations on the scale ξ/b, where $b > 1$.

This is accomplished by mapping the parameter space of "coupling constants" in a general-model Hamiltonian onto itself, while "integrating away" fluctuations on the shortest microscopic length scales. As a result, a modified, "coarse-grained" Hamiltonian is obtained with all the length scales, including the correlation length, scaled by b^{-1}, so that the new "microscopic" unit of resolution of fluctuations is of size b^D in terms of the original-model smallest resolution dimensions.

For $b \to \infty$, the critical point "flows" into a fixed point with $\xi = \infty$. Various systems are represented as special cases of the same general, all-encompassing model, with different initial parameters. The critical points of all models with the same universal properties, i.e., in the same universality class, are in the domain of attraction of the same fixed point of the renormalization-group transformation. The universality of critical exponents is obtained as the property of the renormalization-group flows linearized near the fixed point. The universality of scaling functions and various amplitude combinations is more subtle. It relates to the flow near the unstable manifold, i.e., that portion of the parameter space that is transformed away from the fixed point by the renormalization-group transformations.

The parameters of a given system are related to the parameters of the general model transformed by the renormalization group, in a complicated fashion. However, near criticality, a linear approximation is appropriate. For ordinary continuous phase transitions, such as the uniaxial ferromagnet transition that we use as a prototype, there are two directions in the parameter space that correspond to deviations from criticality. These are called the *relevant* renormalization-group fields: For a ferromagnet, they are proportional to t and h near the critical point. This implies that there are two independent metric factors for both thermodynamic and correlation properties. This result is termed two-scale-factor universality or *hyperuniversality*. It turns out that the metric-factor relation corresponds to the following: The combination $c_f c_\xi^D$ is universal, where D is the dimensionality of space. This is related to the observation that the free-energy density transforms like (length)$^{-D}$, while ξ transforms as length. A more widely used form is the universal (or rather hyperuniversal) amplitude combination

$$R_\xi^+ = A^{1/D}\xi_0. \tag{39}$$

The appropriate universal exponent relations, termed hyperscaling relations, also follow—for instance,

$$2 - \alpha = D\nu. \tag{40}$$

A physically interesting interpretation of the hyperscaling/hyperuniversality relations (39)–(40) is to consider the free energy of the large-scale fluctuations that presumably contribute the singular part of the total free energy. The free energy of such fluctuations in a volume ξ^D, when expressed as a dimensionless number (by measuring it per k_BT), is $\xi^D f_{\text{sing}}$. The metric factors entering this combination are $c_\xi^D c_f$, and so the hyperuniversality corresponds to the statement that the free energy of "singular" fluctuations in the volume defined by the correlation length is a universal multiple of k_BT. The underlying physical mechanism for this universality is the assertion that the correlation length is the only "macroscopic" length scale remaining after the microscopic fluctuations were excluded or "renormalized away" in the sense of being lumped into the metric factors.

It is important to note that these observations do not apply within the mean-field or effective-field theory of critical behavior (Stanley, 1971). The reason is that certain dependences on the microscopic parameters enter the mean-field singular behavior nontrivially. This relates to the fact that mean-field theories single out the uniform order-parameter fluctuations rather than all the large-scale fluctuations; see Stanley (1971). Thus the mean-field "law of corresponding states" (see EQUATIONS OF STATE) is a dimensional-analysis type rather than a scaling result.

For a finite-size system of linear dimension L, with its interaction parameters at their critical-point values ($t = 0, h = 0$), the total free energy (per k_BT) in the actual system volume $\propto L^D$ is universal (Privman, 1990). One can show that the appropriate scaling law takes the form

$$f_{\text{sing}} \approx L^{-D} Y(a_t t L^{1/\nu}, a_h h L^{\Delta/\nu}). \tag{41}$$

This entails a universal finite-size amplitude,

$$Y(0,0) = \lim_{L\to\infty} f_{\text{sing}}(t = 0, h = 0) L^D. \tag{42}$$

Similarly, the ratio of two macroscopic lengths,

$$X(0,0) = \lim_{L\to\infty} \xi(t = 0, h = 0)/L, \tag{43}$$

is universal, where the scaling relation for the correlation length takes the form

$$\xi \approx LX(a_t t L^{1/\nu}, a_h h L^{\Delta/\omega}). \tag{44}$$

Several comments are in order. First, we note that finite-size scaling relations (41)–(44) apply in the limit $t \to 0$, $h \to 0$, $L \to \infty$, with the appropriate scaling combinations kept of order 1. The last of these limits assumes fixed system shape, and in fact the universal scaling functions depend on the shape. Second, the "singular" subscript in the free energy refers to the bulk limit of $L \to \infty$ with fixed (small) t and h. For a fully finite system, the thermodynamic functions are of course not singular. Finite-size scaling relations also apply to systems such as "slabs" infinite in two dimensions and finite in one, or "strips" in $D = 2$ infinite in one dimension and finite in another; see Privman (1990) for details. The "bulk" limit $L \to \infty$ corresponds to the large-argument behavior of $Y(\lambda,\zeta)$ as a function of its arguments λ and ζ,

$$Y(\lambda \text{ large}, \zeta \text{ large}) \simeq |\lambda|^{D\nu} Q_\pm(\zeta |\lambda|^{-\Delta}), \tag{45}$$

where ± corresponds to the limits $\lambda \to \pm\infty$. To identify fully the bulk critical behavior (5), the hyperscaling relation (40) is needed, and we also obtain metric-factor relations

$$c_f = a_t^{D\nu} \tag{46}$$

and

$$c_h = a_h a_t^{-\Delta} \tag{47}$$

(we assume that all the metric factors are positive).

Our final comment on the finite-size scaling relations (41)–(44) is that they apply only to systems with periodic, helical, or other boundary conditions such that each microscopic system part is essentially in the "bulk." For more realistic boundary conditions, there will be surface, edge, and corner contributions to the free-energy density and other quantities. Their interplay with the leading scaling expressions such as (41) may be nontrivial. For instance, for short-range boundary-interaction models, the corner term in the free energy leads to an added universal term with a logarithmic size dependence; see Privman (1990) for details.

4. CROSSOVER SCALING AND RELATED TOPICS

Scaling forms appropriate for multicritical points, at which lines of phase transitions meet, are termed *crossover scaling*. Typically, additional relevant renormalization-group fields are needed to describe behavior near multicritical points such as bicritical, tricritical, tetracritical, etc. (Fisher, 1974; Aharony, 1983; Knobler and Scott, 1984).

As an illustration, we consider crossover scaling at tricritical points. A tricritical point can be found in the Ising model (3) when additional interactions are present that compete with the ferromagnetic nearest-neighbor interactions. For actual examples of systems with tricritical points, see Lawrie and Sarbach (1984), and Knobler and Scott (1984). The generic phase diagram is illustrated in Fig. 4. Here G denotes the added-interaction coupling constant. The lines of second-order and first-order transitions meet at the tricritical point (Fig. 4).

In addition to the temperature-like relevant scaling field t measuring deviations from the tricritical point at (T_t,G_t) "perpendicular" to the phase-transition lines, there is also the second relevant field, g, "along" the lines of phase transition. These variables are linear combinations of the deviations $(T - T_t)/T_t$ and $(G - G_t)/G_t$. With an applied field, not considered here, the phase-transition structure near the tricritical point is even richer (Lawrie and Sarbach, 1984).

The crossover scaling description for the magnetization corresponds to replacing (17) with the scaling form

$$M \approx B_t(-t)^{\beta_t}\mathcal{X}(c_g g(-t)^{-\phi}), \tag{48}$$

where ϕ is termed the crossover exponent. If $T(G)$ denotes the temperature of the transition line, then at fixed G, $M \equiv 0$ for $T > T(G)$. For other quantities, two scaling functions (labeled ± as before) are needed. The phase-transition behavior near (T_t,G_t) is "hidden" in the universal scaling function $\mathcal{X}$.

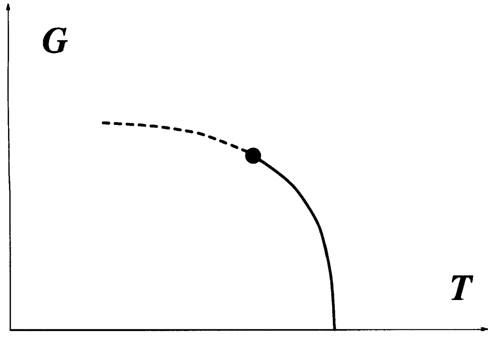

FIG. 4. Schematic illustration of the tricritical point (marked by heavy dot) and the lines of second-order (solid line) and first-order (dashed line) phase transitions, in the plane of temperature and added coupling constant, G; see text.

It is best to explain this by example. Let us consider the case of the mean-field theory. With the appropriate choice of the metric factors B_t and c_g, the mean-field expression for the scaling function is

$$\mathcal{X}(\omega) = \sqrt{\omega + \sqrt{\omega^2 + 3}}, \tag{49}$$

where we use the convention that $g > 0$ [$\omega = g(-t)^{-1/2} > 0$] in the direction of the first-order transition line, i.e., for $G > G_t$ in the notation of Fig. 4. Note that

$$\beta_t = \tfrac{1}{4} \text{ and } \phi = \tfrac{1}{2} \tag{50}$$

in the mean-field theory.

The form of the relation (49) for $g < 0$ corresponds to the vanishing magnetization at the phase-transition line in the limit $t \to 0^-$, i.e., to the continuous (second-order) phase transition. For small fixed $g < 0$, the exponent β equals $\frac{1}{2}$ since the scaling function behaves as

$$\mathcal{X} \propto (-\omega)^{-1/2} \text{ as } \omega \to -\infty. \tag{51}$$

The magnetization, therefore, vanishes as

$$M \propto (-t)^{1/4}[(-t)^{-1/2}]^{-1/2} = (-t)^{1/2}. \tag{52}$$

However, for small fixed $g > 0$, i.e., in the limit $\omega \to +\infty$, the magnetization remains finite, of order $\sqrt{g}$, corresponding to a discontinuous jump to zero at the phase transition line, as expected for a first-order transition.

Universal amplitude combinations at multicritical points were reviewed by Privman *et al.* (1991). Scaling for dynamics (Hohenberg and Halperin, 1977; Privman *et al.*, 1991), as well as for certain surface-interaction couplings in systems that are not infinite in all dimensions (Diehl, 1986), also involves new scaling combinations. Typically, there is a new exponent and a new nonuniversal amplitude (metric factor) for each added scaling variable. For instance, for dynamics, the large-time slow-relaxation modes near the critical point have their time scales (termed the relaxation times) scaled by

$$\xi^z \propto |t|^{-z\nu}, \tag{53}$$

where z is the new, dynamic critical exponent.

5. NUMERICAL AND ANALYTICAL METHODS AND SELECTED RESULTS

In this section we survey different techniques used to calculate universal exponents and amplitude combinations. Our aim is to enumerate the methods and provide literature citation; we avoid discussion of any details. However, we do comment on their relative advantages and limitations. Selected results are then given.

We first comment on two general principles that yield information mostly in two dimensions (2D), namely, conformal invariance (also termed conformal field theory) and duality. Conformal invariance (Cardy, 1987; Christe and Henkel, 1993) provides exact values of the 2D critical exponents and universal finite-size amplitudes, for a wide variety of universality classes. Certain conclusions regarding bulk amplitudes are also possible. The property of duality or self-duality relating quantities for $T > T_c$ to those for $T < T_c$ holds for many lattice models in two dimensions—e.g., Potts models (Wu, 1982) or percolation (Deutscher *et al.*, 1983). For example, we have the universal ratio

$$A/A' = 1, \tag{54}$$

due to duality, for the square-lattice q-state Potts models (Baxter, 1982; Wu, 1982), which have second-order phase transition for $0 \leq q \leq 4$. By universality, this result applies to all models in the appropriate universality classes. Note that $q = 2$ corresponds to the Ising model, while the limit $q \to 1$ can be interpreted to yield results for percolation.

Some models are exactly solvable. They yield important sources of universal values for approximate description of more realistic systems and for theoretical developments. These include the mean-field approach (infinite-range interactions; effectively, infinite dimensionality; see Stanley, 1971), and the spherical models (Joyce, 1972) solvable in general dimension. Ising and certain other lattice models have been solved in two dimensions (McCoy and Wu, 1973; Baxter, 1982). There are also several exact results for fractal and hierarchical lattices; see FRACTAL GEOMETRY.

Series expansions (Domb and Green, 1974; Guttmann, 1989; Baker, 1990) have traditionally yielded accurate information on the critical behavior. Expansions about the disordered state—the high-temperature series—are available to large orders for many lattice models. Low-temperature series (expansions about ordered states) are frequently more difficult to derive to high orders. Elaborate analysis methods have been devised for series expansions to evaluate behavior at "ordinary" critical-point singularities, including effects of corrections to scaling, etc. However, in mapping out phase diagrams that contain multicritical points, only limited results are available and the field is wide open to introduction of new, reliable analysis techniques.

Other numerical methods are based on finite-size scaling and related extrapolation techniques. They include the Monte-Carlo (Binder and Heermann, 1988; Privman, 1990; MONTE-CARLO METHODS) and transfer-matrix (Nightingale, 1982; Privman, 1990) approaches. The Monte-Carlo computer simulation method can be applied to nearly any equilibrium model, and, with stochastic evolution rules, also to dynamics. It is more versatile than other approaches, and it has become the method of choice with the advent of powerful modern computers. On account of computational difficulties, the transfer-matrix approach, in which the system is built up as a finite–cross-section "cylinder" from narrow slices, has been used extensively only in two dimensions.

Techniques based on the renormalization-group approach include ϵ expansions (Domb and Green, 1976), i.e., expansions in the deviation of the dimensionality of space from its "upper critical" value above which mean-field behavior applies. Expansions about the spherical-model limit, which corresponds to an infinite number of spin components, also can be cast in the renormalization-group form (Ma, 1973). Field-theoretical renormalization-group calculations directly in three dimensions (Domb and Green, 1976; Privman *et al.*, 1991), and certain other approximation schemes, also fall in this group. All renormalization-group methods yield qualitative results for the phase diagram, such as type of multicriticality, universality class, etc. Only for a few main universality classes (such as the three-dimensional Ising) have the renormalization-group calculations been carried out to high enough orders and analyzed in sufficient detail to yield quantitatively accurate results for universal exponents and amplitudes. However, as already mentioned, the renormalization-group methods are invaluable in deriving qualitatively the "global" properties, including various scaling relations, limiting properties and general behavior of universal scaling functions, etc.

In Table 1 we list selected results for universal exponents of the Ising universality class in two and three dimensions, as well as certain mean-field results. We list theoretical values of several universal quantities; for further results see Domb and Green (1976), Baker (1990), Privman (1990), and Privman *et al.* (1991). We note that all the nonexact results presented (mostly in three dimensions) are typical ranges obtained by combining results of several theoretical methods discussed above. Two universal quantities shown at the end of the table are defined in Sec. 6. Some mean-field entries are left blank because of unavailability of an estimate, inapplicability of hyperscaling above the upper critical dimension, which is $D = 4$ for the Ising universality class, or inapplicability of the amplitude definition. Specifically, $\alpha = 0$ in mean-field theory corresponds to a discontinuous jump in the specific heat, so that the ordinary definition of A/A' does not apply. Similarly, the $\alpha = 0$ value for $D = 2$ actually corresponds to a symmetric logarithmic divergence, represented nominally by the $A/A' = 1$ entry, although the amplitudes must be appropriately redefined. The finite-size results are for cubic (square in 2D) shapes with periodic boundary conditions; see Privman (1990) and Privman *et al.* (1991) for other results for different system shapes and boundary conditions.

Table 1. Selected universal exponents, amplitudes, and amplitude ratios of the Ising universality class in two dimensions (2D), three dimensions (3D), and the mean-field regime ($D > 4$).

	2D	3D	$D > 4$
α	0(log)	0.11 ± 0.01	0
β	$\frac{1}{8}$	0.325 ± 0.006	$\frac{1}{2}$
γ	$\frac{7}{4}$	1.241 ± 0.004	1
ν	1	0.630 ± 0.002	$\frac{1}{2}$
A/A'	1	0.53 ± 0.02	
Γ/Γ'	37.69 ...	4.9 ± 0.2	2
R_C	0.318 5699 ...	0.057–0.066	
R_χ	6.78 ± 0.01	1.7 ± 0.1	1
ξ_0/ξ'_0	2	1.91–1.98	$\sqrt{2}$
Q_3	0.291 ...	0.90–0.92	1
R_ξ^+	$1/\sqrt{2\pi} = 0.3989$ ...	0.27 ± 0.01	
$Y(0,0)$	-0.6399...	-0.64 ± 0.04	
g_*	14.66 ± 0.06	28.85 ± 0.02	
g_∞	1.83 ± 0.01	1.3–1.4	0.8–1.0

While Table 1 illustrates variation with dimensionality, Table 2 illustrates variation with the universality class. Thus, selected universal values are given for O(N)-symmetric order-parameter models in $D = 3$. The Ising model has uniaxial symmetry (scalar order parameter), $N = 1$. The $N = 2$, plane-vector–symmetry, *XY*-model results are also given, as are the results for the $N = 3$, Heisenberg spin models. These values are also compared with expressions from the exact solution of the spherical model, which, up to certain N-dependent factors, corresponds to the limit $N \to \infty$. Exponent values for $N = 0$, which formally map onto a polymer problem (to be discussed in Sec. 6), are also included in Table 2. For further theoretical results and tabulations for these and many other models in different universality classes, notably, Potts models, percolation, and various

Table 2. Selected universal exponents and amplitude ratios of the three-dimensional Ising ($N = 1$), *XY* ($N = 2$), Heisenberg ($N = 3$), and spherical-model ($N = \infty$) universality classes. All the values for $N < \infty$ are approximate. The results for $N = \infty$ are exact. Exponent values shown for $N = 0$ correspond to the polymer-conformation universality class.

	$N = 1$	$N = 2$	$N = 3$	$N \to \infty$	$N = 0$
ν	0.63	0.67	0.71	1	0.59

multicritical points, see Fisher (1974), Domb and Green (1976), Wu (1982), Baker (1990), Privman (1990), Privman *et al.* (1991), as well as CRITICAL PHENOMENA and PHASE TRANSITIONS: RENORMALIZATION AND SCALING.

We note that most of the two- and three-dimensional results summarized in Table 1 have been tested experimentally, some exponents quite accurately and other values, especially amplitude ratios, semiquantitatively. The $N = 2$ and $N = 3$ values (Table 2) were tested accurately for some exponents and semiquantitatively for most other exponent and amplitude values. The experimental status of tests of universality in critical phenomena is generally quite satisfactory, especially for the most familiar universality classes such as Ising models, percolation, etc.; see Privman *et al.* (1991) for a comprehensive review.

6. POLYMERS, PERCOLATION, CHEMICAL REACTIONS, MISCELLANEOUS RESULTS

In this section we address several additional topics of interest in universality of various exponents, amplitudes, and amplitude ratios. First, let us define the "renormalized coupling constant" amplitude combination g_*, encountered in Table 1. We consider the leading nonlinear susceptibility,

$$\chi^{(\mathrm{nl})} = \frac{\partial^3 M}{\partial h^3}, \tag{55}$$

with the $h = 0$, $t > 0$ amplitude defined by

$$\chi^{(\mathrm{nl})} \approx \Gamma^{(\mathrm{nl})} t^{-2\beta-3\gamma}. \tag{56}$$

We then introduce the amplitude ratio

$$g_* = -\Gamma^{(\mathrm{nl})} / \xi_0^D \Gamma^2. \tag{57}$$

This quantity has received attention in the literature because its universality is a hyperuniversal property relatively easy to probe by various numerical methods. Furthermore, there exists a finite-size counterpart of this quantity, also encountered in Table 1, defined for a finite-size system of linear dimension L, at $h = 0$, $t = 0$, via

$$g_\infty = \lim_{L\to\infty} [-\chi^{(\mathrm{nl})} / L^D \chi^2]. \tag{58}$$

For further discussion and results for these quantities, see Privman (1990) and Privman *et al.* (1991).

Phase separation in polymer mixtures belongs to the Ising universality class. The length of the chains, i.e., the polymerization index $\mathcal{N}$, is a nonuniversal "microscopic" parameter. The $\mathcal{N}$ dependence must therefore cancel out in universal quantities. The $\mathcal{N}$ dependence of various amplitudes has been considered in the literature. There has been certain controversy over the precise form of this dependence and over experimental verification of the theoretical predictions; see Privman *et al.* (1991) for details.

Scaling for first-order phase transitions is different from that for critical points (second-order transitions) in several aspects. The only large-scale fluctuations are those associated with coexistence of phases (see PHASE EQUILIBRIA; PHASE SEPARATION). These lead to no power-law singularities at the Ising (scalar order parameter) transitions (although there is a weak "essential" singularity associated with droplet excitations). However, for continuous symmetries, such as the O(N)-symmetric spin models with $N \geq 2$, there are the soft-mode spin-wave "Goldstone boson" singularities present at the phase transition point. Finite-size scaling introduces a new length (system size). For finite-size systems, scaling forms involving the system size have been identified, and universal scaling functions were calculated exactly; see Privman (1990).

"Geometrical" critical phenomena include fractals, polymer conformations, percolation models, etc.; see FRACTAL GEOMETRY. In some instances there exist direct connections between these geometrical-criticality models and spin-system phase transitions. Specifically, let us consider polymer conformations in the fixed-fugacity ensemble, i.e., statistical averages over the configurations of $\mathcal{N}$-step chains (random walks with or without self-avoidance constraints) with statistical weight $y^{\mathcal{N}}$. Here y is the fugacity per step. The random-walk statistics can be mapped onto the $N \to 0$ limit of the O(N)-symmetric spin model (de Gennes, 1979), critical-point amplitudes and exponents defined, and their universality studied. We list $N = 0$ exponent estimates in Table 2.

Similarly, for the percolation model, defined by averaging over connected clusters of sites or bonds with the appropriately defined weights (Deutscher *et al.*, 1983), universal exponents and amplitudes can be defined in the "phase-transition" nomenclature; see Deutscher *et al.* (1983) or Privman *et al.* (1991) for tabulations of results. Furthermore, the percolation model can be mapped onto the q-state Potts model in the limit $q \to 1$. Another geometrical model where the phase-transition type universal quantities were extensively studied is the lattice-animal statistics, which corresponds to averaging over connected clusters by the site- or bond-content fugacity only (while in the percolation model there is a statistical weight "cost" of the reduced connectivity at the cluster boundary).

All three models—polymers (walks), percolation, lattice animals—have been studied in detail for their universal-exponent values. However, universal amplitude combinations have attracted less interest. Detailed results are available only for the percolation model; see Deutscher *et al.* (1983) and Privman *et al.* (1991). Instead, attention has been devoted to the universality of various cluster shape and size ratios. The shape and size of $\mathcal{N}$-element clusters is characterized by D-dimensional tensors such as the moment-of-inertia tensor or the squared-radius-of-gyration tensor. Let us consider the latter object. For an $\mathcal{N}$-site (or -bond) cluster, the (i,j) element of this tensor is defined by

$$\frac{1}{2\mathcal{N}^2}\sum_{k=1}^{\mathcal{N}}\sum_{m=1}^{\mathcal{N}}(r_k^{(i)} - r_m^{(i)})(r_k^{(j)} - r_m^{(j)}), \qquad (59)$$

where $r_n^{(p)}$ is the pth component of the coordinate vector $\mathbf{r}_n$ of the nth cluster site (bond). Universal shape measures can be defined by forming ratios of, and statistically averaging, various size measures derived from the radius-of-gyration tensor. The averaging in this case is over cluster shapes only, with fixed number of elements $\mathcal{N}$.

Consider, for instance, the most familiar of the cluster-size measures, the squared radius of gyration $R_{\mathcal{N}}^2$, which is obtained by averaging the trace of the tensor (59) over all the fixed-$\mathcal{N}$ cluster geometries, with the appropriate statistical weights. One can then identify the amplitude of the large-$\mathcal{N}$ asymptotic form,

$$R_{\mathcal{N}}^2 \approx \rho_G \mathcal{N}^{2\nu}, \qquad (60)$$

where ν is the familiar universal correlation-length exponent. The amplitude ρ_G is not universal. However, it can be used to form universal ratios involving other size-measure amplitudes. For instance, for self-avoiding random walks, one can define a similar amplitude of the squared averaged end-to-end distance, ρ_E. The ratio

$$\rho_E/\rho_G \qquad (61)$$

is universal; its values are 1, $\simeq$7.1, and $\simeq$6.4 in one, two, and three dimensions, respectively. Tabulation of several other universal amplitude ratios can be found in Privman *et al.* (1991).

As mentioned already in Sec. 3, scaling for dynamics in systems that reach equilibrium is reminiscent of the crossover scaling in that a new scaling combination involving the dynamic critical exponent enters (Hohenberg and Halperin, 1977; Privman *et al.*, 1991). There are, however, systems with irreversible dynamics, such as chemical reactions, certain deposition-with-relaxation models, and cluster growth and nucleation models, in which power laws with universal exponents and, in some instances, universal amplitudes, have been found (Privman, 1994). Specifically, we consider reaction–diffusion systems in low dimensions (Privman, 1997), which have been investigated extensively recently with emphasis on fluctuation-dominated effects leading to the breakdown of the standard chemical rate equations that correspond to the "mean-field" approximation of the reaction kinetics (see CATALYSIS; CHEMICAL REACTIONS).

As an illustration, we consider the simplest reactions of two-particle coagulation,

$$\mathcal{A} + \mathcal{A} \to \mathcal{A}, \qquad (62)$$

and annihilation,

$$\mathcal{A} + \mathcal{A} \to \text{inert}. \qquad (63)$$

The mean-field rate equations predict that the particle density decreases proportionally to $1/\mathcal{T}$, where $\mathcal{T}$ denotes the time. This large-time result gives the mean-field exponent 1 of the time dependence. It turns out that in dimensions below the upper critical dimension for these reactions, $D = 2$, an effect of fluctuations is to change the power law. For instance, in $D = 1$, the density is proportional to $u/\mathcal{T}^{1/2}$, where by the appropriate definition of dimensionless quantities, the amplitude u can be made universal (for each type of model). For heterospecies reactions such as

$$\mathcal{A} + \mathcal{B} \rightarrow \text{inert}, \tag{64}$$

with equal initial concentrations of both diffusing species, the density decreases according to a power law with the universal exponent $\frac{1}{4}$ in $D = 1$. The upper critical dimension for the heterospecies reactions turns out to be $D = 4$.

Finally, let us consider briefly corrections to scaling. Renormalization-group theory predicts that typically the leading power-law singularity will be accompanied by weaker, subleading singularities, and also by analytic corrections to scaling. Specifically, the ratio of the full quantity $\Phi(t)$ to its leading singular behavior, $\Psi t^{-\psi}$, has the following form for small t:

$$\Phi(t)/[\Psi t^{-\psi}] \approx 1 + \tau t^{\theta} + \sigma t + \dots . \tag{65}$$

The amplitudes of the first subleading correction-to-scaling terms in different physical quantities can be used to form certain universal ratios. The latter have been calculated theoretically and some measured experimentally (Privman *et al.*, 1991). The power-law exponent $\theta > 0$ is universal, and, unlike the leading exponent ψ or the amplitudes τ and σ, it is the same for various thermodynamic and correlation quantities as long as their t dependence is considered, where for simplicity we took $h = 0$ and $t > 0$ in writing (65). Amplitudes of the leading analytic corrections to scaling, σ, satisfy certain universal sum rules; details of all these developments are not discussed here; see Privman *et al.* (1991).

In summary, we have reviewed the concept of universality in modern physics and its applications to behavior of systems that in their "critical" range of parameters are dominated by large-scale spatial or temporal fluctuations.

GLOSSARY

Corrections to Scaling: Singular behavior subleading to the main singularities at critical points.

Correlation Length: Linear size of the region of correlated fluctuations in a thermodynamic system.

Critical Exponents: Power-law exponents of the singular behavior at critical points, as well as exponents of powers entering scaling combinations that in turn serve as arguments of scaling functions.

Critical Point: A point in the space of thermodynamic parameters at which the thermodynamic system develops anomalous fluctuations.

Critical Region: Vicinity of the critical point. See CRITICAL PHENOMENA.

Crossover Scaling: Scaling relations involving scaling variables other than the "basic" ones: temperature, applied field, system size. This term is sometimes reserved for those scaling relations in which the scaling function itself contains singularities corresponding to a crossover to phase transitions along lines ending at the point near which the scaling relation applies.

Heisenberg Model: Model of systems with the three-component, continuous-symmetry order parameter, such as the isotropic-symmetry magnets (see MAGNETIC ORDERING IN SOLIDS).

Hyperscaling: Relations between thermodynamic and correlation critical exponents that involve the dimensionality of space and are associated with the property of hyperuniversality (or two–scale-factor universality).

Hyperuniversality: Relation between free-energy and correlation amplitudes implying that the thermodynamic and correlation quantities have the same metric factors entering their scaling relations. See the related concept of **Two–Scale-Factor Universality.**

Ising Model: Lattice model of ±1 (or "up-down") spin variables.

Lattice-Animal Model: Statistics of connected clusters.

Metric Factors: Nonuniversal parameters relating the physical "deviation from criticality" variables to the scaling fields of the renormalization-group transformation. Metric factors are introduced in scaling relations in order to make the scaling functions universal.

Multicritical Points: "Critical" phase-transition points at which several lines of first-order and second-order transitions meet.

Percolation: Model of connectivity (conductivity) in a disordered medium, defined by considering connected (conducting) clusters. For lattice models, these clusters may be defined, for instance, as groups of connected bonds or sites.

Potts Model: Lattice model of scalar, q-value spins with interaction that favors spin "alignment" in the sense of adjacent spins having the same value out of the q possible. For $q = 2$ the Ising model is obtained.

Renormalization Group: Theory relating systems with fluctuations on different length scales; see PHASE TRANSITIONS: RENORMALIZATION AND SCALING.

Scaling: Reduction of the number of independent variables, achieved typically by separating "macroscopic" spatial and temporal scales from "microscopic" scales.

Tricritical Point: Point at which lines of first-order and second-order transitions meet.

Two-Scale-Factor Universality: Conclusion that a single metric factor is needed for each scaling variable, the same in thermodynamic and correlation quantities. See the related concept of **Hyperuniversality.**

Universality: Application of the same laws and relations, notably dimensional analysis and scaling, to different physical systems.

Universality Class: Different physical systems with similar singular behavior of thermodynamic and correlation quantities at their critical points.

***XY* Model:** Model of systems with a two-component, continuous-symmetry order parameter, including the plane-symmetry magnets (see MAGNETIC ORDERING IN SOLIDS), superfluids (SUPERFLUIDITY: LIQUID-HELIUM SYSTEMS), and superconductivity (SUPERCONDUCTIVITY, LOW-TEMPERATURE).

INTRODUCTION

Every culture, from the ancient tale spinners of the Indus Valley to the modern technocrats of the Silicon Valley, has held its own unique view of the cosmos. Astronomy, the oldest science mainly based on observation, cannot be separated from physical law and mathematics. Big advances in space science and technology in this century have al-

lowed astronomers to look both deeper into space and farther back in time, thereby discovering a close connection between particle physics and cosmology. The study of the creation, evolution, and structure of the universe has become a legitimate subject for astronomers, physicists, and mathematicians.

This article presents an outline of the current knowledge about the structure—more precisely the structural elements—of the universe from the point of view of the standard "big-bang" model (dubbed macrocosmos) and the standard model of fundamental particles (dubbed microcosmos). In this regard an important point has to be made that the article does not consider the time-dependent phenomena that ought to characterize the evolution of the universe but is focused on the structural elements of the universe as discovered by observation at the present stage of the evolution of the universe. One can ask the question, How is it possible to understand the universe on the basis of its structural elements? The ancient atomic philosophers may have answered: This objection is similar to that of someone saying, How can the entire poem of Homer, the *Iliad*, be composed of only 24 letters, those 24 letters of the Greek alphabet? Hidden in that thought is that the richness of the poem is not compromised by the fact that a method exists to trace it back ultimately to a few, very elementary and simple elements, such as the formal contents of the Greek language—to the 24 characters that are being referred to as the Greek alphabet. However, the degree of the current understanding of the structural elements of the universe (compared with the 24 letters of the Greek alphabet) reveals the fact that the scientific establishment is still far from understanding the beauty of the structure and evolution of the universe as a whole (compared with the *Iliad*).

The article is divided into six parts. The first three parts recount the development of macrophysical and microphysical knowledge from prehistory to the present. Part four is devoted to the elements of the standard model of fundamental interactions, namely, the leptons, quarks, and gauge bosons. The fifth part discusses the structural elements of the universe, from the large-scale structure down to the stars. Finally, the sixth part emphasizes the importance of mathematics for the physics and astronomy of the structure of the universe.

1. STRUCTURE OF THE ANCIENT UNIVERSE

1.1 Prehistoric Astronomy

From half a millennium before 4000 B.C., long barrows—elongated burial mounds of earth—were arranged so as to be aligned on the rising and setting of bright stars. In the middle of the third millennium, this technique was transferred to circular grave architecture, the so-called round barrows, and in this form it lasted for well over a thousand years. Why this particular phase in prehistorical astronomical activity is so important is that it testifies to the marriage of astronomy with geometry. There is clear evidence that the Sun and the Moon were observed. Stonehenge, shown in Plate 1, is the most famous prehistoric megalith (standing-stone monument) in Europe and lies north of Salisbury, England. Stonehenge had an exceptionally long history of use as a religious center and is also believed to have functioned as an astronomical observatory.

1.2 Egypt

Some concern with astronomy had already been shown in a cosmology associated with the rulers Seti I (r.c. 1318–c. 1304 B.C.) and Ramses IV (r.c. 1166–c. 1160 B.C.). The Egyptians had by then long been adept at measuring time and designing calendars, using simple astronomical techniques. They too aligned their buildings on the heavens. Some early Egyptian sources speak of a cult relating the Sun god Re (represented in art with a man's body and a falcon's head surmounted by a solar disk) and an earlier creator god Atum. The cult of Re-Atum was well established by the time of the first great pyramids, that is, about 2800 B.C. At first this was centered mainly on a temple to the north of the old Egyptian capital of Memphis. The place was known by the Greeks as Heliopolis, "City of the Sun," but by the Egyptians as On (located northeast of Cairo, Egypt). By historical times, the priests of Heliopolis had laid down a cosmogony that held Re-Atum to have generated himself out of Nun, the primordial ocean. His offspring were the gods of air and moisture, and only after them, and as their offspring, were Geb, the Earth god, and Nut, the sky goddess, created. The deities of Heliopolis (the Great Ennead) were made up with Osiris, Seth, Isis, and Nephthys, the offspring of Geb and Nut.

1.3 Mesopotamia

In the dynasty of Hammurabi (r.c. 1792–c. 1750 B.C.) in Babylonia, not all gods can be identified with stars. The three highest—Anu, Enlil, and Ea—corresponded to the heavens, Earth, and water.

1.4 India and Persia

The oldest of the Vedic writings in Hinduism, the Rigveda (dating from between 1500 and 500 B.C.), gives more than one account of the creation of the world (Fig. 1). The main version is that the world was made by the gods, as a building of wood, with heaven and Earth somehow supported by posts. Later it is suggested that the world was created from the body of a primeval giant. This last idea gave rise to the principle, found in later Vedic literature, that the world is inhabited by a world soul. Various other cosmogonies followed, with the creation of the ocean sometimes being given precedence, and place being made for the creation of the Sun and the Moon. There is a certain circularity in it all, however, since heaven and Earth are generally regarded as the parents of the gods in general, and water was sometimes introduced into the parentage. The Vedic literature gives no clear indication that mathematical techniques for describing the motions of heavenly bodies were discussed in India before the 5th century B.C.

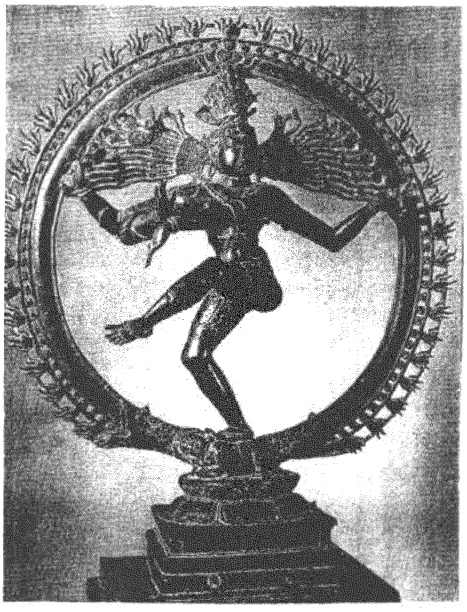

FIG. 1. Shiva is one of the two principal Hindu gods (the other being Vishnu), his most celebrated appearance being the one as Nataraja, the King of Dancers. Indian artists have represented Shiva's cosmic dance in magnificent bronze sculptures of dancing figures with four arms whose superbly balanced and yet dynamic gestures express the rhythm and unity of life. The upper right hand of the god holds a drum to symbolize the primeval sound of creation, the upper left bears a tongue of flame, the element of destruction. The balance of the two hands represents the dynamic balance of creation and destruction in the universe, accentuated further by the Dancer's calm and detached face in the center of the two hands, in which the polarity of creation and destruction is dissolved and transcended. The second right hand is raised in the sign of "do not fear," symbolizing maintenance, protection, and peace, while the remaining left hand points down to the uplifted foot, which symbolizes release from the spell of maya. The god is pictured as dancing on the body of a demon, the symbol of human ignorance that has to be conquered before liberation can be attained.

1.5 The Puranas and the Brahmapaksa

Although influenced by texts going back to Vedic times, and by Iranian sources too, the Puranas are Sanskrit writings about primordial times with cosmological sections dating from the 4th to 16th centuries A.D. of the Christian era. The Puranas deal with five topics: the creation of the Universe; the destruction and re-creation of the Universe, including the history of humankind; the genealogy of the gods; the reigns of the Manur; and the history of the lunar and solar dynasties. The Earth is now represented as a flat circular disc, with a world-mountain, Meru, at its center. The Meru is anchored to the yasti, which symbolizes the axis of the universe. The mountain is surrounded by alternating rings of sea and land, so that there are seven continents and seven seas. Wheels are conceived to carry the celestial bodies, these turned around the star at the north pole by Brahma, using cords made of mind. This cosmology was taken over by Jainism, a monastic religion that, like Buddhism, denies the authority of the Veda, but from the 5th and 6th centuries onward, it was undermined by the influx of a new form of Greek cosmology, with pre-Ptolemaic roots. In short, Aristotelianism reached India (see North, 1995).

2. MACROCOSMOS: FROM ANAXIMANDER TO EINSTEIN

2.1 Greek and Roman World

Anaximander of Miletus (c. 610–545 B.C.) is said to have made a map of the inhabited world, and to have invented a cosmology that could explain the physical state of the Earth and its inhabitants. The infinite universe was said to be the source of an infinity of worlds, of which ours was but one, that separated off and gathered their parts together by their rotary motion. Masses of fire and air were supportedly sent outward and became the stars. The Earth was some sort of floating circular disc, and the Sun and the Moon were ring-shaped bodies, surrounded by air. The Sun acted on water to produce animate beings, and people were descended from fish.

Anaximenes (c. 545 B.C.) elaborates on Anaximander's ideas and argues that air is the primeval infinite substance, from which bodies are produced by condensation and rarefaction; he produces logical arguments based on everyday experience. Again he introduces rotary motions as the key to understanding how the heavenly bodies may be formed out of air and water.

Pythagoras of Samos (c. 560–c. 480 B.C.) took the cosmic ideas of Anaximander and Anaximenes one stage further, saying that the universe was produced by the heaven inhaling the infinite so as to form groups of numbers. The Pythagoreans proposed a geometrical model of the universe, involving a central fire around which the celestial bodies move in circles. The central fire was not the Sun, although the Earth was certainly of the character of a planet to it. To account for lunar eclipses, the Pythagoreans postulated a counter Earth.

The discovery that the Earth is a sphere was traditionally assigned to Parmenides of Elea (c. 515–c. 450 B.C.), who was also said to have discovered that the Moon is illuminated by the Sun. A generation later, Empedocles (c. 484–c. 424 B.C.) and Anaxagoras (c. 500 B.C.) seem to have given a correct qualitative account of the reason for solar eclipses, namely, the obscuration of the Sun's face by the intervening Moon.

The discovery of the sphericity of the Earth, and of the advantages of describing the heavens as spherical, captured the imagination of the Greeks of the time of Plato (c. 428–c. 347 B.C.) and Aristotle (384–322 B.C.), in the 4th century, and of one man in particular: Eudoxus of Cnidus (c. 400–c. 355 B.C.), who produced a very remarkable planetary theory based entirely on spherical motions.

2.2 Aristotle's Universe

At the time of the Greek philosopher and naturalist Aristotle (384–322 B.C.), the Earth and the universe were seen as constructed out of five basic elements: earth, water, air, fire, and ether. The natural place of the motionless Earth was at the center of that universe. The stars in the heavens were made up of an indestructible substance called ether (aether) and were considered as eternal and unchanging. Aristotle's cosmology was the first "steady-state" universe. The other basic elements—water, air, and fire—were earthly elements. The celestial bodies, including the Sun, the planets, and the stars, were considered to be attached to rigid, crystalline spheres, which were supposed to revolve in perfect circles about the Earth. The three innermost spheres, closest to the Earth, contained water, air, and fire, respectively. The Egyptian–Greek astronomer Ptolemy (c. 100–170 A.D.) left the Earth to be located at the center of the universe but ascribed to the Sun and the planets a new place within the cosmological views of his time. The Sun and the planets would revolve in small circles whose centers revolve in large circles about the Earth ("epicycles"). The element of perfection and beauty ascribed to the divine heavens remained the circle out of which the orbits of heavenly bodies were composed. Basically, Ptolemaic ideas were devised to accommodate astronomical observations of planetary motions.

His "Almagest" described the motions of the heavens on this geocentric basis, employing wheels within wheels (epicycles) to obtain a plausible match with observations. Ptolemy's geocentric system dominated western thought on astronomy (including cosmology) until the time of Copernicus, fourteen centuries later (Fig. 2).

Eratosthenes (c. 270–c. 190 B.C.) was the first to measure accurately the radius of the Earth, in 196 B.C., by determining the minimum angle between the Sun's direction and the vertical at Alexandria on the day of the summer solstice. He knew that a zero angle occurs approximately when the Sun was at its highest point at the city of Syene (now

FIG. 2. Dante Alighieri's (1265–1321) scheme of the universe in illustration from "Paradise" in "The Divine Comedy" extends Aristotelian cosmology in a modern way. Dante traverses the material world from the icy core of Earth, the abode of Lucifer, to the Mount of Purgatory. He continues through the *nine heavenly spheres*, each sphere larger and more rapidly turning than the last, until he reaches the Primum Mobile, the ninth and largest sphere and the boundary of space. His goal was to see the Empyrean, the abode of God.

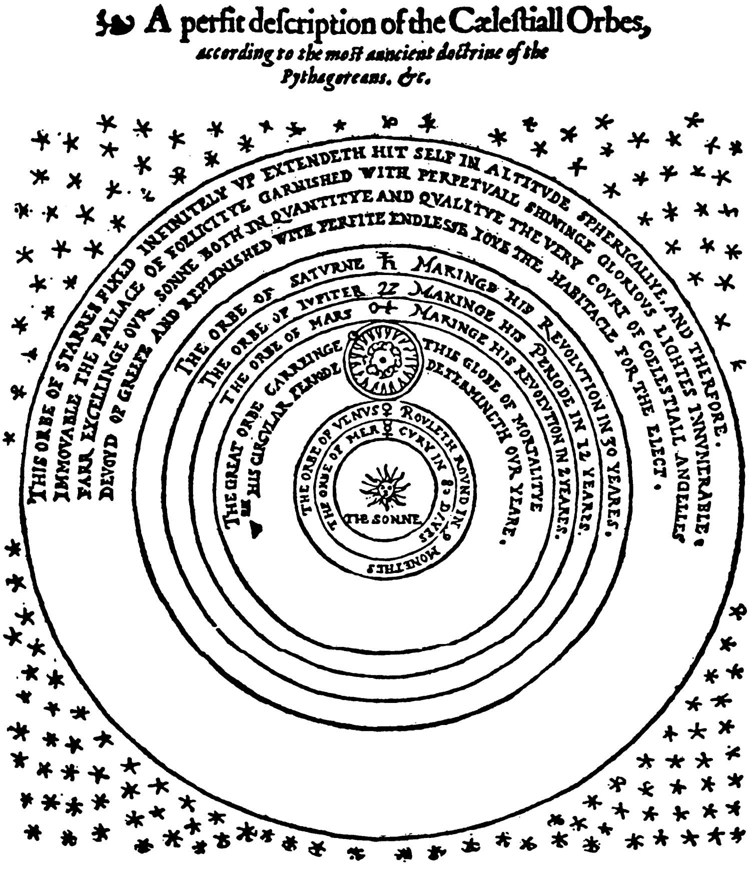
Aswan), and he knew the base of the triangle, i.e., the distance from Alexandria to Syene.

2.3 Copernicus's Universe

Copernicus (1473–1543), a Polish astronomer, placed the Sun at the center of the solar system with the Earth orbiting around the Sun, thus proposing a heliocentric cosmology (*De revolutionibus orbium coelestium*, 1543). This entirely new basis of cosmological consideration did not fit the observations much better than the Aristotelian–Ptolemaic system but was justified by the "divine" principle of simplicity in comparison to the rather complicated construction using epicycles as employed in Ptolemy's cosmology. However, like Aristotle and Ptolemy, Copernicus retained the conventional idea that the planets moved in perfectly circular orbits and continued to believe that the stars were fixed and unchanging. Kepler (1571–1630), a German astronomer and physicist, adopted the Copernican system but introduced the concept of planets with elliptical orbits. He still believed that the Sun was the center of the universe. The cosmologies of Aristotle and Ptolemy had nevertheless been abandoned.

2.4 Newtons' Universe

The Italian philosopher Bruno (1548–1600) laid the groundwork for Newtonian cosmology by emphasizing that the universe is infinite and stars are scattered outward through infinite space (see, however, Fig. 3).



A perfit deſcription of the Cæleſtiall Orbes, according to the moſt auncient doctrine of the Pythagoreans, &c.
This orbe of starres fixed infinitely up extendeth hit self in altitude sphericallye, and therfore immovable the pallace of foelicitye garnished with perpetuall shininge glorious lightes innumerable, farr excellinge our sonne both in quantitye and qualitye the very court of coelestiall angelles. Devoyd of greefe and replenished with perfite endlesse ioye the habitacle for the elect.

The great orbe carryinge this globe of mortalitye
The orbe of Venus ♀ rouleth round in 9 monethes.
The orbe of Mercury ☿
The Sonne

FIG. 3. The first diagram to illustrate the proposal that the universe is infinite. From the edition by Thomas Digges of his father's *A Prognostication everlastinge* . . . , published in 1576 in London, eight years before its publication by Giordano Bruno to whom the idea is often credited. (By permission of The Royal Society.)

Bruno even went so far as to say that stars are Suns, perhaps with orbiting planets and life on them (*De l'infinito, universo e mondi,* 1584). This far-reaching statement signaled a transfer of attention away from the planets in the solar system to the stars in the Milky Way. The laws describing the behavior of planets are the same laws that describe the behavior of the stars. That the physical laws are of universal nature, and can be applied on Earth as well as in the heavens, was discussed on a philosophical basis by the French philosopher and mathematician Descartes (1596–1650). He compared the universe with a giant clock obeying mechanical laws, a concept that later on had a major influence on Newton's (1643–1727) thinking. It was his belief that the universe was infinite and that the primary qualities of the universe were mathematical in nature.

A major step in observational techniques was achieved through the invention of the reflecting telescope between, say, 1545 and 1559 by the Briton Leonhard Digges (c. 1520–1559). But it was not until 1609 that the Italian astronomer and physicist Galileo (1564–1642) realized observationally that the Milky Way is actually a collection of individual stars. Galileo also observed mountains on the Moon and discovered four satellites around Jupiter. He had taken the first step toward deducing the structure of the Milky Way. The discovery of heavenly bodies that evidently did not circle the Earth and his support for the Copernican heliocentric cosmology were described in his work *Dialogo sopra i due massimi sistemi del mondo, Tolemaico e Copernicano* (1632).

Cassini (1625–1712), an Italian–French astronomer, used the telescope to make accurate measurements of the "dimensions of the universe," particularly determining the distance of the Earth from the planet Mars. A rigorous mathematical foundation of Descartes's notion of the universe as a giant mechanical clock was provided by Newton's theory of gravity and his laws of motion (*Philosophiae naturalis principia mathematica,* 1687). From these he explained Galileo's results on falling bodies, Kepler's three laws of planetary motion, and the motion of the Moon, Earth, and tides. Newton clearly realized that gravity is the dominant force for understanding the structure of the universe; however, he argued that the universe must be static in a famous letter he sent to the theologian Richard Bentley (1662–1742) in 1692. Mainly for religious reasons, at this time, constancy and stability were associated with the perfection of God and change with friction and decay. Philosophical and religious ideas served as the scaffolding upon which scientific systems of thought developed. It was Bentley who derived for the first time, on the basis of Newton's gravitational theory, what is still considered to be one of the fundamental constants of nature, the gravitational constant.

In Kant's (1724–1804) cosmology, the gravitational attraction of stars for each other was exactly balanced by the orbital motions of the stars and he argued that forces can act at a distance without the necessity for a transmitting medium. In 1755 Kant proposed the nebular hypothesis for the formation of the solar system. In 1788 Laplace (1749–1827) attempted a mathematical proof of the stability of the solar system (*Système du monde,* 1796). Stability and order of the universe were considered as eternal principles in the heavens and on Earth. The cosmology of Copernicus, as refined by Kepler, is now believed to be essentially correct.

2.5 Einstein's Universe

In 1915 Einstein (1879–1955) put forth his general relativity theory (a new theory of gravity); he applied this theory to cosmology in 1917. The theory describes gravity as a distortion of the geometry of space and time. Unlike Newton's theory of gravity, general relativity was consistent with special relativity, which Einstein had introduced in 1905. Cosmology, based on general relativity, broadened the problem into one of finding a model of the space-time structure of the universe. Einstein's original solutions of his gravitational field equations left the universe in a stable state of static equilibrium, and he provided physical conditions required to maintain such static (time-independent) equilibrium (the "cosmological constant"). Only in 1922 did Friedmann (1888–1925) succeed in finding solutions of Einstein's field equations that evolved in time, describing an expanding (or contracting, if one cares to reverse the sense of time) universe.

Persuasive observational evidence that the universe is indeed expanding and changing in time was found by Hubble (1889–1953) in 1929 while employing the technique known as Doppler shift for measuring the redshift of colors in the spectrum of nebulae. "Modern cosmology" may be said to have begun with Einstein (1917) and Friedmann (1922, 1924), based on observations of cosmological relevance made by Slipher (1875–1969) in 1914 and Hubble in 1929. Slipher discovered the redshift of nebulae, later on identified by Hubble to be entire galaxies similar to the Milky Way; however, until 1929 their cosmological significance remained obscure. In 1929 Hubble had counted a great number of galaxies (to determine their distribution throughout the observable universe) and plotted the galaxies' redshifts against magnitudes for the brightest E-type cluster galaxies (Hubble diagram). Hubble found evidence that the outward speed of a galaxy is directly proportional to its distance away from the observer (Hubble law). This observational fact was exactly what would be expected if the universe is expanding, as discussed in an article of Lemaître (1894–1966) in 1927. Hubble's diagram reveals a linear increase of the magnitude of galaxies with increasing redshift. In 1956, Hoyle and Sandage developed the q_0 criterion that could be used to distinguish one cosmological model from others. Lemaître's model and Hoyle's steady-state model were ruled out by predicting $q_0 = -1$, whereas Hubble's linearity gave $q_0 = +1$. Cosmology focused on the search for two numbers: H_0, the rate of expansion of the universe at the position of the Milky Way; and q_0, the deceleration parameter, characterizing the change of the rate of universal expansion. The value of q_0 is believed to lie in the range between 0 and 0.5; the value of H_0 is thought to be uncertain by a factor of about 2 ($H_0 = 100h$ km s^{-1} Mpc^{-1}, where $0.5 \leq h \leq 1$). Theoretical ideas on which big-bang cosmology is based were contained in the publications of Friedmann and Lemaître by 1930 (for an in-depth review, see North, 1965).

2.6 Big Bang

Astrophysical arguments were introduced into the cosmological models with Gamow's (1946) prediction that helium (and possibly heavier elements) was generated at an early stage of the evolution of the universe. At this time it was believed that the relative abundance of cosmic nuclei represents truly cosmic abundances. On the basis of Gamow's arguments, the cosmological criterion of the origin of chemical elements in the primeval fireball was substantiated by Alpher and Herman (1949, 1950) and Alpher *et al.* (1953). However, after Burbidge *et al.* (1957) it became evident that the bulk of the chemical elements beyond helium were not synthesized at the early stages of the expansion of the universe but in the stars. Only the synthesis of helium (Hoyle and Tayler, 1964), which is not produced in sufficient quantities in stars, and deuterium (Peebles, 1966), which is destroyed during galactic evolution, continued to need Gamow's primordial nucleosynthesis to arrive at reasonable abundances as observed in the universe. Later on Wagoner *et al.* (1967) were able to show that in addition to D, ^{3}He, and ^{4}He, the only other cosmologically significant element was ^{7}Li. In 1965 the microwave background radiation of 3 K was discovered by Penzias and Wilson (1965), as predicted by Alpher and Herman in 1949 on the basis of Gamow's considerations of a hot and dense origin of the universe.

Today the big-bang cosmological model, the temperature of the microwave background radiation, the abundances of D, ^{3}He, ^{4}He, and ^{7}Li, and the astrophysically observed average density of galactic material are starting points for developments in cosmology.

2.7 Beyond the Big Bang

In the big-bang cosmology, the universe has been expanding throughout its history. Mathematical calculations would suggest that the temperature and the density were infinite at the instant of the big bang. The universe is supposed to originate in the big bang, but the mathematical and physical structure of the model does not permit matter to originate. Additionally, the big-bang model leaves unanswered several important questions regarding

1. the number of protons and neutrons in the universe, relative to the number of photons;

2. the large-scale homogeneity of the observed universe;
3. the actual density of the universe, which is close to the critical density (that average density of the universe dividing big-bang models that will keep on expanding forever from those that will ultimately recontract); and
4. the origin of density perturbations from which small-scale (stars and systems of them) and large-scale (galaxies and systems of them) inhomogeneities have been developed (Kolb and Turner, 1990).

A new approach to explaining some of the questions left over by big-bang cosmology began with Guth's (1981) paper inventing an "inflationary" period in the evolution of the universe. The phase transition associated with the breakup of the unified force in the Grand Unification epoch could leave the universe in a state of false vacuum, in which the vacuum has a very high energy density. This vacuum energy density acts like a cosmic repulsion, and the universe embarks on an exponential expansion that "inflates" the universe by a factor of 10^{30} in a brief instant of time. This inflationary period ends when the vacuum energy density transforms into matter and radiation, and the expansion of the universe continues. Besides offering explanation of the four questions above, it makes one concrete prediction: The present universal expansion should exhibit flatness to the extent of $\Omega_0 = 1 \pm \epsilon$ with $\epsilon < 10^{-6}$, if inflation was sufficient to extend to a distance $\geq cH_0^{-1}$ today. Observations of the luminous matter content of the universe reveal only $\Omega_0 < 0.002$, and the quantity of dark or nonbaryonic material necessary to explain the flat rotation curves of spiral galaxies and the viral equilibrium of large groups and clusters of galaxies requires at most $\Omega_0 \approx 0.2$. The only way that $\Omega_0 = 1$ from inflationary cosmological models can be reconciled with observation is by the existence of nonbaryonic weakly interacting particles. The unknown nature of dark matter has led to considerable activities in fundamental particle physics to speculate about new basic constituents of matter. Additionally, the inflationary universe picture has stimulated far-reaching speculation about the ultimate origin of the universe.

Cosmology based on general relativity has thus moved close to fundamental particle physics based on quantum field theory. A new challenge emerged for physical theory and observation subsumed under the term "quantum gravity." Interaction between mathematics and physics, as exemplified by the role of Riemannian geometry in general relativity and functional analysis in quantum mechanics, became lively again. Cosmology is currently based on the two fundamental theories in twentieth-century physics, general relativity and quantum field theory. General relativity describes the gravitational force on an astronomical scale, while quantum field theory describes the weak, electromagnetic, and strong interaction of fundamental particles. A formal quantization of general relativity leads to unphysical infinities; encompassing gravity in quantum field theories leads to a new connection of theoretical physics to modern mathematics, called string theory. However, there is still no quantum cosmology. Particularly, an inflationary era may have taken place in the early universe, but there is no proof that it did so (Manin, 1981; Schmid, 1992).

3. MICROCOSMOS: FROM LEUCIPPUS TO YUKAWA

3.1 Atomism

With regard to the structure of the universe, the belief persists that certain objects are fundamental and that others are derived, in the sense that the latter are composed of the former. In one version of this distinction, the fundamental objects are particles, or points of matter. Although the view of which objects qualify as fundamental particles has changed many times, the notion that the universe is ultimately made of such material points, moving through space, has endured in some form ever since the theory of atomism was first proposed by the Greeks Leucippus (5th century B.C.) and Democritus (c. 460–c. 370 B.C.) in the 5th century B.C. (Whittaker, 1951, 1953/1989).

An atom is the smallest unit of matter that is recognizable as a chemical element. Atoms of different elements may also combine into systems called *molecules*, which are the smallest units of chemical compounds (Fig. 4). In all these processes, atoms

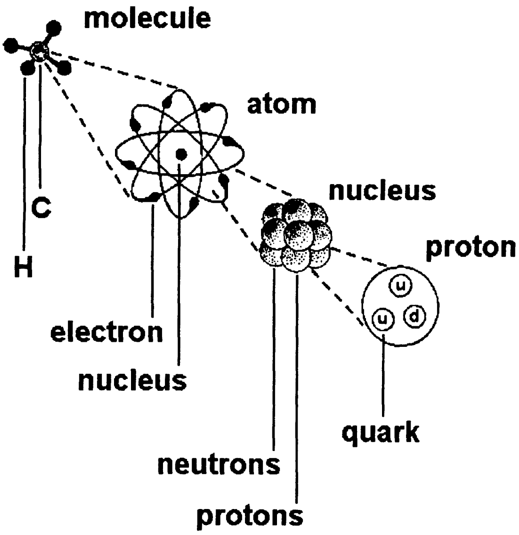

FIG. 4. The continuum of size and organizational level appears throughout the range of structural elements, from the fundamental particles to the highest-level systems of matter. Particles such as the quarks are known to be bound by strong forces. Protons and neutrons are bound within the atomic nucleus. The outer shell of atoms is bound to the nucleus by electromagnetic forces. A molecule may be thought of either as a structure built of atoms bound together by chemical forces or as a structure in which two or more nuclei are maintained in some definite geometrical configuration by attractive forces from a surrounding cloud of negative electrons. The evolution of the universe created a hierarchy of structural elements.

may be considered as the ancient Greeks imagined them to be: the ultimate building blocks of matter. When stronger forces are applied to atoms, however, the atoms may break up into smaller parts. Thus atoms are actually composites and not units and have a complex inner structure of their own.

The first recorded speculations that matter consisted of atoms are found in the works of Leucippus and Democritus. The essence of their views is that all phenomena are to be understood in terms of the motions, through empty space, of a large number of tiny and indivisible bodies. The name "atom" comes from the Greek word "atomos," for "indivisible." According to Democritus, these bodies differ from one another in shape and size, and the observed variety of substances derives from these differences in the atoms composing them.

Greek atomic theory was not an attempt to account for specific details of physical phenomena. It was instead a philosophical response to the question of how change can occur in nature. Little effort was made to make atomic theory quantitative—that is, to develop it as a physical theory for the study of matter. Greek atomism, however, did introduce the valuable concept that the nature of everyday things was to be understood in terms of an invisible substructure of objects with unfamiliar properties. Democritus stated this especially clearly in one of the few sayings of his that has been preserved: "color exists by convention, sweet by convention, bitter by convention, in reality nothing exists but atoms and the void."

Although adopted and extended by such later ancient thinkers as Epicurus (341–270 B.C.) and Lucretius (c. 95–55 B.C.), Greek atomic theory had strong competition from other views of the nature of matter. One such view was the four-element theory of Empedocles. These alternative views, championed by Aristotle among others, were also motivated more by a desire to answer philosophical questions than by a wish to explain scientific phenomena.

3.2 Atom

The atomic theory languished until the 18th and early 19th centuries, when physicists and chemists revived it to explain the properties of gases and some of the facts of chemistry. In these theories the fundamental particles, the atoms, remained indivisible points. The discovery in the late 19th and the 20th centuries that atoms were composite, rather than indivisible, set the stage for modern discoveries about fundamental particles (Pais, 1986; Whittaker, 1951, 1953/1989).

When interest in science revived in Europe in the 16th and 17th centuries, enough was known about Greek atomism to form the basis for further thought. Among those who revived the atomic theory were Pierre Gassendi (1592–1655), Robert Boyle (1627–1691), and especially Isaac Newton. The latter part of Newton's book *Optics* is a series of detailed speculations on the atomic nature of matter and light, indicating how some of matter's properties are to be understood in terms of atoms.

In the 19th century, two independent

lines of reasoning strengthened the belief in the atomic theory. Both approaches also began to reveal some quantitative properties of atoms. One approach, pioneered by John Dalton (1766–1844), involved chemical phenomena. The other, involving the behavior of gases, was carried out by physicists such as Rudolf Clausius (1822–1888) and James Clerk Maxwell (1831–1879).

Dalton's main step forward was his introduction of atomic weights. Dalton studied the elements then known and analyzed the data of their reactions with one another. He discovered the law of multiple proportions, which states that when several distinct reactions take place among the same elements, the quantities that enter the reactions are always in the proportions of simple integers—that is, 1 to 1, 2 to 1, 2 to 3, and so on. From this came the concept that such reacting quantities contain equal numbers of atoms and are therefore proportional to the masses of individual atoms. Dalton gave the lightest known element, hydrogen, an atomic weight of 1, and developed comparative atomic weights for the other known elements accordingly.

The study of gases in terms of atomic theory was begun by Daniel Bernoulli (1700–1782) in the 18th century. Bernoulli showed that the pressure exerted by a gas came about as the result of collisions of the atoms of the gas with the walls of its container. In 1811, Amedeo Avogadro (1776–1856) suggested that equal volumes of different gases, under the same conditions of pressure and temperature, contain equal numbers of atoms. Avogadro himself never estimated the magnitude of this value, although it is now known as the Avogadro number.

3.3 Electron

The history of particle physics has gone through four stages. In the first stage, Joseph J. Thomson (1856–1940) discovered (1897), by studying electricity passing through gases, that all atoms contain certain particles, called electrons, that carry a negative electric charge. Because atoms are electrically neutral, there must be a balancing of positive charges somewhere in the atom. Ernest Rutherford (1871–1937) proposed (1911), on the basis of a series of experiments by Hans Geiger (1882–1945) and Ernest Marsden (1889–1970), that these positive charges are concentrated in a very small volume, called the atomic nucleus, at the center of the atom.

By the end of the 19th century almost all scientists had become convinced of the truth of the atomic theory. By that time, however, evidence was just beginning to accumulate that atoms are not in fact the indivisible particles suggested by their name. One source of such evidence came from studies using gas discharge tubes. In such tubes, a gas at low pressure is subjected to intense electrical forces. Under these conditions various colored glows are observed to traverse the tube. One blue glow at one end of the tube, around the electrode known as the cathode, was observed for a wide variety of gases. The glow was shown by Joseph Thomson in 1897 to involve a stream of negatively charged particles with a charge-to-mass ratio indicating the existence of a particle with a very small mass on the atomic scale. These particles were called electrons, and they were soon recognized to be a constituent of all atoms. That is, atoms are not indivisible but contain parts.

In the late 19th and the early 20th century it was also found that some kinds of atoms are not stable. Instead they transform spontaneously into other kinds of atoms. For example, uranium atoms slowly change into lighter thorium atoms, which themselves change into still lighter atoms, eventually ending up as stable atoms of lead. These transformations, first observed by Antoine Henri Becquerel (1852–1908), came to be known as radioactivity, because the atomic changes were accompanied by the emission of several types of radiation.

Atoms are ordinarily electrically neutral. Therefore the negative charge of the electrons in an atom must be balanced by a corresponding positive charge. Because the electrons have so little mass, the positive constituents of an atom must also carry most of the atom's mass. The obvious question arose as to how these varied parts are arranged within an atom. The question was answered in 1911 through the work of Ernest Rutherford and his collaborators. In their experiments they passed alpha particles—a type of radiation emitted in some radioactive decays—through thin gold foils. They observed that in some instances the alpha particles emerged in the opposite direction from their initial path. This suggested a collision with a heavy object within the atoms of the gold. Because electrons are not massive enough to produce such large deflections, the positive charges must be involved. Analyzing the data, Rutherford showed that the positive charge in an atom must be concentrated in a very small volume with a radius less than 10^{-12} cm, or 1/10 000 the size of the whole atom. This part of the atom was called the nucleus.

3.4 Atomic Nucleus and Photon

Rutherford proposed an atomic model in which the atom was held together by electrical attraction between the nucleus and the electrons. In this model the electrons traveled in relatively distant orbits around the nucleus. The model eventually proved successful in explaining most of the phenomena of chemistry and everyday physics. Subsequent studies of the atom divided into investigations of the electronic parts of the atom, which came to be known as atomic physics, and investigations of the nucleus itself, which came to be known as nuclear physics. This division was natural, because of the immense difference in size between the nucleus and the electron orbits and the much greater energy needed to produce nuclear as compared to electronic changes.

The Rutherford model of the atom, however, had to face two immediate problems. One was to account for the fact that different atoms of the same element behaved in physically and chemically similar ways. According to the Rutherford model, electrons could move in any of the infinite number of orbits allowed by Newtonian physics. If that were so, different atoms of the same element could behave quite differently. This is actually a problem for any atomic model based on Newtonian physics, and it had already been recognized by Maxwell in 1870. The other problem was that, according to the principles of electromagnetism, electrons should continuously emit radiation as they orbit in an atom. This would cause the electrons to lose energy and to spiral into the nucleus.

An important step toward solving these problems was taken by Niels Bohr (1885–1962) in 1913. According to Bohr, the electrons in atoms cannot exist in arbitrary orbits. Instead they are found only in certain "states." The states in which they can exist are those in which the angular momentum of their orbits is an integer multiple of $h/2\pi$, where h is a quantity known as Planck's constant. This constant had been introduced by Max Planck (1858–1947) in his theory describing blackbody radiation.

According to the Bohr model of the atom, there is a so-called ground state for any atom. This ground state has the lowest energy allowed to the atom, and it is the same for all atoms containing the same number of electrons. An atom normally exists in this ground state, which determines the observed properties of a given element. Furthermore, according to Bohr, no radiation is emitted by an atom in its ground state. This is because energy must be conserved in the radiation process, and no available state of lower energy exists for the atom to balance any energy lost through radiation.

An atom can be removed from its ground state only when enough energy is given to it, by radiation or collisions, to raise an electron to an "excited" state. When the atom is excited, it will usually emit electromagnetic radiation rapidly and return to the ground state. The radiation is emitted in the form of individual packets, or quanta, of light, called photons. Each photon has an energy equal to the difference between the energy of the excited state and the ground state of the atom. According to a formula developed by Planck and Einstein, this energy corresponds to a specific wavelength of the emitted light. Using his assumption about the allowed angular momenta for electrons, Bohr was able to calculate the precise wavelengths in the spectrum of the simplest atom, hydrogen.

In 1869, Dimitri I. Mendeléev (1834–1907) stated the rule that chemical elements arranged according to the value of their atomic weights exhibit a clear periodicity of properties. Eventually, Bohr was able to extend his atomic theory to describe, qualitatively, the chemical properties of all the elements. Each electron in an atom is assigned a set of four so-called quantum numbers. These numbers correspond to the properties of energy, total orbital angular momentum, projection of orbital angular momentum, and projection of spin angular momentum. It is also assumed—as had first been suggested by Wolfgang Pauli (1900–1958) in 1924—that no two electrons in an atom can have the same values for all four quantum numbers. This came to be known as Pauli's exclusion principle. This principle influences the way in which the chemical properties of an element depend on its atomic number, that is, the number of electrons in each atom of the element. A maximum number of electrons can occur for each energy level, and no more than that. For example, the lowest energy level of an atom—the one in which the electrons have zero orbital angular momentum—can contain up to two electrons. The one electron in a hydrogen atom exists at this energy level, as do the two electrons in a helium atom. For the next heavier atom, lithium, one of its three electrons must exist in a higher energy state, and as a result, this electron can more easily be lost to another atom. Those electrons with approximately the same energy are said to form a "shell."

Although Bohr's model gives a qualitatively accurate description of atoms, it does not give quantitatively accurate results for atoms more complex than hydrogen. In order to describe such atoms, it is necessary to use quantum mechanics (see QUANTUM THEORY). This theory of atomic and subatomic phenomena was created by Erwin Schrödinger (1887–1961), Werner Heisenberg (1901–1976), Paul Dirac (1902–1984), and Pascual Jordan (1902–1980) in the 1920s. In quantum mechanics, the electron orbits are replaced by probability distributions that only indicate in which regions of space each electron is most likely to be found. An equation discovered by Schrödinger allows this distribution to be calculated for each atom. From the distribution, properties of the atom such as energy and angular momentum can be determined.

In the second stage, particle physics accommodated, through an analysis of isotopes of elements, that all atomic nuclei could be thought of as composed of two types of particles: the proton, which carries both mass and electric charge, and the neutron, which has about the same mass as a proton but is electrically neutral. This model was confirmed through the discovery (1932) of free neutrons by James Chadwick (1891–1974).

3.5 Neutron

Physicists by the late 1920s were convinced that they sufficiently understood the electronic structure of atoms. Attention therefore turned to the nucleus. It was already known that nuclei sometimes change into one another through radioactive decay. Rutherford had also shown, in 1919, that this could be accomplished artificially by bombarding nitrogen nuclei with high-energy alpha particles. In the process the nitrogen nucleus is converted into an oxygen nucleus, and a hydrogen nucleus, or proton, is ejected. It had further been discovered by Joseph J. Thomson, Francis W. Aston (1877–1945), and others that for a given element the nucleus sometimes occurs in several different forms that differ in mass. These chemically similar but physically distinct atoms were called isotopes. All of this provided evidence that atomic nuclei also had some kind of internal structure that could be explored through experiments and calculations.

Differences in the integer values of the electric charge and of the mass of many nuclei soon indicated that protons were not the only kind of particle to be found there. That is, the electric charge of a nucleus is always exactly an integer multiple of the charge of a proton, so that knowledge of this electric charge always indicates how many protons a nucleus contains. The mass of a nucleus is also approximately—but not exactly—an integer multiple of the mass of a proton. For many atoms, however, these two integer values are not the same. For example, a helium nucleus has twice the charge but four times the mass of a proton. Clearly, nuclei contain something other than protons.

This problem was solved in 1932 with the discovery by James Chadwick of the neutron. This particle has no electric charge and is slightly more massive than a proton. Thus most nuclei are composed of both protons and neutrons, which collectively are known as nucleons. A helium nucleus contains two protons and two neutrons, which correctly give the total charge and mass of the nucleus. The isotopes of any given element contain equal numbers of protons but different numbers of neutrons. For example, an isotope of hydrogen, called deuterium, contains one proton and one neutron, and a heavier isotope, called tritium, contains one proton and two neutrons.

The problem then arose as to how atomic particles could be held together in such a small region as the nucleus. The force holding them had to be different from others then known to physicists. It was stronger than the electric forces that can break electrons away from nuclei. On the other hand, the nuclear forces between different nuclei that are far apart are very weak, much weaker than electric forces at such distances.

3.6 Fundamental Particles

The third stage of particle physics came with the recognition that protons, neutrons, and electrons—the constituents of ordinary matter—were but three of a vast number of similar particles, which differed only in a few properties, such as their mass, and in their stability against spontaneous decay. Experiments with particle accelerators indicated that these many subatomic particles could be readily produced from protons and neutrons, provided that enough energy was available to produce the additional mass of the new particles predicted by the rules of Einstein's relativity theory. These discoveries in the 1940s and 1950s indicated that the proton and neutron were not really fundamental particles and that they would have to be understood as part of a much larger family of similar objects.

By 1932 nuclei were known to be composed of protons and neutrons. It was then necessary to explain how nuclei were held together, and in 1935, the Japanese physicist Hideki Yukawa (1907–1981) predicted a smaller fundamental particle that was the carrier of a theorized strong interaction, one of the four fundamental interactions, or forces. This particle, called a π-meson or pion, was discovered in 1947. Since then a host of particles smaller than protons and neutrons have been discovered in the nucleus, all falling within two classes: fermions, which obey the Pauli exclusion principle, and bosons, which carry the fundamental force. Modern nuclear physics centers on fundamental interactions between fermions and bosons. Protons and neutrons are composed of particles representing all four forces.

In the fourth stage, modern particle physics provided a successful explanation for the large number of particles. There are six different leptons: electron (e), muon (μ), tauon (τ), electron neutrino (ν_e), muon neutrino (ν_μ), and tau neutrino (ν_τ). There are also six quarks denoted up (u), down (d), charm (c), strange (s), top (t), and bottom (b). For each of these particles there exists an antiparticle. Many of the models for particle interactions pair the leptons and quarks into families: (e-ν_e), (μ-ν_μ), (τ-ν_τ), and (u-d), (c-s), (t-b). Experiments suggest that it is unlikely that there are more than these families. The interactions between these fundamental particles are mediated by gauge bosons (photon, intermediate bosons $W^\pm$ and Z^0, gluons).

4. WEAK, ELECTROMAGNETIC, AND STRONG INTERACTIONS: STRUCTURE OF THE MICROCOSMOS

4.1 Fundamental Interactions

At sufficiently low energies, there are four types of fundamental interactions whose existence is well established. Most studied are two of them: the gravitational and the electromagnetic interactions. The foundations of the classical (nonquantum) theory of the two interaction types were laid a long time ago by Newton and Maxwell.

In particle physics, the standard model encompasses all the particles known today and three of the fundamental interactions. The basic building blocks are two sets of matter particles, the quarks and the leptons (Table 1). These particles interact with each other through the exchange of gauge bosons (see Sec. 4.3, Table 2). The three fundamental interactions of the standard model are the electromagnetic, the strong, and the weak interactions, respectively. Gravity remains outside the standard model, but this does not invalidate the model as gravitational effects on particles are far smaller than the effects of the other interactions. The standard model has two components. One is the theory of strong interaction, called quantum chromodynamics. The other component is the theory that gives a unified description of electromagnetic and weak interactions, called the electroweak theory. The physical concepts used in the standard model are generalizations of concepts familiar in quantum electrodynamics (Kolb and Turner, 1990; Kaku, 1993).

4.1.1 Gravitational Interaction Gravitational interaction that governs the motion of celestial bodies is characterized by New-

Table 1. Fundamental fermions divided into two groups: leptons and quarks (Barnett *et al.*, 1996).

Leptons (spin = $\frac{1}{2}$)

Electric charge	Flavor	Mass (GeV/c^2)	Flavor	Mass (GeV/c^2)	Flavor	Mass (GeV/c^2)
0	ν_e, electron neutrino	$<1 \times 10^{-8}$	ν_μ, muon neutrino	1.7×10^{-4}	ν_τ, tau neutrino	$<2.4 \times 10^{-3}$
-1	e, electron	5.1×10^{-4}	μ, muon	0.106	τ, tau	1.777

Quarks (spin = $\frac{1}{2}$)

Electric charge	Flavor	Approx. mass (GeV/c^2)	Flavor	Approx. mass (GeV/c^2)	Flavor	Approx. mass (GeV/c^2)
$\frac{2}{3}$	u, up	$(2–8) \times 10^{-3}$	c, charm	1–1.6	t, top	180
$-\frac{1}{3}$	d, down	$(5–15) \times 10^{-3}$	s, strange	0.1–0.3	b, bottom	4.1–4.5

ton's constant $G = 6.7 \times 10^{-8}$ g^{-1} cm^3 s^{-2}. An excellent approximation that describes the gravitational interaction of two point masses m, a distance r apart, is Newton's formula,

$$F = Gm^2/r^2. \tag{1}$$

All fundamental particles are affected by gravity. The relativistic generalization of Newton's theory of gravity is Einstein's theory of general relativity.

4.1.2 Electromagnetic Interaction

Electromagnetic interaction determines the motion of charged bodies and acts only on charged particles. In the general case, their law of motion is described by Maxwell's equations. In the quasistatic approximation, an analog to Newton's law, the Coulomb approximation,

$$F = e^2/r^2, \tag{2}$$

proves to work well. Here, e denotes the charge of each point mass. The quantum field theory of electromagnetism, quantum electrodynamics, is the best theory available for describing effects of the electromagnetic force. One of this theory's important features is its gauge symmetry, which means that when independent changes to local field values are made at different points in space, the equations of quantum electrodynamics are not changed. This symmetry is ensured only if the quantum description of a charged particle contains an electromagnetic field with its gauge boson; i.e., the gauge symmetry demands the existence of the electromagnetic force and the photon. The symmetry is also linked to the ability to renormalize quantum electrodynamics so that it yields sensible, finite results.

The magnitudes of Gm^2 and e^2 depend on the choice of the system of units. To facilitate comparison in the framework of quantum field theory, one combines these quantities with universal physical constants, the Planck constant $\hbar$ and the velocity of light c, to obtain dimensionless constants. Thus, the nondimensional gravitational constant (see end of Sec. 4, Table 3),

$$\alpha_g = Gm^2/\hbar c, \tag{3}$$

and the nondimensional electromagnetic fine structure constant (see end of Sec. 4, Table 3),

$$\alpha_e = e^2/\hbar c, \tag{4}$$

are obtained, $e \approx 10^{-19}$ C being the electron (proton) charge. There is a difference in the definition of the two constants, α_e being in a way more universal than α_g. The definition of the number α_e contains fundamental constants only, whereas the constant α_g involves a mass m that is, generally speaking, arbitrary. To eliminate this arbitrariness, it is common to fix the value of m by setting it equal to the proton mass m_p. This choice is quite natural, for the proton is one of the two stable particles constituting the structure of the universe; the other one is the electron, with mass m_e. The choice between m_p and m_e is a matter of convention ($m_p \approx 1837 m_e$).

4.1.3 Weak Interaction The weak interaction governs the decay of particles into lighter ones and acts upon all quarks and leptons, including those with no electric charge. Historically, the first decay discovered was the decay of a neutron within an atomic nucleus (the β decay), according to the reaction $n \rightarrow p + e^- + \bar{\nu}$ (n, p, e^-, and $\bar{\nu}$ denoting a neutron, a proton, an electron, and an antineutrino, respectively). Subsequently, the discovery of new particles was intensified by progress in the development of accelerators. It turned out that all newly discovered particles have a common property: Heavy particles decay into lighter ones. Numerous investigations led to the conclusion that many decays are controlled by a unique interaction, referred to as the weak interaction, which is characterized by the Fermi coupling constant $g_F = 10^{-49}$ erg cm^3. The corresponding dimensionless coupling constant for the weak interaction is (see end of Sec. 4, Table 3)

$$\alpha_w = g_F m^2 c/\hbar^3. \tag{5}$$

The processes of collisions of neutrinos with matter are determined by the weak interaction as well.

There are many attempts to develop unified descriptions of all four interactions. In quantum theory every particle is associated with a particular field. How such a field transforms under the Lorentz transformation depends on the spin of the particle described by the respective field. A spin-0 particle can be described by a scalar field (Higgs field), a spin-$\frac{1}{2}$ particle by a spinor field, and a spin-1 particle by a vector field. The Lagrangian describing the field will carry information about the mass of the particle and its interactions. It is possible to construct a model that describes electromagnetic and weak interactions using a Lagrangian that possesses invariance under two transformation groups, U(1) and U(2).

The Higgs fields have a Lagrangian with a potential $V(\phi)$ that has nontrivial minima. If such a system comes into contact with matter fields that are in thermal equilibrium at some temperature T, then the effective potential energy will acquire a temperature dependence. That is, $V(\phi)$ will become $V(\phi,T)$. Such a temperature dependence can lead to several nontrivial effects—like phase transitions—in the early universe (Kolb and Turner, 1988). Even though the transformation group underlying the theory can be determined from some general principles, the detailed transformation properties of the fields representing specific particles cannot be derived from any fundamental considerations. These details are fixed using the known laboratory properties of these particles. For example, consider the fields describing the leptons. Given a spinor field ψ, one can construct its "right-handed" and "left-handed" components by the decomposition

$$\psi_L = \tfrac{1}{2}(1 - \gamma_5)\psi, \quad \psi_R = \tfrac{1}{2}(1 + \gamma_5)\psi, \tag{6}$$

where γ_5 is the 4×4 matrix

$$\gamma_5 = \begin{pmatrix} 0 & I \\ I & 0 \end{pmatrix}. \tag{7}$$

In the standard electroweak theory, the right-handed components behave as singlets (that is, they do not change) while the left-handed components transform as a doublet [that is, under an SU(2) transformation these fields are changed into linear components of themselves]. It is a consequence of this feature that in the simplest electroweak theory there is no necessity for the right-handed neutrino ν_R and that the left-handed neutrino ν_L is massless. Since the transformation properties of the fields are put into the theory by hand, it is possible to generalize these models in many ways. In particular, it is possible—though not necessary—to have massive neutrinos in the theory. This arbitrariness is of great importance for the existence of dark matter in the universe and for the solar neutrino problem.

4.1.4 Strong Interaction The strong interaction was identified with the nuclear interaction, which acts only on quarks and is ultimately responsible for binding protons and neutrons within the nucleus. The attempts to develop a consistent theory of nuclear interaction took a long time. A breakthrough was achieved with the progress of the dynamical theory of quark systems that led to the advent of quantum chromodynamics. In that scheme, the nuclear interaction was identified with the interaction in many-quark systems. It is instructive to trace briefly the evolution of the quark interpretation of nuclear interaction. To do so, we briefly outline the quark model proposed by Murray Gell-Mann (b. 1929) and George Zweig (b. 1937) in 1964. According to this model, each proton and neutron consists of three pointlike particles that are referred to as quarks and possess a charge that is a fraction of the electron charge e: $\pm\frac{1}{3}e$ or $\pm\frac{2}{3}e$. This theoretical conclusion was seemingly in contradiction to the experimental evidence that all the observable particles have integer electric charges. Nevertheless, numerous experimental confirmations of the quark hypothesis (such as systematics of the elementary particles, the magnitude of the magnetic moments, the ratios of the interaction cross sections, etc.) suggested that it deserves serious consideration. But then a profound question arose: How can the existence of quarks be reconciled with their nonobservability in experiments? At present, this problem is referred to as that of quark confinement. A postulate is invoked that has rather a character of magic: Quarks do exist, but in bound states. Even though no final solution of the confinement problem is available, one bases some expectations on the construction of a mathematical model that claims to provide a theory of the interaction between the quarks. It is this interaction that is identified with the strong interaction governing nuclear interaction. In 1954, Chen N. Yang (b. 1922) and Robert L. Mills (b. 1927) proposed a theory that is basically different from electrodynamics but accounts for the interaction caused by the transfer of zero-mass particles. The only such particle known at that time was the photon. The photon is the gauge particle in electrodynamics. That is why the Yang–Mills theory was considered just a mathematical exercise. The picture changed when a need emerged for a theory describing the dynamics of quarks. It seemed natural to consider the massless particles introduced by Yang and Mills to be responsible for the quark interaction. These particles were named gluons; by analogy with quantum electrodynamics, the quantum field theory of electromagnetism, one of the variants of the Yang–Mills theory is referred to as quantum chromodynamics. While gluons are analogs of photons, quarks are analogs of electrons. They carry not only color charges but also ordinary electric charge. For example, a proton consists of three quarks ($p = uud$), and a neutron consists of three quarks ($n = udd$), held together by continuing exchange of gluons. In the early 1970s the Yang–Mills equations were subjected to more scrutiny. As a result, the constant α_s was found to exhibit quite remarkable behavior, as distinct from quantum electrodynamics. This constant determines the quark–quark interaction that is currently believed to be the true strong interaction. It should be remembered that from the viewpoint of contemporary field theory the interaction is mediated by gauge bosons, i.e., quanta of the corresponding field. Energy momentum and hence—according to the special theory of relativity—mass is transferred along with a quantum. Elaborate calculations have demonstrated that the strong-interaction coupling constant α_s essentially depends on the energy-momentum and the mass m transferred. In a way, one had encountered a mass dependence of the constants α before (e.g., α_g and α_w), but quantum chromodynamics introduces a basic difference. In this theory, the dependence $\alpha_s(m)$ is deduced from quantum field theory, and not postulated, as was done earlier for the constants α_g and α_w on the basis of dimensional considerations. In addition, the variation of the constant α_s with the mass m has a specific feature: α_s decreases with increasing m. It should be remarked here that the terminology repeatedly used above might appear contradictory. On the one hand, one speaks of the constants α; on the other hand, one keeps stressing their dependence on m. In fact, the constants α are only constant at a fixed m; they vary with changing m. Accordingly, they are referred to as "running" constants. The final expression for the dependence of α_s on m reads, in the asymptotic approximation when $m \gg m_p$ (see end of Sec. 4, Table 3),

$$\alpha_s \sim \frac{a}{\ln(m/m_p)}\,. \tag{8}$$

The quantity a depends on N_q, the number of the sorts of quarks. In a standard theory ($N_q = 6$), $a \sim 1$. It follows from this formula that $\alpha_s \to 0$ as $m \to \infty$. This is the phenomenon of asymptotic freedom. A similar dependence also follows from a more exact expression. Unfortunately, the latter also has been obtained by methods whose validity breaks down for $m < m_p$. A "true" expression for α_s at small m is missing, because α_s is large, thus rendering standard computation techniques inapplicable. One can only state that for a small characteristic mass m, corresponding to the proton (or neutron) size, $r_N \approx 10^{-13}$ cm, the coupling constant is large. Furthermore, a rapid increase of the constant α_s with r approaching r_N inhibits progress in solving another problem, namely, that of nuclear forces. Today, quantum chromodynamics is considered as a theory that describes the interactions among quarks and gluons, out of which atomic nuclei are made.

4.2 Classification of Fundamental Particles

Fundamental particles are classified with respect to various parameters. A particle classification appears to be provided by the value of the spin, s. The behavior of particles depends on whether their spin is characterized by an integer (0,1,2,. . .) or a half-integer ($\frac{1}{2}$,$\frac{3}{2}$,$\frac{5}{2}$,. . .). Particles with a half-integer spin are referred to as fermions, those with an integer spin as bosons. In the framework of quantum mechanics, the difference in the behavior of fermions and bosons is expressed by the kind of symmetry of the wave functions describing these particles. A system consisting of fermions obeys Pauli's exclusion principle, as distinct from a boson system on which no such exclusion principle is imposed. Pauli's principle reads as follows: No two fermions may be in exactly the same quantum state.

An excellent illustration of Pauli's principle is the atomic level structure underlying the periodic system of the chemical elements. It is known that the first period of this system is composed of two elements, hydrogen and helium. For the first period, the principal quantum number equals unity. The atomic states associated with the first period are therefore determined only by the value of the spin projection of orbital electrons. There are two such values. Thus, only two elements can occur in the first period. For the second period, the principal quantum number equals two, giving rise to eight possible different states and thus to eight elements, etc. The Pauli principle is one of the foundations of the very structure of the periodic system. If this principle did not work, all the atomic electrons would populate the ground energy level (i.e., the hydrogen level), and, consequently, the periodicity of the system as well as the valency of chemical bonding would vanish. It is the Pauli principle that prevents atomic electrons from occupying the energetically most favorable ground state.

Another basis for the classification of the fundamental particles is their interaction. All particles participating in the strong interaction are referred to as hadrons (from the Greek word "hadros," meaning "strong"). All fermions that do not participate in the strong interaction are called leptons. A special place in this classification is reserved for the bosons, particles that mediate the interactions. The hadrons, in turn, are subdivided into the baryons and the mesons. The baryons are fermions; the lightest baryon is the proton. The hadrons with integer spin are referred to as mesons; the lightest meson is the pion ($m_\pi \approx 140$ MeV).

4.3 How Fundamental Particles Interact

Particles interact by exchange of gauge bosons; the exchange in the process of interaction involves not only energy, momentum, and mass but also the internal quantum numbers: spin, isospin, charge, and color. The properties of the exchange particles in the context of quantum field theory determine the interaction to a great extent. All exchange particles are bosons. The properties of the exchange particles are summarized in Table 2.

4.3.1 Graviton The graviton is a massless particle with zero charge and a spin $s = \pm 2$ and has not been detected because of its extremely weak interaction. Although most physicists have no doubts about the existence of gravitons, some caution is advisable, since the quantum theory of gravitation itself

Table 2. Properties of the force carriers (Barnett *et al.*, 1996).

	Bosons (spin = 0,1,2, . . .)	
	Electric charge	Mass (GeV/c^2)
Unified elektroweak (spin = 1)		
γ, photon	0	0
W^-	−1	80
W^+	+1	80
Z^0	0	91
Stronger or color (spin = 1)		
g, gluon	0	0

is far from being complete. Because of the weakness of the gravitational field, there is no hope for rapid progress in detecting and investigating gravitons. Because the graviton is a massless particle, the gravitational interaction is long range.

4.3.2 Photon Photons have spins of $s = \pm 1$ and a rest mass of zero, and are their own antiparticles. The electromagnetic interaction has a long range because the photon is massless.

4.3.3 Intermediate Bosons The weak interaction is mediated by three intermediate gauge bosons $W^{\pm}$ and Z^0, which have masses of ~80 and ~91 GeV, respectively. Since the range of an interaction is inversely related to the mass of the gauge boson, the weak interaction has an extremely short range.

4.3.4 Gluons The gluons, like the quarks, are not observable in the free state. However, in the late 1970s, considerable progress in the indirect verification of gluons was achieved by investigating the annihilation of high-energy positrons and electrons with hadron generation. It turned out that three hadronic jets occur in such processes; two jets are attributed to quarks, and the third one, to gluons. The experimental data on the three-jet processes accompanying positron–electron annihilation are in good agreement with the predictions of quantum chromodynamics, which indirectly confirms the existence of gluons, one of the basic elements of that theory. The strong interaction is mediated by a set of gauge bosons, containing at least eight gluons.

The data presented in Table 3 list the properties of the four interactions. A new entry here is the value of the interaction radius. For the gravitational, the weak, and the electromagnetic interaction, the magnitude of the radius r is determined from the uncertainty relation, $\hbar/m_B c$, m_B denoting the mass of an exchange particle. In the case of the strong interaction, the interaction radius r_N may be regarded either as an empirical constant or as the distance at which the value of the coupling constant α_s becomes unity.

5. GRAVITATIONAL INTERACTION: STRUCTURE OF THE MACROCOSMOS

5.1 Structural Elements of the Universe

The structure of the macrocosmos is manifested on many different scales, ranging from the universe on the largest scale, down to galaxies, stars, and planets. Only objects of the microcosmos, such as quarks and leptons, may be devoid of further substructure. (However, a recent experiment is suggesting that quarks and gluons may be composed of more fundamental particles; see Wilczek, 1996.) Most scales are determined to an order of magnitude by a few physical constants. In particular, the mass scale and length scale (in units of the proton mass m_p and the Bohr radius a_0) of structures down to the planets can be expressed in terms of the electromagnetic fine-structure constant α_e, Eq. (4), the gravitational fine-structure constant α_g, Eq. (3), and the electron-to-proton mass ratio ($m_p \approx 1837 m_e$).

The following considerations are based on order-of-magnitude arguments, factors of order unity (like π) being neglected. These results have been published in the astrophysical literature on several occasions and are collected here for easy reference (a detailed discussion is contained in Carr and Rees, 1979; Barrow and Tipler, 1988).

5.1.1 The Planck Scales The only quantities of dimensions mass and length that can be constructed from G, $\hbar$, and c are the Planck scales:

Table 3. Properties of the four fundamental interactions.

	Coupling constant		
Interaction	Analytic expression	Numerical value at $m = m_p$	Interaction radius (cm)
Gravitational	$\alpha_g = Gm^2/\hbar c$	$\sim 10^{-38}$	∞
Weak	$\alpha_w g_F m^2 c/\hbar^3$	10^{-5}	10^{-17}
Electromagnetic	$\alpha_e = e^2/\hbar c$	1/137	∞
Strong	$\alpha_s = a/[\ln(m/m_p)]$, $m \gg m_p$	≈ 1	10^{-13}

$$M_{\mathrm{Pl}} \sim (G/\hbar c)^{-1/2} \sim 10^{-5}\ \mathrm{g},$$
